**Notices**

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

# Associate Editors

**Jonathan R. Dillman, MD, MSc**
Associate Professor
Associate Chief of Research
Medical Director, Imaging Research Center
Department of Radiology
Cincinnati Children's Hospital Medical Center
University of Cincinnati College of Medicine
Cincinnati, Ohio

**Donald P. Frush, MD, FACR, FAAP**
Professor of Radiology and Pediatrics
Duke University Medical Center
Durham, North Carolina

**Marta Hernanz-Schulman, MD, FAAP, FACR**
Professor of Radiology and Pediatrics
Departments of Radiology and Radiological Sciences
Vanderbilt University Medical Center
Radiology Vice-Chair in Pediatrics
Medical Director, Diagnostic Imaging
Monroe Carell Jr. Children's Hospital at Vanderbilt
Nashville, Tennessee

**Lisa H. Hutchison, MD, FAAP, FACR**
Director, Pediatric Radiology
Alliance Radiology
Overland Park Regional Medical Center
Overland Park, Kansas

**Geetika Khanna, MD, MS**
Professor of Radiology
Mallinckrodt Institute of Radiology
Radiologist-in-Chief
St. Louis Children's Hospital
Washington University School of Medicine
St. Louis, Missouri

**Arthur B. Meyers, MD**
Department of Radiology
Nemours Children's Health System
Nemours Children's Hospital
Associate Professor of Radiology
University of Central Florida College of Medicine
Clinical Associate Professor of Pediatric Radiology
The Florida State College of Medicine
Orlando, Florida

**Beverley Newman, BSc, MB BCh**
Professor of Radiology
Department of Radiology
Lucile Packard Children's Hospital
Stanford University
Stanford, California

**Ashok Panigrahy, MD**
Professor
Radiologist-in-Chief
Children's Hospital of Pittsburgh of UPMC
Vice Chair, Clinical and Translational Imaging Research
Department of Radiology
University of Pittsburgh Medical Center
Pittsburgh, Pennsylvania

**Cynthia K. Rigsby, MD, FACR**
Pediatric Radiologist
Department of Medical Imaging
Ann & Robert H. Lurie Children's Hospital of Chicago
Professor
Departments of Radiology and Pediatrics
Northwestern University Feinberg School of Medicine
Chicago, Illinois

# Contributors

**Wael Abdalla, MD**
Asisstant Professor
Children's Hospital of Pittsburgh of UPMC
Department of Radiology
University of Pittsburgh Medical Center
Pittsburgh, Pennsylvania

**Kalie Adler, DO**
Diagnostic Radiologist
Kansas City, Missouri

**Prachi P. Agarwal, MD**
Clinical Professor
Division of Cardiothoracic Radiology
Department of Radiology
University of Michigan
Ann Arbor, Michigan

**Tahani M. Ahmad, MD**
Staff Pediatric Radiologist and Neuroradiologist
Department of Diagnostic Imaging
IWK Health Center
Assistant Professor
Department of Medical Imaging
Dalhousie University
Halifax, Nova Scotia, Canada

**Evelyn Y. Anthony, MD**
Professor of Radiology and Pediatrics
Department of Radiological Sciences
Wake Forest School of Medicine
Winston-Salem, North Carolina

**Christopher G. Anton, MD**
Associate Professor
Department of Radiology
Cincinnati Children's Hospital Medical Center
Cincinnati, Ohio

**Sudha A. Anupindi, MD**
Director of Pediatric Gastrointestinal & Hepatic Imaging
Associate Professor of Radiology
Division of Body Imaging, Department of Radiology
The Children's Hospital of Philadelphia
University of Pennsylvania Perelman School of Medicine
Philadelphia, Pennsylvania

**Kimberly E. Applegate, MD**
Division Chief of Pediatric Radiology
Department of Radiology
University of Kentucky
Lexington, Kentucky

**Lauren W. Averill, MD**
Nemours Children's Health System
Associate Professor of Radiology and Pediatrics
Sidney Kimmel Medical College of Thomas Jefferson University
Philadelphia, Pennsylvania

**E. Michel Azouz, MD, FRCPC**
Pediatric Radiologist
Department of Medical Imaging
Montreal Children's Hospital
Montreal, Quebec, Canada

**Paul Babyn, MDCM**
Head
Department of Medical Imaging
University of Saskatchewan
Saskatoon, Saskatchewan, Canada

**Patrick N. Bacon, MD**
Pediatric Radiologist
TRA-MINW
Tacoma, Washington

**D. Gregory Bates, MD**
Clinical Professor
Department of Radiology
Ohio State University College of Medicine and Public Health
Pediatric Radiologist
Nationwide Children's Hospital
Columbus, Ohio

**Gerald G. Behr, MD**
Associate Attending Physician
Department of Radiology
Memorial Sloan Kettering Cancer Center
New York, New York

**Ellen Cecilia Benya, MD**
Associate Professor
Department of Radiology
Northwestern University Feinberg School of Medicine
Chicago, Illinois

**Larry A. Binkovitz, MD**
Associate Professor
Department of Diagnostic Radiology
Mayo Clinic
Rochester, Minnesota

**Susan Blaser, MD**
Staff Neuroradiologist
Division of Paediatric Neuroradiology
The Hospital for Sick Children
Toronto, Ontario, Canada

**Stefan Bluml, PhD**
Director, New Imaging Technology Lab
Department of Radiology
Children's Hospital Los Angeles
Associate Professor of Research, Radiology & Biomedical Engineering
University of Southern California
Los Angeles, California

**Timothy N. Booth, MD**
Professor
Department of Radiology and Otolaryngology
Children's Medical Center
University of Texas Southwestern Medical Center
Dallas, Texas

**Brandon P. Brown, MD**
Assistant Professor
Department of Radiology and Imaging Sciences
Riley Hospital for Children at Indiana University Health
Indiana University School of Medicine
Indianapolis, Indiana

**Dorothy Bulas, MD**
Professor of Pediatrics and Radiology
Department of Diagnostic Imaging and Radiology
Children's National Health Systems
Washington, DC

**Angela Byrne, MD**
Department of Radiology
Children's Hospital of British Columbia
Vancouver, British Columbia, Canada

**Joseph A. Camarda, MD**
Pediatric Cardiologist
Ann & Robert H. Lurie Children's Hospital of Chicago
Assistant Professor
Division of Cardiology
Department of Pediatrics
Northwestern University Feinberg School of Medicine
Chicago, Illinois

**Christopher I. Cassady, MD**
EB Singleton Department of Pediatric Radiology
Texas Children's Hospital
Houston, Texas

**Kim M. Cecil, PhD**
Professor and MR Spectroscopist
Radiology and Imaging Research Center
Cincinnati Children's Hospital Medical Center
Cincinnati, Ohio

**Rafael C. Ceschin, PhD**
Assistant Professor
Department of Radiology
Children's Hospital of Pittsburgh of UPMC
Department of Biomedical Informatics
University of Pittsburgh School of Medicine
Pittsburgh, Pennsylvania

**Frandics P. Chan, MD, PhD**
Associate Professor
Department of Radiology
Stanford University Medical Center
Stanford, California

**Teresa Chapman, MD**
Director, Fetal MRI
Department of Radiology
Seattle Children's Hospital
Professor
Department of Radiology
University of Washington School of Medicine
Seattle, Washington

**Govind B. Chavhan, MBBS, MD, DABR, DNB**
Staff Radiologist
Department of Diagnostic Imaging
The Hospital for Sick Children
Associate Professor
Medical Imaging
University of Toronto
Toronto, Ontario, Canada

**Katrina F. Chu, MD**
Clinical Fellow in Radiology
Massachusetts General Hospital
Harvard Medical School
Boston, Massachusetts

**Winnie C. W. Chu, MD**
Professor
Departments of Imaging and Interventional Radiology
The Chinese University of Hong Kong
Hong Kong, China

**Harris L. Cohen, MD**
Professor and Chairman
Department of Radiology
Professor
Departments of Pediatrics and Obstetrics & Gynecology
University of Tennessee Health Science Center
Radiologist-in-Chief
Le Bonheur Children's Hospital
Memphis, Tennessee

**Mougnyan Cox, MD**
Neuroradiology Fellow
Hospital of the University of Pennsylvania
Philadelphia, Pennsylvania

**J. A. Gordon Culham, MD, FRCPC**
Department of Radiology
BC Children's Hospital
Professor
Department of Radiology
University of British Columbia
Vancouver, British Columbia, Canada

**Alan Daneman, BSc, MBBCh, FRCPC, FRANZCR**
Professor
Department of Medical Imaging
University of Toronto
Department of Diagnostic Imaging
The Hospital for Sick Children
Toronto, Ontario, Canada

**Kassa Darge, MD, PhD**
Professor of Radiology and Surgery
Perelman School of Medicine
University of Pennsylvania
Radiologist-in-Chief
William L. Van Alen Endowed Chair
Department of Radiology
Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

**Joseph T. Davis, MD**
Medical Instructor of Radiology
Duke University Medical Center
Durham, North Carolina

**R. Andrew deFreitas, MD**
Division of Pediatric Cardiology
Ann & Robert H. Lurie Children's Hospital of Chicago
Assistant Professor
Department of Pediatrics
Northwestern University Feinberg School of Medicine
Chicago, Illinois

**Katyucia De Macedo Rodrigues, MD**
Research Fellow
Department of Radiology
Boston Children's Hospital
Research Fellow
Department of Radiology
A.A. Martinos Center
Massachusetts General Hospital
Boston, Massachusetts

**Jonathan R. Dillman, MD, MSc**
Associate Professor
Associate Chief of Research
Medical Director, Imaging Research Center
Department of Radiology
Cincinnati Children's Hospital Medical Center
University of Cincinnati College of Medicine
Cincinnati, Ohio

**Lincoln O. Diniz, MD, MPH**
Assistant Professor
Norton Children's Hospital
Louisville, Kentucky

**Laura Dinneen, MD**
Assistant Professor of Pediatric Radiology
University of Missouri–Kansas City School of Medicine
Kansas City, Missouri

**Michael Ditchfield, MBBS, FRANZCR, MD**
Head, Paediatric Imaging
Monash Health
Professor
Diagnostic Imaging
Monash University
Melbourne, Victoria, Australia

**Mary T. Donofrio, MD**
Professor of Pediatrics
George Washington University School of Medicine and Health Sciences
Director, Fetal Heart Program and Critical Care Delivery Program
Children's National Heart Institute
Children's National Health System
Washington, DC

**Adam L. Dorfman, MD**
Clinical Professor
Department of Pediatrics and Communicable Diseases
Department of Radiology
University of Michigan
Ann Arbor, Michigan

**Andrea Schwarz Doria, MD, PhD**
Staff Radiologist/Senior Scientist
Research Director, Department of Diagnostic Imaging
The Hospital for Sick Children
Professor, Associate Vice-Chair of Research (Injury, Repair and Inflammation)
Department of Medical Imaging
University of Toronto
Toronto, Ontario, Canada

**Laura A. Drubach, MD**
Assistant Professor
Department of Radiology
Boston Children's Hospital
Boston, Massachusetts

**Josée Dubois, MD, FRCP, MSc**
Professor
Department of Radiology, Radio-oncology and Nuclear Medicine
University of Montreal
Head, Department of Medical Imaging
CHU Sainte-Justine
Montreal, Quebec, Canada

**Jerry Dwek, MD**
Clinical Adjunct Professor
Department of Radiology
University of California at San Diego
San Diego, California

**Wendy Drew Ellis, MD**
Assistant Professor of Radiology and Radiologic Sciences and Pediatrics
Monroe Carell Jr. Children's Hospital at Vanderbilt
Nashville, Tennessee

**Monica Epelman, MD**
Vice-Chair of Radiology
Nemours Children's Health System
Nemours Children's Hospital
Professor of Radiology
University of Central Florida College of Medicine
Orlando, Florida

**Judy A. Estroff, MD**
Division Chief, Fetal-Neonatal Imaging
Department of Radiology
Boston Children's Hospital
Associate Professor
Department of Radiology
Harvard Medical School
Boston, Massachusetts

**Eric P. Eutsler, MD**
Assistant Professor
Department of Radiology
Mallinckrodt Institute of Radiology
Washington University School of Medicine
St. Louis, Missouri

**Eric Faerber, MD, FACR**
Department of Radiology
St. Christopher's Hospital For Children
Philadelphia, Pennsylvania

**Nancy R. Fefferman, MD**
Associate Professor of Radiology
Vice Chair of Education
Section Chief, Pediatric Radiology
Department of Radiology
NYU School of Medicine
New York, New York

**Mark Ferguson, MD**
Assistant Professor
Seattle Children's Hospital
University of Washington School of Medicine
Department of Radiology
Seattle, Washington

**Tamara Feygin, MD**
Associate Professor of Clinical Radiology
Perelman School of Medicine
University of Pennsylvania
Staff Neuroradiologist
The Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

**Kristin A. Fickenscher, MD**
Associate Professor
Department of Radiology
Children's Mercy Hospital
University of Missouri–Kansas City
Kansas City, Missouri

**A. Michelle Fink, MRCP, FRCR, FRANZCR**
Honorary Consultant Radiologist
Department of Medical Imaging
The Royal Children's Hospital
Melbourne, Victoria, Australia

**Tyson R. Finlinson, DO**
University of Missouri–Kansas City
Kansas City, Missouri

**Donald P. Frush, MD, FACR, FAAP**
Professor of Radiology and Pediatrics
Duke University Medical Center
Durham, North Carolina

**Andre Dietz Furtado, MD**
Assistant Professor
Children's Hospital of Pittsburgh of UPMC
Department of Radiology
University of Pittsburgh Medical Center
Pittsburgh, Pennsylvania

**Asvin M. Ganapathi, MD**
Department of Surgery
Duke University Medical Center
Durham, North Carolina

**Michael S. Gee, MD, PhD**
Chief of Pediatric Radiology
Massachusetts General Hospital
Associate Professor of Radiology
Harvard Medical School
Boston, Massachusetts

**Maryam Ghadimi Mahani, MD**
Clinical Assistant Professor
Divisions of Pediatric and Cardiothoracic Radiology
Department of Radiology
University of Michigan
Ann Arbor, Michigan

**Hyun Woo Goo, MD, PhD**
Department of Radiology and Research Institute of Radiology
Asan Medical Center
University of Ulsan College of Medicine
Seoul, South Korea

**P. Ellen Grant, MD**
Associate Professor
Department of Radiology
Director
Fetal Neonatal Neuroimaging and Developmental Science, Newborn Medicine
Children's Hospital Boston
Boston, Massachusetts

**J. Damien Grattan-Smith, MBBS**
Department of Radiology
Children's Healthcare of Atlanta
Atlanta, Georgia

**S. Bruce Greenberg, MD**
Professor of Radiology and Pediatrics
Department of Radiology
University of Arkansas for Medical Sciences
Little Rock, Arkansas

**Mary-Louise C. Greer, MBBS**
Pediatric Radiologist
Department of Diagnostic Imaging
The Hospital for Sick Children
Assistant Professor
Department of Medical Imaging
University of Toronto
Toronto, Ontario, Canada

**R. Paul Guillerman, MD**
Professor
Department of Radiology
Baylor College of Medicine
Houston, Texas

**Matthew R. Hammer, MD**
Assistant Professor
Department of Pediatric Radiology
Children's Health and UT Southwestern Medical Center
Dallas, Texas

**James René Herlong, MD**
Division Chief, Pediatric Cardiology
Sanger Heart and Vascular Institute
Charlotte, North Carolina

**Marta Hernanz-Schulman, MD, FAAP, FACR**
Professor of Radiology and Pediatrics
Departments of Radiology and Radiological Sciences
Vanderbilt University Medical Center
Radiology Vice-Chair in Pediatrics
Medical Director, Diagnostic Imaging
Monroe Carell Jr. Children's Hospital at Vanderbilt
Nashville, Tennessee

**Melissa A. Hilmes, MD**
Assistant Professor
Division of Pediatric Radiology
Department of Radiology and Radiological Sciences
Monroe Carrell Jr Children's Hospital
Vanderbilt University Medical Center
Vanderbilt University
Nashville, Tennessee

**Ross Holwerda, MD**
Department of Radiology
University of Missouri–Kansas City
Kansas City, Missouri

**Nazia Husain, MBBS, MPH**
Division of Pediatric Cardiology
Ann & Robert H. Lurie Children's Hospital of Chicago
Assistant Professor
Department of Pediatrics
Northwestern University Feinberg School of Medicine
Chicago, Illinois

**Lisa H. Hutchison, MD, FAAP, FACR**
Director, Pediatric Radiology
Alliance Radiology
Overland Park Regional Medical Center
Overland Park, Kansas

**Celso Hygino da Cruz Jr., MD, PhD**
CDPI/DASA, Americas Medical City
Rio de Janeiro, Brazil

**Andrew Johansen, MD**
Department of Radiology
Children's Mercy Hospital
University of Missouri–Kansas City
Kansas City, Missouri

**Joyce T. Johnson, MD**
Assistant Professor
Department of Pediatrics
Ann & Robert H. Lurie Children's Hospital of Chicago
Chicago, Illinois

**J. Herman Kan, MD**
Section Chief, Musculoskeletal Imaging
E.B. Singleton Department of Pediatric Radiology
Texas Children's Hospital
Associate Professor
Baylor College of Medicine
Houston, Texas

**Yassine Kanaan, MD**
Attending Physician
Department of Radiology
Texas Scottish Rite Hospital for Children
Dallas, Texas

**Ronald J. Kanter, MD**
Director, Electrophysiology
Nicklaus Children's Hospital
Miami, Florida

**Boaz Karmazyn, MD**
Professor of Radiology
Department of Radiology and Imaging Sciences
Riley Hospital for Children at Indiana University Health
Indiana University School of Medicine
Indianapolis, Indiana

**Sue Creviston Kaste, DO**
Full Member
Departments of Diagnostic Imaging and Oncology
St. Jude Children's Research Hospital
Full Professor
Department of Radiology
University of Tennessee Health Science Center
Memphis, Tennessee

**Travis H. Kauffman, DO**
Department of Radiology
University of Missouri–Kansas City
Kansas City, Missouri

**Geetika Khanna, MD, MS**
Professor of Radiology
Mallinckrodt Institute of Radiology
Radiologist-in-Chief
St. Louis Children's Hospital
Washington University School of Medicine
St. Louis, Missouri

**Amy B. Kolbe, MD**
Assistant Professor
Department of Radiology
Mayo Clinic
Rochester, Minnesota

**Korgün Koral, MD, MBA**
Professor
Director of Pediatric Neuroradiology and Pediatric MRI
Cohen Children's Medical Center
Donald and Barbara Zucker School of Medicine at Hofstra/Northwell
Hempstead, New York

**Steven Kraus, MD**
Staff Radiologist
Division Chief, Fluoroscopy
Department of Radiology
Cincinnati Children's Hospital Medical Center
Associate Professor of Radiology and Pediatrics
University of Cincinnati College of Medicine
Cincinnati, Ohio

**Rajesh Krishnamurthy, MD**
Radiologist-In-Chief
Nationwide Children's Hospital
Clinical Professor of Radiology
Ohio State University
Columbus, Ohio

**Ramkumar Krishnamurthy, PhD, DABMP-MRI**
MRI Physicist
Department of Radiology
Nationwide Children's Hospital
Columbus, Ohio

**Ralph S. Lachman, MD**
Clinical Professor
Stanford University
Stanford, California;
Professor Emeritus
Associate Director
International Skeletal Dysplasia Registry
UCLA
Los Angeles, California

**Hollie A. Lai, MD**
CHOC Children's
Department of Radiology
Orange, California

**Brooke S. Lampl, DO**
Clinical Assistant Professor of Radiology
Interim Co-Section Director, Pediatric Radiology
Imaging Institute, Cleveland Clinic
Cleveland, Ohio

**Tal Laor, MD**
Professor
Department of Radiology
Boston Children's Hospital
Boston, Massachusetts

**Bernard F. Laya, MD, DO**
Director of Radiology
Institute of Radiology
St. Luke's Medical Center–Global City
Taguig City, Philippines;
Professor of Radiology and Associate Dean
St. Luke's College of Medicine–WHQM
Quezon City, Philippines

**James Leach, MD**
Professor of Radiology
Department of Radiology and Medical Imaging
Cincinnati Children's Hospital Medical Center
University of Cincinnati College of Medicine
Cincinnati, Ohio

**Henrique M. Lederman, MD, PhD**
Senior Professor of Radiology
Department of Diagnostic Imaging
Paulista School of Medicine
Federal University of Sao Paulo (UNIFESP)
Chief, Division of Diagnostic Imaging
Pediatric Oncology Institute, GRAACC
Sao Paulo, Brazil

**Edward Y. Lee, MD**
Chief, Division of Thoracic Imaging
Associate Professor
Departments of Radiology and Medicine
Pulmonary Division
Boston Children's Hospital
Harvard Medical School
Boston, Massachusetts

**Simon Lee, MD**
Assistant Professor
Departments of Pediatrics and Cardiology
Ann & Robert H. Lurie Children's Hospital of Chicago
Chicago, Illinois

**Andrew J. Lodge, MD**
Associate Professor, Surgery
Associate Professor, Pediatrics
Duke University Medical Center
Durham, North Carolina

**Joseph V. Loeb, DO**
Radiology Resident
Department of Radiology
University of Missouri–Kansas City
Kansas City, Missouri

**Jimmy C. Lu, MD**
Clinical Associate Professor
Department of Pediatrics and Communicable Diseases
Department of Radiology
University of Michigan
Ann Arbor, Michigan

**Karen Lyons, MD**
Assistant Professor of Radiology
Arkansas Children's Hospital
Little Rock, Arkansas

**Alexis B. Rothenberg Maddocks, MD**
Assistant Professor of Radiology
Morgan Stanley Children's Hospital
Columbia University Medical Center
New York, New York

**John B. Mawson, MB, ChB**
Director, Department of Radiology
BC Children's Hospital
Assistant Professor
Department of Radiology
University of British Columbia
Vancouver, British Columbia, Canada

**M. Beth McCarville, MD**
Member
Department of Diagnostic Imaging
St. Jude Children's Research Hospital
Memphis, Tennessee

**Amie M. McPherson, MD**
House Officer
Department of Radiological Sciences
Wake Forest Baptist Medical Center
Winston-Salem, North Carolina

**James S. Meyer, MD**
Associate Professor of Radiology
University of Pennsylvania School of Medicine
Associate Radiologist-in-Chief
Department of Radiology
Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

**Arthur B. Meyers, MD**
Department of Radiology
Nemours Children's Health System
Nemours Children's Hospital
Associate Professor of Radiology
University of Central Florida College of Medicine
Clinical Associate Professor of Pediatric Radiology
The Florida State College of Medicine
Orlando, Florida

**Stephen F. Miller, MD**
Department of Radiology
Le Bonheur Children's Hospital
Associate Professor
Department of Radiology
University of Tennessee Health Science Center
Memphis, Tennessee

**Grace S. Mitchell, MD, MBA**
Department of Radiology
Children's Mercy Kansas City
Assistant Professor
University of Missouri–Kansas City
Kansas City, Missouri

**Karen K. Moeller, MD**
Director of Neuroradiology
Norton Children's Hospital
Louisville, Kentucky

**Kevin R. Moore, MD**
Vice Chair of Radiology
Director of MR Imaging
Department of Medical Imaging
Primary Children's Medical Center
Adjunct Associate Professor of Radiology
Department of Radiology
University of Utah
Salt Lake City, Utah

**Srikala Narayanan, MD**
Assistant Professor
Department of Pediatric Radiology
Children's Hospital of Pittsburgh
University of Pittsburgh Medical Center
Pittsburgh, Pennsylvania

**Oscar M. Navarro, MD**
Associate Professor
Department of Medical Imaging
University of Toronto
Fellowship Program Director
Department of Diagnostic Imaging
The Hospital for Sick Children
Toronto, Ontario, Canada

**Josephine M. Ndolo, MBChB, MMed**
Clinical Fellow in Pediatric Radiology
Department of Radiology and Radiological Sciences
Vanderbilt University Medical Center
Monroe Carell Jr. Children's Hospital at Vanderbilt
Nashville, Tennessee

**Marvin D. Nelson Jr., MD**
Chairman, Department of Radiology
Children's Hospital Los Angeles
Professor
Department of Radiology
USC Keck School of Medicine
Los Angeles, California

**Beverley Newman, BSc, MB BCh**
Professor of Radiology
Department of Radiology
Lucile Packard Children's Hospital
Stanford University
Stanford, California

**David B. Nielsen, MD**
Assistant Professor
University of Missouri–Kansas City
Pediatric Radiologist
Children's Mercy Hospital and Clinics
Kansas City, Missouri

**Kay North, DO**
Department of Radiology
Children's Mercy Hospital
Kansas City, Missouri

**Julie Currie O'Donovan, MD**
Pediatric Radiologist
Department of Radiology
Nationwide Children's Hospital
Columbus, Ohio

**Erin K. Opfer, DO**
Pediatric Radiologist
Assistant Professor
Department of Pediatric Radiology
Children's Mercy Hospital and Clinics
Kansas City, Missouri

**Robert C. Orth, MD, MPH, PhD**
Assistant Professor
Department of Pediatric Radiology
Texas Children's Hospital
Houston, Texas

**Randolph Otto, MD**
Associate Professor
Department of Radiology
Seattle Children's Hospital
University of Washington School of Medicine
Seattle, Washington

**Deepa R. Pai, MD, MHSA**
Associated Chief of Critical Care
Department of Radiology
Children's Hospitals and Clinics of Minnesota
Minneapolis, Minnesota

**Harriet J. Paltiel, MD**
Radiologist
Department of Radiology
Boston Children's Hospital
Associate Professor
Department of Radiology
Harvard Medical School
Boston, Massachusetts

**Ashok Panigrahy, MD**
Professor
Radiologist-in-Chief
Children's Hospital of Pittsburgh of UPMC
Vice Chair, Clinical and Translational Imaging Research
Department of Radiology
University of Pittsburgh Medical Center
Pittsburgh, Pennsylvania

**Angira Patel, MD**
Assistant Professor
Department of Pediatrics
Ann & Robert H. Lurie Children's Hospital of Chicago
Chicago, Illinois

**Amanda M. Perak, MD**
Fellow
Department of Preventive Medicine
Northwestern University Feinberg School of Medicine
Instructor
Division of Cardiology
Ann & Robert H. Lurie Children's Hospital of Chicago
Chicago, Illinois

**Daniel J. Podberesky, MD**
Radiologist-in-Chief
Department of Radiology
Nemours Children's Health System
Associate Professor of Radiology
University of Central Florida and Florida State University Colleges of Medicine
Orlando, Florida

**Avrum N. Pollock, MD, FRCPC**
Clinical Professor of Radiology
Department of Radiology
Division of Neuroradiology
The Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

**Andrada R. Popescu, MD**
Physician
Department of Medical Imaging
Ann & Robert H. Lurie Children's Hospital
Assistant Professor
Department of Radiology
Northwestern University Feinberg School of Medicine
Chicago, Illinois

**Tina Young Poussaint, MD**
Attending Neuroradiologist
Department of Radiology
Boston Children's Hospital
Professor of Radiology
Department of Radiology
Harvard Medical School
Boston, Massachusetts

**Sanjay P. Prabhu, MBBS, FRCR**
Director, Advanced Image Analysis Lab
Staff Pediatric Neuroradiologist
Department of Radiology
Boston Children's Hospital
Assistant Professor of Radiology
Harvard Medical School
Boston, Massachusetts

**Sumit Pruthi, MD**
Associate Professor
Departments of Radiology and Pediatrics
Chief, Pediatric Neuroradiology
Monroe Carell Jr. Children's Hospital at Vanderbilt
Nashville, Tennessee

**Anand Dorai Raju, MD**
Assistant Professor
Department of Radiology
Le Bonheur Children's Hospital
University of Tennessee Health Science Center
Memphis, Tennessee

**Brian Reilly, RT(R)**
3D Imaging Specialist
Department of Medical Imaging
Ann & Robert H. Lurie Children's Hospital of Chicago
Chicago, Illinois

**Ricardo Restrepo, MD**
Chief of Interventional Radiology Section
Department of Radiology
Niklaus Children's Hospital
Voluntary Professor
Department of Radiology
Florida International University
Miami, Florida

**John F. Rhodes, MD**
Director
Congenital Heart Center and Pediatric/Adult Congenital Interventional Cardiology
Medical University of South Carolina
Charleston, South Carolina

**Cynthia K. Rigsby, MD, FACR**
Pediatric Radiologist
Department of Medical Imaging
Ann & Robert H. Lurie Children's Hospital of Chicago
Professor
Departments of Radiology and Pediatrics
Northwestern University Feinberg School of Medicine
Chicago, Illinois

**Douglas C. Rivard, DO**
Assistant Professor
Department of Radiology
Children's Mercy Hospital and Clinics
Kansas City, Missouri

**Michael Rivkin, MD**
Co-Director, Stroke and Cerebrovascular Center
Intensive Care Neurology Service
Department of Neurology
Boston Children's Hospital
Associate Professor
Department of Neurology
Harvard Medical School
Boston, Massachusetts

**Ashley James Robinson, MB, ChB, FRCR, FRCPC**
Associate Professor of Clinical Radiology
Department of Radiology
Weill Cornell Medical College
New York, New York;
Vice-Chair, Radiology
Sidra Medical and Research Center
Doha, Qatar

**Joshua D. Robinson, MD**
Pediatric Cardiologist
Ann & Robert H. Lurie Children's Hospital of Chicago
Assistant Professor
Division of Cardiology

# Foreword

A book. A book! Such a wonderful thing, and especially, a book on pediatric radiology! In the days of the internet and random access to learning, there is still an important place for a comprehensive text, such as *Caffey's Pediatric Diagnostic Imaging*.

In 1945, John Caffey wrote and edited the first edition of this text, then called *Caffey's Pediatric X-Ray Diagnosis*. Caffey's text ushered the infancy of the specialty of pediatric radiology. It was meticulously illustrated with cases from Caffey's work at Babies Hospital in New York City. The book was carefully referenced. At the time, it was a comprehensive guide to anything that might be diagnosed or evaluated with radiographs in children. Emphasis was placed on normal—normal Roentgen anatomy, normal variants, and normal development. The book was an invaluable aid to anyone interpreting radiographs in children. It helped to establish the specialty of pediatric radiology—we were big time!

Caffey's 1945 1st edition was *not* the first textbook in pediatric radiology. A few decades earlier, in 1910, Morgan Rotch published *Living Anatomy and Pathology: The Diagnosis of Diseases of Early Life By the Roentgen Method*. While undoubtedly useful to radiology practitioners at the time, the limited utility of radiographs at the time is illustrated throughout the text. Other early texts were published in Germany. Caffey himself published a 160-page section on pediatric radiology in *Golden's Looseleaf Radiology* in 1941 entitled "Roentgen Diagnosis in Infants and Children." This effort was clearly a precursor for the much larger, more comprehensive 1st edition of *Caffey's Pediatric X-Ray Diagnosis*. Very few copies of this "pre-Caffey's" exist.

Looking back at the "pre-Caffey's" and the subsequent 1st edition of *Caffey's Pediatric X-Ray Diagnosis*, one gets a sense of the contemporary excitement with the benefits of radiography and careful image interpretation to improving the healthcare of children. Radiology was integral to pediatric medicine. Glaringly, one is struck by the absence of any discussion of child abuse—these books preceded Caffey's seminal article on this subject, published in 1946 in *The American Journal of Roentgenology and Radium Therapy*. Careful perusal of the texts shows nothing related to the topic of child abuse although undoubtedly Caffey's mind was already spinning with the challenge of these cases (the six cases in the 1946 article ranged back to 1933).

Recognizing the rapid advancement of medicine and improvement and ever-increasing utilization of radiography, fluoroscopy, and later other imaging modalities, Caffey, Caffey and colleagues, Caffey protégés, and eventually distant academic descendants (which we all are) have churned out edition after edition of *Caffey's Pediatric X-Ray Diagnosis*, morphing into *Caffey's Pediatric Diagnostic Imaging* with the 10th edition in 2004. With each edition, new information about injury and disease in children was incorporated, better examples of pathologies were illustrated, imaging techniques and photography were updated, and new modalities were introduced. The text grew and grew. With the 6th edition, in 1972, the text expanded to two volumes. With the 11th edition, in 2008, the two volumes totaled 3,195 pages (plus a gargantuan index)—a hefty weight good for muscle building but a challenge for a reader to consume from cover to cover. You didn't lug *Caffey's Pediatric Diagnostic Imaging* around, rather you kept multiple copies handy—in the reading room, in your office, at home.

Nonetheless, the text was a comprehensive reference. If you needed to look up something, it was in the book. If you read the book cover to cover, you didn't miss anything. Writing was by true experts in the subspecialties of pediatric radiology. Many chapters (e.g., the bone marrow chapter by Guillerman, the metabolic bone disease chapters by Shore in the 11th edition) are the best writing that exists on the respective subjects.

With the 12th edition, parts of the book migrated online, including references and some of the "less essential" images. For those of us who love books and reading, this was a troublesome development. Being tethered to a computer and having to log in and find this supplemental information was somewhat burdensome. This change, however, represented a smart compromise between content and size and harkened the coming of age of *Caffey's Pediatric Diagnostic Imaging* in the digital era. The online features have been continued with the 13th edition.

With the 13th edition, Dr. Coley and his team have again reinvigorated the text, building from a solid foundation of the 12th edition and subfoundations from every preceding edition. Again, an awesome array of authors has been assembled, bringing in exciting new blood in the field of pediatric radiology. Of the 187 contributing authors, 72 are new to the 13th edition. Authors are drawn from around the world. Medicine, and specifically pediatric radiology, continues to advance at a breathtaking pace. The new text reflects this—with updated information on new modalities, new techniques, and new perspectives on old diseases. Particular attention has been given to expanding the focus on prenatal imaging. This melds well with discussions of embryology and neonatal conditions. Additional attention to the exploding and varied use of MRI is noted throughout the text. Indeed, imaging is much more complex than in Caffey's day; however, as with all previous editions, the current text maintains an emphasis on radiography, not to be overlooked.

Hearty congratulations go to Dr. Coley and his nine associate editors for a job very well done. Putting together a multi-editor, multi-author comprehensive textbook and keeping it cohesive, consistent, and timely is not an easy task. Thank you!

*Caffey's Pediatric Diagnostic Imaging* remains a comprehensive go-to reference and text on pediatric radiology. If you wish to know more about an entity in pediatric radiology, it is here. If you want to get everything, you can start on page 1 and read it through to the end. You don't know what you don't know. If you want to know it all, use this book.

# Preface to First Edition

> *Shadows are but dark holes in radiant streams, twisted rifts beyond the substance, meaningless in themselves.*
>
> *He who would comprehend Röntgen's pallid shades need always to know well the solid matrix whence they spring. The physician needs to know intimately each living patient through whom the racing black light darts, and flashing the hidden depths reveals them in a glowing mirage of thin images, each cast delicately in its own halo, but all veiled and blended endlessly.*
>
> *Man—warm, lively, fleshy man—and his story are both root and key to his shadows; shadows cold, silent and empty.*
>
> (JOHN CAFFEY)

Within a few weeks after Röntgen announced his now renowned discovery to the world in December, 1895, the X-ray method of examination was applied to infants and children. The Vienna letter of February 29 (M. Rec. 49:312, 1896) contained a roentgen print of the arm of an infant made of Kreidl in Vienna: this is the second reproduction of a roentgen image in the American literature. Credit for the first recorded roentgen examination of an infant in the United States undoubtedly belongs to Dr. E. P. Davis of New York City, who described the roentgen shadows cast by the trunk of a living infant and the skull of a dead fetus in March, 1896. In his remarkable article (The study of the infant body and the pregnant womb by the roentgen ray, Am. J. M. Sc. 111:263, 1896) Dr. Davis also included three drawings of shadows visualized by means of a skiascope—shadows visualized by means of a skiascope—shadows of the feet, elbows and orbit of a living infant. Feilchenfeld's discussion of spina ventosa in May, 1896, is probably the first roentgen description of morbid anatomy in children (Berlin. Klin. Wchnschr. 33:403, 1896). There were only two roentgen pediatric publications in 1896; the number increased to 14 in 1897.

In 1898, Escherich of Graz had had sufficient experience with pediatric roentgen examinations to write a general exposition on the merits and weaknesses of the method (La valeur diagnostique de la radiographie chez les enfants, Rev. d. mal. de l'enf. 16:233, May 1898). This is a highly interesting and illuminating discussion in which Escherich points out the roentgen examination was already not being used as commonly in young patients as in adults. He states that a roentgen laboratory was established especially for children at Graz in 1897, and it seems probable that this was the first of its kind.

A single film is reproduced—a print of an infantile hand and forearm which shows rachitic changes. The uncertainties of the mediastinal shadows, which still bedevil us, were fully appreciated by Escherich, and he was quite unhappy about this baffling structure "in which so many important infantile lesions lie concealed." He was enthusiastic in regard to the possible estimation of the state of hydration of soft tissues in infantile diarrhea from their roentgen densities.

Reyher's German monograph in 1908 is the earliest review of the world literature of pediatric roentgenology which I have found (Reyher, P.: Die roentgenologische Diagnostik in der Kinderheilkunde, Ergebn. d. inn. Med. U. Kinderh. 2:613, 1908). In it there are 276 references to articles published during the first 12 years following Röntgen's discovery, and these furnish a good key for the study of the early writings in this field. The appendix contains 40 small but clear roentgen prints.

Rotch's The Roentgen Ray in Pediatrics appeared in 1910—the first book in any language devoted exclusively to pediatric X-ray diagnosis and still, I believe, the only one in English. Dr. Thomas Morgan Rotch was Professor of Pediatrics, Harvard University, and an outstanding podiatrist of his time.[*]

In this pioneer treatise he stresses the importance of mastering the shadows of normal structure before attempting the recognition and interpretation of the abnormal, and he carefully correlates the clinical findings with the roentgen findings in the cases illustrated; 42 of 264 figures depict the "normal living anatomy of infants and children." This material was taken largely from the files of the Boston Children's Hospital, and the author's statement that more than 2,300 cases were available for study demonstrates that roentgen examination had long been a commonplace in his clinic. Dr. Rotch's early fostering of roentgen examination of infants and children, his appreciation of the special problems in applying this method to the young, his careful anatomicroroentgen studies and his text, monumental for this time, all mark him as the father of pediatric roentgenology in America.

Two years later—1912—the first German book, Reyher's Das Roentgenverfahren in der Kinderheilkunde, was published. Later and more familiar texts are Gralka's Roentgendiagnostik im Kindesalter (1927), Becker's Roentgendiagnostik und Strahlentherapie in der Kinderheilkunde (1931) and the Handbuch der Roentgendiagnostik und Therapie im Kindesalter by Engel and Schall (1933). As far as I have been able to determine, no book on pediatric roentgen diagnosis has been published in English during the 35 years which have passed since Rotch's unique publication in 1910. The absence of pediatric roentgenology in the flood of medical texts which has streamed from the American and English presses during the last three decades constitutes a dereliction unmatched in other equally important fields of medical diagnosis — a literary developmental hypoplasia which it is hoped *Pediatric X-Ray Diagnosis* will remedy.

This book stems from the roentgen conferences held semimonthly at the Babies Hospital during the last 20 years. The films reproduced herein were all selected from our own roentgen files save those for which credit to others is indicated in the legends. The purpose of the author is two-fold: description of shadows cast by normal and morbid tissues, and clinical appraisal of roentgen findings in pediatric diagnosis. Roentgen physics, technic and therapy have been omitted intentionally. As references and acknowledgments testify, the writer has borrowed freely from the literature and is indebted to many contributors for subject matter and illustrations. To all of them I am sincerely grateful. In the broad and deep field of pediatric diagnosis, selection of the most appropriate material has posed many dilemmas. In the main, data have been chosen which have proved the most useful and instructive in solving the common and important diagnostic problems which have arisen during two decades in a large and busy pediatric hospital and out-patient clinic.

The limitations of space do not permit adequate recognition here of all those to whom credit is due for the making of this book. The roentgen examinations which are its foundation could not have been made without the cooperation of thousands of patients—many weak and painweary; to all of these I am profoundly thankful. Intimate clinical contacts have been maintained and essential collateral examinations have been made possible through the sustained collaboration of my colleagues—attending physicians and surgeons, resident physicians and nurses. I am under deep and solid obligation to Dr. Rustin McIntosh who read the entire manuscript; his discerning criticism and valuable suggestions are responsible for numerous corrections and improvements in the text. The sympathetic reception given to our early endeavors by Dr. Ross Golden will always be remembered gratefully, as well as his continuing wise and friendly counsel. We have benefited much and often from the discipline of the necropsy table—from the instructive dissections of Dr. Martha Wollstein, Dr. Beryl Paige and Dr. Dorothy Anderson.

---

[*] Jacobi, A.: In memoriam Thomas Morgan Rotch, Am. J. Dis. Child. 8:245, 1914.

To none, however do I owe more than to my loyal coworkers in the roentgen department of the Babies Hospital—Edgar Watts, Cecelia Peck, Moira Shannon, Mary Fennell and Mary Jean Cadman—for their gentle handling of patients, unfailing industry and superlative technical skill. Mrs. Cadman typed the manuscript; I am grateful to her for the speedy completion of a thorny chore. The drawings are the work of Alfred Feinberg, and they reflect his rich experience in medical illustration.

The final phase in the preparation of the manuscript was saddened by the death of Mr. H. A. Simons, President of the Year Book Publishers. His stimulating enthusiasm and generosity were indispensable to the completion of the book during these unsettled war years. His passing was a grievous loss. The task of publication has fallen to the capable and patient hands of Mr. Paul Perles and Mrs. Anabel Ireland Janssen.

*June 10, 1945*

# Preface

A small number of valuable and influential texts have outlived their creators, evolving over years through the efforts of new authors and editors. Sir William Osler's *The Principles and Practice of Medicine* was published from 1892 to 2001; Sir Vincent Zachary Cope's *Early Diagnosis of the Acute Abdomen*, currently in its 22nd edition, first appeared in 1921; other such venerable texts still being published include Harrison's *Principles of Internal Medicine* (1950), Nelson's *Textbook of Pediatrics* (1945), and Goodman & Gilman's *The Pharmacological Basis of Therapeutics* (1941). *Caffey's Pediatric Diagnostic Imaging* (originally *Caffey's Pediatric X-ray Diagnosis* through the first nine editions) is the longest continuously published textbook in the subspecialty, having proven its value over seven decades.

This book began as a labor of love for John Caffey in an era without computers, digital images, or PubMed. Each chapter was meticulously dictated, typed, corrected, and typed again. Each radiograph was carefully selected from Dr. Caffey's own teaching file at Babies Hospital in New York City. Dr. Caffey, initially trained as a pediatrician, was an astute clinician who stressed that the radiographic findings were only one part of the diagnostic evaluation; proper patient care required the integration of the history, physical exam, laboratory data, and imaging. Despite the great effort involved, he was the sole author of the first four editions.

With the 1967 fifth edition, former Caffey fellow Dr. Frederic N. Silverman of Children's Hospital Cincinnati participated in preparation of the text, and continued as a co-editor of the sixth and seventh editions. With the death of Dr. Caffey in 1978, Silverman became sole editor of the eighth edition in 1985. Over time, Dr. Silverman added authors and expanded sections. Dr. Jerald P. Kuhn joined Silverman as co-editor with the 1993 ninth edition, and then succeeded him as editor. For the 2003 tenth edition, Dr. Kuhn added Drs. Jack O. Haller and Thomas L. Slovis as co-editors, two important figures in pediatric radiology education. Dr. Slovis lead the production of the eleventh edition, which was a significant modernization of the text and figures. This addition had eight associate editors overseeing subsections of the text, reflecting the growing complexity and expertise required in delivering pediatric imaging care. The twelfth edition was the first to be available electronically, with expanded image and video content. New associate editors were added to provide the best expertise possible. This has continued with the current thirteenth edition, with updated content reflecting the changes in the field.

Given how we now access information and educational content, it is fair to ask if books like this are still relevant. Clearly, I have a biased viewpoint. The quality of the information retrieved online is often unclear, and much of that content is condensed and truncated, leaving out important details and associations. I believe that well-constructed prose from an author with expert knowledge and practical real-world experience, coupled with illustrative images, remains a powerful and efficient way to transmit information and facilitate learning. Lists of facts and bullet point paragraphs cannot convey more complex concepts and syntheses. No matter what the medium, content counts. And books like this one have tremendously valuable content.

Still, as we learn more about the science of education, what is the best method of presenting information to learners young and old? There is ongoing debate as to the best medium in which to disseminate complex and comprehensive content. Books are simple to use. They are familiar. It is easy to flip from section to section, to go back a few pages without losing your place. You can take notes in the margins. Books can also be heavy and cumbersome. They are costly to manufacture. Electronic formats have their pros and cons as well. A light, portable laptop or tablet may contain thousands of books' worth of information. Images can be manipulated like in actual practice. Video and animations can augment the learning experience. Online texts can be accessed anywhere with an Internet connection. Content length need not be dictated by physical page limitations. However, screen size dictates and somewhat limits the amount and method of information displayed. Moving back and forth between content sections can be awkward.

This thirteenth edition reflects this tension. There is a physical book, but there is also an online and electronic presence. Additional content is available online to supplement the print volume and to allow those who prefer electronic media to take advantage of the material in an alternate way.

I would like to thank the team at Elsevier, beginning with Robin Carter, the acquisition editor who still believes in the importance of works such as this. Ann Anderson is our content development specialist, among whose many tasks included prodding me to actually get my work done. Stephanie Turza is our project manager, who calmly kept the book moving along. Our designer Renee Duenow and our art buyer Nichole Beard helped create the book's look, and multimedia producer Vinod Kothaparamtath made the online content possible. And of course, thank you to the authors and editors who shared their time and expertise to make this edition possible.

**Brian D. Coley, MD**

# Video Contents

## Chapter 14 Prenatal, Congenital, and Neonatal Abnormalities

- Fetal Swallowing
- Normal Fetal Swallowing

## Chapter 55 Neoplasia

- Mucoepidermoid Carcinoma

## Chapter 67 Magnetic Resonance Imaging for Congenital Heart Disease

- Aortic Stenosis, Sagittal and Coronal Time-Resolved
- Aortic Coarctation
- Aortic Stenosis

## Chapter 69 Surgical Considerations for Congenital Heart Disease

- Cardiac MRI in a Patient with Previously Repaired Tetralogy of Fallot, View 1
- Cardiac MRI in a Patient with Previously Repaired Tetralogy of Fallot, View 2

## Chapter 73 Left Heart Lesions

- Marginally Hypoplastic Left Ventricle to Evaluate for a Two-Ventricle Versus Single-Ventricle Repair
- Bicuspid Aortic Valve in a 25-Year-Old with History of Aortic Coarctation
- Bicuspid Aortic Valve in a 25-Year-Old with History of Aortic Coarctation, Showing Upward Ballooning of the Aortic Valve Leaflets and Turbulent Poststenotic Jet
- Systolic Flow Void Beyond the Coarctation Consistent with Turbulent Flow Across the Coarctation

## Chapter 75 Conotruncal Anomalies

- Tetralogy of Fallot, Status Post-Repair, Status Post–Pulmonary Valve Replacement
- Tetralogy of Fallot, Status Post-Repair, Status Post–Transcatheter Pulmonary Valve Replacement
- Markedly Dilated Right Ventricle with Overall Mildly Depressed Systolic Function
- Dilated Right Ventricular Outflow Tract with Dyskinetic Anterior Wall in the Region of the Prior Transannular Patch
- To-and-Fro Flow in the Main Pulmonary Artery
- Hypertrophy of the Right Ventricle with Bowing of the Interventricular Septum into the Lower Pressure Left Ventricle
- Anterior and Leftward Aorta Arising From the Morphologic Right Ventricle
- Dephasing Jet at the Pulmonary Valve

## Chapter 78 Syndromes and Chromosomal Anomalies

- Tortuous Aorta and Iliac Arteries with Multiple Stenoses: Infant with Loeys Dietz Syndrome
- Diffuse Arterial Tortuosity and Multiple Stenoses
- Thickening of the Right and Left Ventricle Myocardium with Small Ventricular Cavities: 6-Month-Old Girl with Features of LEOPARD Syndrome
- Spectrum of Anatomic Abnormalities: 2-Day-Old Female with Cantrell Syndrome (Pentalogy of Cantrell)

## Chapter 79 Myocardial, Endocardial and Pericardial Diseases

- Hypertrophic Cardiomyopathy with Severe Asymmetric Thickening of the Left Ventricular Septal Wall

## Chapter 80 Cardiac and Pericardial Tumors

- Cardiac Fibroma with Gorlin Syndrome

## Chapter 85 Prenatal Gastrointestinal and Hepatobiliary Imaging

- Duodenal Obstruction with Hyperperistalsis

## Chapter 97 Disorders of Swallowing

- Laryngeal Penetration
- Laryngeal Penetration and Tracheal Aspiration

## Chapter 100 Hypertrophic Pyloric Stenosis

- Sonographic Sweep to Find Antropyloric Canal: Sweep Terminating at Normal Pylorus 100-1
- Sonographic Sweep to Find Antropyloric Canal: Sweep Terminating at Abnormal, Hypertrophied Pylorus of HPS
- Transient Appearance of HPS during Normal Peristaltic Activity in a Normal Infant
- Passage of Air Through Abnormal Pyloric Canal
- Changes in the Length and Thickness of the Abnormal Antropyloric Canal in Real Time

## Chapter 102 Congenital and Neonatal Abnormalities

- UGI Evaluation of the Duodenum
- Midgut Volvulus
- Midgut Volvulus
- Chronic Midgut Volvulus

## Chapter 104 Acquired Lesions of the Small Intestines

- Crohn Stricture Causing Partial Small Bowel Obstruction
- Crohn Disease Ileal Stricture

## Chapter 107 Intussusception

- Active Peristalsis in Transient Small Bowel Intussusception
- Air Reduction of Intussusception

## Chapter 112 Prenatal Imaging and Intervention

- Fetal Autosomal Recessive Polycystic Kidney Disease on Ultrasound

## Chapter 130 Prenatal Musculoskeletal Imaging

- Amniotic Band Syndrome

# 1

# Radiation Bioeffects, Risks, and Radiation Protection in Medical Imaging in Children

*Joseph T. Davis and Donald P. Frush*

Diagnostic imaging has evolved from the single technique of radiography discussed in the first edition of *Caffey's Pediatric X-Ray Diagnosis* in 1945 to a specialty with many modalities and techniques. Many of these modalities use ionizing radiation, and some, such as computed tomography (CT) and nuclear imaging, entail relatively high doses of radiation.[1] Therefore the imaging community (and our medical colleagues) must jointly adhere to two of the principles of radiation protection for our patients: justification (i.e., the examination is warranted) and optimization (i.e., the appropriate technique is used). For example, in computed or direct digital radiographic examinations, image processing can accommodate overexposures. The image can be adjusted to appear as if it were obtained using standard techniques, whereas with screen film technology, the film image would be recognized as overexposed (dark) (Fig. 1.1). Without accountability for displaying dose metrics (such as the exposure index available with digital radiography), it is difficult or impossible to account for patient exposures in clinical practice.[2] Additionally, uninformed and potentially irresponsible justification of medical imaging occurs when persons are unfamiliar with the methods of estimating an effective radiation dose during CT examinations in children.[3,4] Increasing accountability is expected from the medical community with regard to the use of imaging modalities that expose children (as well as adults) to ionizing radiation. As such, a basic understanding of radiation biology, including bioeffects, radiation doses of various types of imaging examinations, and risks of radiation, is essential for the pediatric imager. A glossary of terms and dose descriptors is found in the addendum at the end of this chapter.

## TRENDS IN MEDICAL RADIATION EXPOSURE TO CHILDREN

Approximately 4 billion imaging examinations using ionizing radiation (i.e., radiography, fluoroscopy/angiography, CT, and nuclear imaging) are performed annually worldwide.[5] In the United States, medical imaging currently accounts for a significant percentage of the annual radiation exposure to the population.[6] Natural or background sources account for about 50% of the annual radiation exposure in the United States, and diagnostic medical radiation accounts for most of the remainder, an approximately sixfold increase during the past 30 years (Figs. 1.2A and B). CT alone accounts for nearly 25% of all radiation exposure to the US population.[6,7] Many reasons exist for the increased use of diagnostic medical radiation, and much use of such radiation is based on sound medical decision making. However, other factors determine use as well, including defensive medicine.

## PATHOPHYSIOLOGY OF RADIATION EFFECTS

Hall has written an excellent review of radiobiology for the radiologist.[8] The biologic effects of radiation result primarily from damage to deoxyribonucleic acid (DNA). The x-ray particle, the photon, gives up its energy to produce a fast recoil electron, which may damage DNA directly but which also can interact with a molecule of water to produce a free radical (Fig. 1.3). A free radical is a highly reactive atom or molecule with an unpaired electron in the outer shell:

$$H_2O \rightarrow H_2O^+ + e^-$$

$$H_2O^+ + H_2O \rightarrow H_3O^+ + OH^*$$

where the asterisk indicates a free radical.

Two-thirds of x-ray damage occurs via OH radicals, suggesting that someday this component of radiation damage might be reduced through the use of chemical radioprotectants. The topic of radioprotectants was recently well reviewed.[9]

The biologic effects of radiation result primarily from damage to double-stranded DNA as opposed to single-strand injury (see Fig. 1.3). Single-strand breaks of DNA are readily repaired and are presumed to have a negligible effect. Breaks in both DNA strands that are opposite or separated by a few base pairs are much more difficult to repair. These double-strand breaks can cause important biologic effects, including genetic mutations, carcinogenesis, and cell death. Dicentric and fragmented breaks typically result in cell death, whereas nonlethal translocation repairs may cause impaired cellular function, including development of an oncogene.[8]

The biochemical and physiologic damage produced by radiation generally occurs within hours or days, but the impact of these changes, such as the induction of cancer, can take decades to manifest. This carcinogenic process has several steps. Aberrations in chromosomes (e.g., deletions, translocations, or aneuploidy) are produced by DNA damage. Because these damaged cells survive, they become "stable aberrations" (some with neoplastic transformation), the first step to radiation-induced carcinogenesis. The second step is cellular immortality; that is, most cancer cells are descendants of a single cell that originally underwent neoplastic transformation. The third step is tumorgenicity. The radiation exposure induces a cellular genomic instability that is transmitted to progeny, which Little described as "a persistent enhancement in the rate of which genetic changes arise in the descendants of the irradiated cells after many generations of replication…[this process] has been termed a nontargeted effect of radiation as genomic damage occurs in the cells that in themselves receive no direct radiation exposure."[10]

Most childhood tumors occur sporadically, but in 10% to 15% of the cases, a strong family association and genetic basis for radiation sensitivity are present. Persons with certain diseases are uniquely sensitive to radiation-induced cancers, although the exact mechanism is unclear (Box 1.1).

## TYPES OF RADIATION BIOEFFECTS

The two types of biologic effects from radiation are tissue effects (also called *deterministic effects*) and stochastic (random) effects.

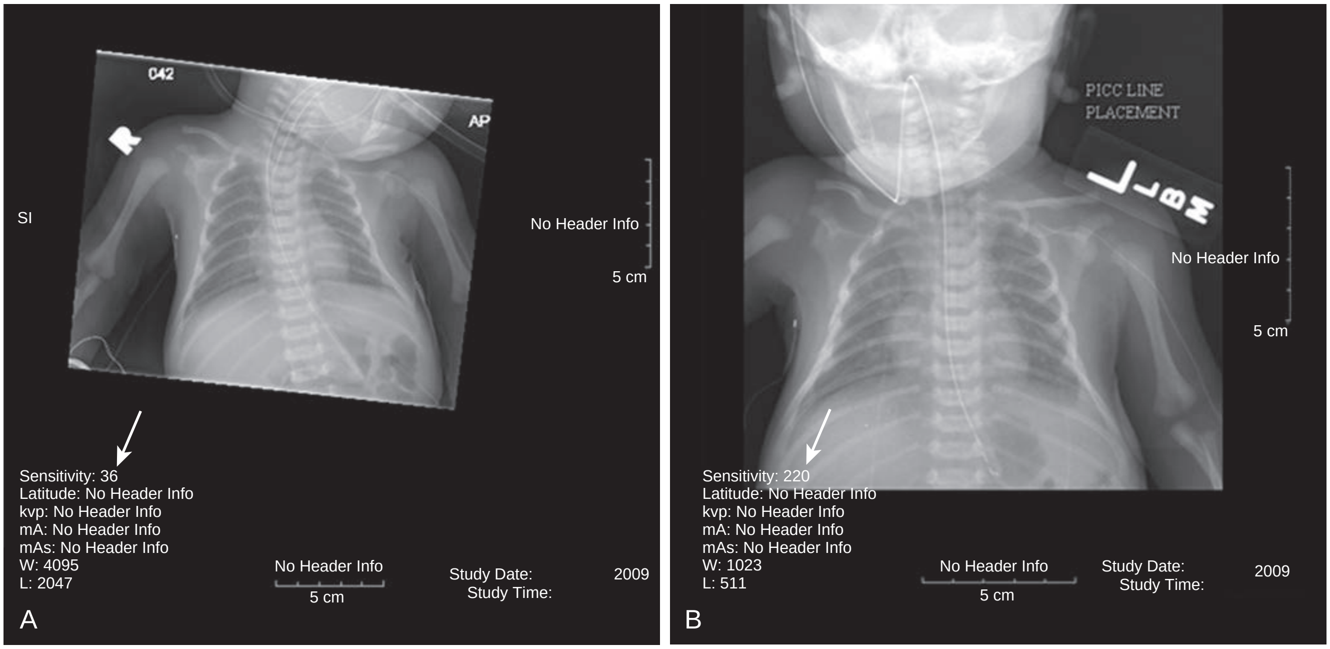

**Figure 1.1.** (A) Neonatal chest radiograph has an exposure index ("S" value 39) *(arrow)* that was very low, indicating a relatively high radiation exposure, which would have rendered this image dark with film screen technology. This radiograph was processed to yield appropriate contrast and brightness. (B) After adjustment to a more appropriate exposure index ("S" value 220) *(arrow)*. The image quality is very similar. The left arm was included because assessment was for percutaneous indwelling central catheter placement. *(From Frush DP. Radiation protection in children undergoing medical imaging. **TABLE 1.1** Deterministic Dose Rates

| Skin Injury | Approximate Threshold |
|---|---|
| **Skin** | |
| Transient erythema | 200 rad (2 Gy) |
| Dry desquamation | 1000 rad (10 Gy) |
| Moist desquamation | 1500 rad (15 Gy) |
| Temporary epilation | 200 rad (2 Gy) |
| Permanent epilation | 700 rad (7 Gy) |
| **Late effects on tissue** | **More variable** |

*Modified from Hall EJ.* Radiobiology for the Radiologist. *5th ed. Philadelphia: Lippincott Williams & Wilkins; 2000.*

Tissue bioeffects are characterized by a threshold dose, and the severity of the effect is dose dependent. For example, cataracts occur above a threshold recent data suggest is near 500 mGy.[11] Table 1.1 shows some of the doses for deterministic effects. In general, such effects from diagnostic imaging doses are extremely rare. Exceptions with head perfusion CT scanning in adults have been reported.[12] Deterministic effects such as skin ulcers and burns should never occur from diagnostic imaging, but they are occasionally seen with relatively lengthy interventional procedures.

Stochastic effects are more of a concern because they have the potential to occur at any dose, and the severity of the effect is independent of the dose. No threshold exists with stochastic effects, but the probability of an effect (e.g., cancer) increases with increasing doses.

## FETUSES AND CHILDREN HAVE GREATER RADIATION RISKS

From a public health perspective, all ionizing radiation, including that from medical imaging, is considered to be potentially harmful because we assume that no threshold exists below which radiation is safe (i.e., no harmful effects will occur). This "linear no threshold" model is applied to low-level radiation exposure.[13,14]

The effects of radiation are greatest on rapidly developing tissues and organs—in fetuses, infants, and young children. In pregnancy, the major biologic effects of fetal demise, growth restriction, organ malformations, and cognitive deficits are seen only with doses far in excess of routine diagnostic imaging.[15] The risk of developing cancer from exposure of a fetus to radiation is uncertain; potential effects could be seen with uterine doses that occur as a result of relatively high direct exposures (e.g., a pelvis CT scan for possible appendicitis). No data in humans indicate that genetic effects result from diagnostic levels of radiation.

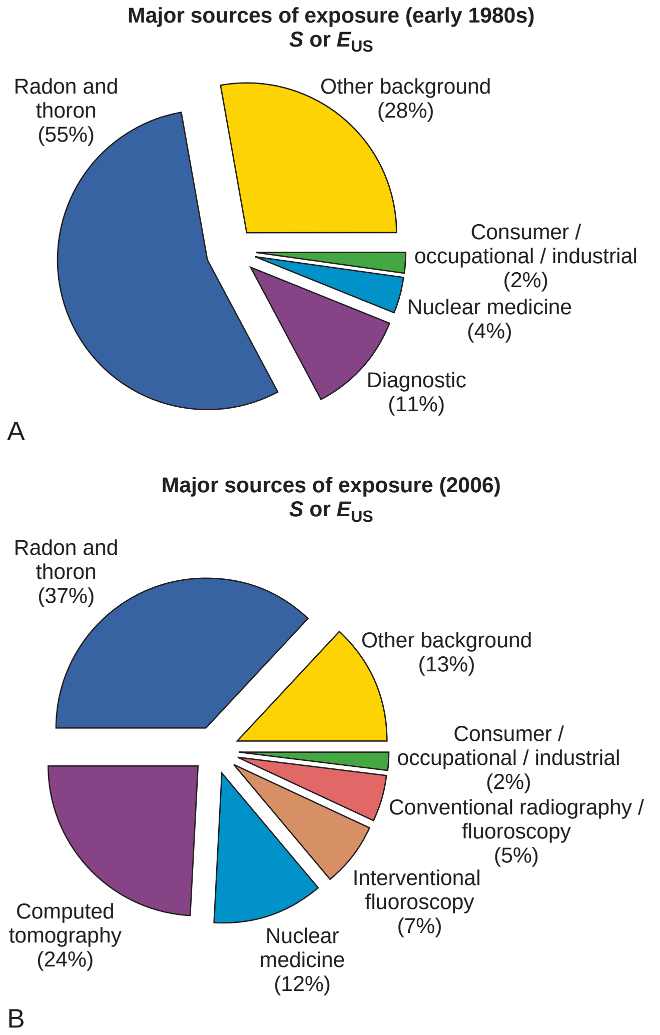

**Figure 1.2.** All exposure categories for the collective effective dose (%), early 1980s (A) and 2006 (B). *(Data from the National Council on Radiation Protection & Measurements.* Ionizing radiation exposure of the population of the United States [NCRP report No. 160]. *Bethesda, MD: National Council on Radiation Protection & Measurements; 2009. Used with permission.)*

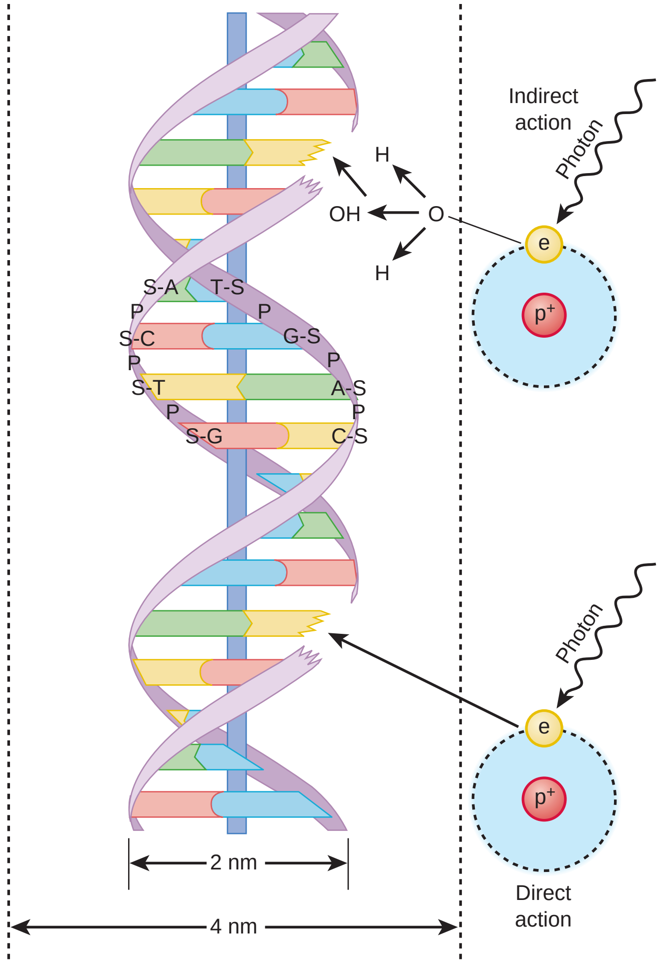

**Figure 1.3. Direct and indirect action.** Indirect action (top part of figure), an electron damages the deoxyribonucleic acid (DNA). In indirect action, the secondary electron interacts with a water molecule to produce a hydroxyl radical that then damages DNA, in this case affecting a single strand. *(From Hall EJ. Radiation biology for pediatric radiologists.* Pediatr Radiol. *2009;39[1]:S57–S64. Used with permission.)*

Compared with middle-aged adults, children are from 2 to 15 times more sensitive to radiation-induced carcinogenesis.[16,17] However, Shuryak et al. recently noted that the cancer induction risk (greater at younger ages) must be balanced with the radiation-induced promotion of premalignant damage (greater in middle age), which may differ for certain types of cancer.[18] Thus cancer risks may be higher in the adult population than traditionally believed.[19]

Low-dose effects have been described by Pierce and Preston, who studied the data from atomic bomb survivors reported by the Radiation Effects Research Foundation.[20] Among persons who had received dosages of 0.005 to 0.2 sievert (500 mrad to 20 rad), 35,000 people survived, and 5000 cases of cancer developed. The authors made the following conclusions: first, the solid cancer risk persists for more than 50 years. Second, there is a 10% increase over the expected cancer rate.[20] Low-dose relative risk factors are shown in Fig. 1.4.

The overall increased risk of excess cancer for the entire population suggested by the International Commission on Radiological Protection is 5% per sievert for low doses and low-dose rate. This value is an average value; for adults in late middle age, the excess risk decreases to only 1% per sievert, whereas for children, the excess risk may be as high as 16% per sievert for girls and 12% per sievert for boys. The female dose is higher because of the greater incidence of breast and thyroid cancers (Fig. 1.5). Radiation risks from diagnostic imaging low-level radiation were reviewed recently.[21] Two excellent reviews also recently were published by Linet et al. (e-Table 1.2).[22,23] We have cautious uncertainty regarding cancer risk and low-level radiation.[24,25] As Hricak et al. state, “In brief, there is reasonable, though not definitive, epidemiologic evidence that organ doses in the range from 5 to 125 mSv result in a very small but statistically significant nonzero increase in cancer risk.”[26]

## RADIATION EXPOSURES FROM VARIOUS IMAGING MODALITIES

When discussing radiation dose, it is important to state clearly whether entrance dose, skin dose, exit dose, or organ (absorbed) dose is considered. For example, a vast difference can exist between skin dose and gonadal dose for the same incident radiation. (The terms for dose and quantitative comparisons are provided in the glossary, and dose metrics are provided in Box 1.2.) “Effective

1. Unit of radioactivity—becquerel (Bq)
   Bq = 1 disintegration/sec
2. Unit of radioactivity—curie (Ci)
   1 Ci = 3.7 × $10^{10}$ Bq (disintegration/sec)
   1 Ci = 2.2 × $10^{12}$ disintegration/min
   10 mCi = 370 mBq

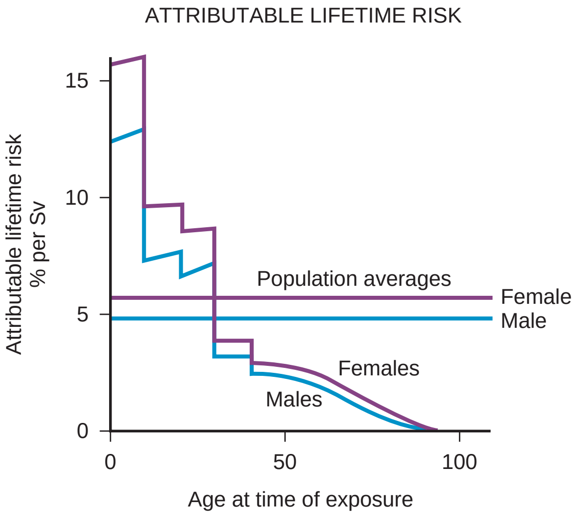

**Figure 1.5. Lifetime risk of excess cancer per sievert (SV) as a function of age at the time of exposure.** Data from atomic bomb survivors. Although the average risk for a population is about 5% per sievert, the risk varies considerably with age; children are much more sensitive than adults. At early ages, girls are more sensitive than boys. *(From Hall EJ. Introduction to session I. helical CT and cancer risk.* Pediatr Radiol. *2002;32:225–227.)*

dose" is one measure of radiation that is widely used in discussions of medical radiation. It is commonly used because it is relatively easily derived and allows gross comparisons of dose estimations between examinations of different regions as well as different modalities. However, the application of effective dose in medical imaging can be problematic.[27,28]

Published estimates for radiation doses in adults and children include those by Fahey et al. and Mettler et al.[29,30] In summary, radiographic dose ranges from a fraction of a millisievert (for extremity evaluation) to somewhat larger doses of more than 1.0 mSv for more extensive examinations, such as a lumbar spine series. Fluoroscopic doses depend on technical parameters, especially fluoroscopy time, filters employed, magnification, and frame rate, and can vary widely from very low–dose cystography to doses in tens of millisieverts for complex interventional procedures. CT can deliver a relatively large dose of ionizing radiation. The number of these examinations has been increasing rapidly, with children up to 15 years old undergoing approximately 11% of all CT examinations.[31] More recent information has shown that the dose (CTDI; see glossary) from CT in adults is less than 1.0 mSv to as much as 40 mSv.[29,30] Typical pediatric CT doses should be less than 10 mSv,[29,32] and with iterative reconstruction technologies, an increasing fraction of body examinations are approaching or being performed in the submillisievert range. Data on radiation doses from select pediatric imaging examinations are found in Tables 1.3 and 1.4.

## STRATEGIES FOR OPTIMIZING RADIATION DOSES FOR CHILDREN

The fundamental principles for protecting children from radiation during imaging include justification and optimization. Justification for a study can be difficult to define, although summary recommendations and appropriateness criteria for medical imaging are available.[33] The possible use of imaging modalities that do not depend on ionizing radiation, especially magnetic resonance imaging and sonography, is fundamental in justification decisions.

When an examination is considered justified, the imaging technique should be optimized. Radiation reduction is not always appropriate because some examinations require multiple and additional projections, greater fluoroscopy time or magnification, or lower image noise (requiring a higher dose) to answer specific clinical questions. Implicit here is the "as low as reasonable achievable" principle, which entails using the amount of radiation necessary for diagnosis and no more (or less).

Patient preparation and examination planning are paramount. Planning includes communicating with the ordering clinician when necessary to clarify examination indications.[34] Communication also is important both before and during fluoroscopic and angiographic examinations to minimize potentially nonuseful fluoroscopy. Use of appropriately trained staff and involvement with qualified medical physicists, along with licensing, certification, and accreditation considerations and routine reviews of equipment function and

§From Galanski M, Nagel HD, Stamm G. *Paediatric CT Exposure Practice in the Federal Republic of Germany—Results of a Nation-Wide Survey in 2005/2006*. Hannover, Germany: Hannover Medical School; 2006. Radiation doses are based on a German nationwide survey on multislice CT. The radiation dose in each age group category is the dose administered to pediatric patients who are newborn (the 0-year category), those ages >0–1 year (the 1-year category), those ages 2–5 years (the 5-year category), those ages 6–10 years (the 10-year category), and those ages 11–15 years (the 15-year category).

protocols as part of quality control and assessment, are becoming expected components of radiation protection in medicine.[35]

Dose management strategies in pediatric radiographic imaging include collimation, evaluation of the number of projections required, consideration of the source to receptor and patient to receptor distances, shielding when appropriate, use of grids, filtering, consideration of exposure factors, and use of postprocessing techniques. General strategies for protecting patients during radiography can be found in International Atomic Energy Agency educational material.[36]

A number of dose management strategies exist for fluoroscopy and interventional radiology, including those by the International Atomic Energy Agency and Alliance for Radiation Safety in Pediatric Imaging (Image Gently Campaign).[37–39] These strategies include avoiding field overlap and electronic magnification, placement of the image intensifier before fluoroscopic activation, use of appropriate grids and positioning (i.e., source to patient and patient to intensifier distances), collimation, and use of pediatric-specific filters. In addition, last image hold, pulsed fluoroscopy, image store, video capture, and alerts are part of examination optimization for children. Video recording during studies can provide review without use of additional fluoroscopy.

Contemporary strategies and examination optimization for radiation dose management in pediatric CT, including protocol optimization, are available.[40–43] Adjustment in the parameters that are primarily responsible for the dose delivered—tube current (milliamperes), gantry cycle time in seconds, peak kilovoltage, and table speed—should be based on the size of the child, examination indication, prior examinations, and region examined. Additional efforts should include minimizing multiphase examinations, excessive scan length, and overlapping regions of examination. Tube current modulation, organ-based dose modulation (in which the tube current is reduced in an arc to reduce the surface dose to anterior structures such as the breasts when the patient is supine), iterative reconstructive technologies, kVp, rapid table translation, and dual-source/dual-energy technology also have provided real or potential opportunities for dose reduction, improved examination quality, or a combination of both. The use of shielding in the region of scanning, which usually is discussed for breast tissue, is debated.[44,45] A more in-depth discussion of radiation protection in children undergoing diagnostic imaging is available.[46]

## COMMUNICATION OF RADIATION RISK

Given existing information regarding the risk of medical radiation, communication of that risk with patients, their families, and health care providers is important, but fraught. Many clinicians are aware of the study by Pearce et al. demonstrating one excess case each of leukemia and brain tumor for every 10,000 pediatric head CT scans.[47] Methodologic issues limited the conclusions drawn; however, even if this reported risk is accurate, when a CT scan is performed in a setting meeting appropriate clinical criteria, the benefits far outweigh the risks. In fact, *not* performing a clinically indicated CT scan because of radiation risk concerns is more likely to cause harm than the indicated scan itself.[48]

As such, educational efforts are extremely important, particularly given increased scrutiny and concern regarding medical radiation and the risk of cancer. To these ends, the Image Gently Alliance[49,50] has been a successful education and awareness organization for informed use of ionizing radiation in medical imaging in children.

Continued needs include more evidence-based research and decision support to improve utilization,[51] better dose estimations,[6,7] ongoing optimization of diagnostic reference levels for pediatric imaging, alerts and notifications on imaging equipment,[52] and dose monitoring for all modalities as well as dose tracking and relevant imaging providers.[53]

## APPENDIX: GLOSSARY AND DOSE DESCRIPTORS

As we probe more deeply into the effects of radiation, it is important to use precise definitions. Some of the most pertinent terms are provided in this glossary.[8]

**Absolute risk:** The risk of an adverse effect that is independent of other causes of that same health effect.

**Absorbed dose (D):** The energy imparted to matter per unit of mass by ionizing radiation at a specific point. The Systeme Internationale (SI) unit of absorbed dose is joules per kilogram (J/kg); the Gray (Gy). The previously used special unit of absorbed dose, the rad, was defined as being an energy absorption dose of 100 erg/g; 1 Gy = 100 rad.

**ALARA (as low as reasonably achievable):** The principle of limiting the radiation dose administered to exposed individuals to levels as low as are reasonably achievable, taking into account economic and social factors.

**TABLE 1.4** Typical Effective Radiation Dose of Common Radiologic Procedures in Children

| Examination | Typical Effective Dose by Age of Exposure (mSv) | | | | Adult |
|---|---|---|---|---|---|
| | **Newborn** | **1 Year** | **5 Years** | **10 Years** | |
| Chest x-ray | 0.02 | | | | |
| Intraoral dental radiography | 0.005 | | | | |
| Dental orthopantomogram | 0.01 | | | | |
| Cone beam craniofacial dental CT | <1 | | | | |
| Head CT | 6 | 3.7 | 2 | 2.2 | 2 |
| Chest CT | 1.7 | 1.8 | 3 | 3.5 | 7 |
| Abdominal CT | 5.3 | 4.2 | 3.7 | 3.7 | 7 |
| FDG PET CT | 15.3 | | | | |
| Tc-99m bone scan | 6 | | | | |
| Fluoroscopic cystogram | 0.33 | | | | |
| Fluoroscopic pediatric interventional cardiology | 1 to 37 | | | | |

**Background radiation:** The radiation in the natural environment, including cosmic rays and radiation from the naturally radioactive elements, found outside and inside the bodies of humans and animals. Background radiation also is called *natural radiation*. The term also may mean radiation that is unrelated to a specific experiment.

**CTDI:** Computed tomography dose index, a radiation exposure index defined as the average dose of a single CT slice acquisition of a given protocol performed on a standard 100 mm pencil chamber dosimeter within a standard phantom.

**Effective dose:** The radiation dose, accounting for the fact that some types of radiation are more damaging than are others and some parts of the body are more sensitive to radiation than are others. It is defined as the sum, over specified tissues, of the products of the equivalent doses in the exposed tissues and the weighting factors for those tissues.

**Exposure:** Exposure is used more often in its more general sense and not as the specially defined radiation quantity. It is a measure of the quantity of radiation based on its ability to ionize air through which it passes. The previously used special unit of exposure, the roentgen (R), has been replaced with the SI unit of exposure, coulombs per kilogram (C/kg); $1\ \text{R} = 2.58 \times 10^{-4}$ C/kg (exactly). The physical quantity exposure may be replaced by the quantity air kerma in air, especially for calibration of monitoring instruments: 1 R = 10 mGy air kerma.

**Free radical:** A fragment of an atom or molecule that contains an unpaired electron in the outer shell and is very reactive.

**Gamma rays:** High-energy, short-wavelength electromagnetic radiation ($\gamma$). Gamma radiation frequently accompanies $\alpha$ and $\beta$ emissions and always accompanies fission. Gamma rays are very penetrating and are best stopped or shielded against by dense materials, such as lead or depleted uranium. Gamma rays are indistinguishable from x-rays except for their source: gamma rays originate inside the nucleus, and x-rays originate from outside.

**Gray (Gy):** The special name for the SI unit of absorbed dose (kerma) and specific energy imparted equal to 1 J/kg. The previous unit of absorbed dose, the rad, has been replaced by the gray: 1 Gy = 100 rad.

**Hereditary effects of radiation:** Radiation effects that can be transferred from parent to offspring; any changes in the genetic material of sex cells caused by radiation.

**Kerma (kinetic energy released per unit mass):** The sum of the initial kinetic energies of all the charged ionizing particles liberated by uncharged ionizing particles per unit mass of a specified material. Kerma is measured in the same unit as absorbed dose. The SI unit of kerma is joules per kilogram (J/kg), and its special name is the gray (Gy). Kerma can be quoted for any specified material at a point in free space or in an absorbing medium.

**Lifetime risk:** The risk of dying of some particular cause over the entire course of a person's life.

**Linear no threshold (LNT):** The theory based on a linear dose response that no level of radiation exposure can be assumed to be absolutely safe.

**Rad:** The old unit of absorbed dose, equivalent to an energy absorption of 100 erg/g. Superseded by the Gray (see absorbed dose).

**Relative risk:** The situation in which the risk of a disease resulting from some injury is expressed as some percentage increase of the spontaneous rate of occurrence of that disease. Relative risk is in contrast to an absolute risk, in which the risk of a disease resulting from an injury does not depend on the normal rate of occurrence of that disease.

**Rem:** Old unit of equivalent or effective dose. It is the product of absorbed dose (in rads), the radiation weighting factor, and the tissue weighting factor; 1 rem = 0.01 Sv.

**Roentgen (R):** A unit of exposure to ionizing radiation named after Wilhelm Röntgen, the German scientist who discovered x-rays in 1895. It is that amount of $\gamma$ rays or x-rays required to produce ions carrying one electrostatic unit of electric charge (either positive or negative) in 1 $\text{cm}^3$ of dry air under standard conditions.

**Sievert (Sv):** Unit of equivalent dose or effective dose: 1 Sv = 100 rem.

**Stochastic effect:** The effect, the probability of which, rather than its severity, is a function of radiation dose without threshold. More generally, stochastic means random in nature.

**Tissue (deterministic) effect:** An effect with a threshold, the severity of which increases as the dose increases.

## KEY POINTS

- Radiation can have a direct action on DNA or operate indirectly through free radicals.
- In medicine, biologic effects from radiation are primarily a result of double-strand DNA breaks.
- In diagnostic imaging, radiation effects are stochastic effects, primarily cancer induction (vs. deterministic effects such as skin burns seen at much higher doses).
- Fetal and childhood tissues are more susceptible to the stochastic effects of radiation.
- Key principles of protecting persons from diagnostic radiation are justification (only perform indicated examinations) and optimization (use appropriate examination techniques).
- Dose metrics (i.e., exposure or dose estimations) should be part of the examination information for every modality that uses ionizing radiation.

# 2

# Magnetic Resonance Safety

*Ramkumar Krishnamurthy and Jean A. Tkach*

Magnetic resonance imaging (MRI) has proved to be a powerful diagnostic imaging tool in children and adults. MRI uses low-energy nonionizing radio waves, and as such it is particularly well suited for pediatric and longitudinal imaging studies. MRI exploits a wide variety of intrinsic tissue-specific properties to generate a wide spectrum of tissue contrast, thus providing detailed information about anatomy, physiology, and function. For clinical MRI examinations, the acquisition techniques used and the specific acquisition parameters selected are manipulated to generate the type of image contrast most relevant to the underlying medical question. Unlike MRI, ultrasound is limited by the restriction of air and bony anatomy, and radiography and computed tomography uses ionizing radiation. Compared with other diagnostic imaging modalities, MRI has proved to be superior at imaging soft tissues. In addition, MRI enables images to be obtained in any plane and can provide true volumetric data acquisition.

MRI, when performed following the right conditions and guidelines, presents no apparent safety risks, and millions of MRI examinations are performed each year without incident. However, when not appropriately managed, safety concerns exist from the following: each of the three electromagnetic fields (Table 2.1), external contrast agent (typically gadolinium-based), associated acoustic noise, and other issues (e.g., sedation). Notably, most MR-related injuries and the few fatalities that have occurred primarily were a result of the failure to adhere to MR safety guidelines for the MRI environment, or they occurred because inaccurate or outdated MR safety-related information was used for biomedical implants and devices.[1,2]

To prevent similar adverse MR safety-related incidents from occurring, it is imperative that the potential safety risks intrinsic to the MR environment be understood and respected by users of this powerful imaging technology.

## SAFETY CONSIDERATIONS: ELECTROMAGNETIC FIELDS

### Main Static Magnetic Field

### Biologic Effects of Static Magnetic Fields

The majority of MRI systems in clinical use today operate at main or static magnetic field strengths of 0.2 to 3.0 tesla (T), with 1.5 T and 3.0 T units being used predominantly. The static field of a 1.5 T scanner is approximately 30,000 times stronger than Earth's magnetic field (roughly 0.00005 T). The most recent United States Food and Drug Administration (FDA) guidelines state that, for adults, children, and infants older than 1 month, diagnostic MRI systems that operate at or below 8 T are considered to be a nonsignificant risk. For neonates, the limit is 4 T.[3] In practice, 3 T is the highest field strength in common clinical use. Initially, some concern was expressed that the strong magnetic fields might have irreversible detrimental biologic/health effects in humans, including alterations in cell growth and morphology, cell reproduction and teratogenicity, DNA structure and gene expression, prenatal and postnatal reproduction and development, blood-brain barrier permeability, nerve activity, cognitive function and behavior, cardiovascular dynamics, hematologic indexes, temperature regulation, circadian rhythms, immune responsiveness, and other biologic processes.[4–22] However, a comprehensive review of the literature indicates that short-term exposures (of a duration comparable to an MR examination) to high-static magnetic fields produce no appreciable long-term detrimental biologic effects.[23,24]

Although no lasting adverse effects of short-term exposures to high magnetic field strengths have been reported, several relatively transient reversible biologic effects are known to occur, including electrocardiographic changes and benign sensory effects. These effects have been reported primarily at field strengths greater than 2 T, and the sensory effects appear to occur most often when a person's head is moved rapidly within the static magnetic field. The elevation in electrocardiographic T waves is believed to be due to magnetohydrodynamic phenomena.[25,26] The voltage associated with the magnetohydrodynamic effect is not considered hazardous at the magnetic field strengths approved for clinical use. However, at higher field strengths, the possibility exists that the induced potential might exceed 40 mV (voltage produced across large arteries are on the order of 5 mV/T), which is the threshold for depolarization of cardiac muscle.[27]

Several short-term, relatively benign sensory effects have been reported at higher field strengths, including vertigo, nausea, headaches, flashing lights (also known as magnetophosphenes), a metallic taste, and/or sensation in dental fillings.[28]

### Interaction of the Main Magnetic Field With Ferromagnetic Objects

**Torque and Attractive Forces.** The field associated with an MR scanner can be separated into two spatial regions defined by the types of interaction with ferromagnetic objects that predominate in each region. The first region surrounds the magnet isocenter and is contained within the bore of the MRI scanner. The magnetic field in this region essentially is temporally constant and homogeneous in strength. A magnetic object introduced into this region of the static field is subjected to a torque that acts to align it with the magnetic field, just as magnetic material aligns itself with the poles of a permanent bar magnet or a compass needle aligns itself with the Earth's magnetic field.[29] Hence any nonspherical metallic object that enters the spatially homogenous static region of the field will be subjected to a rotational force or torque such that its long axis will be aligned with that of the main magnetic field. If the metallic implants are not sufficiently anchored by the surrounding tissue (e.g., bone in the case of an orthopedic implant), the resultant rotational motion will cause trauma to the surrounding tissue. The magnitude of these effects depends on the geometry and mass of the object, as well as the characteristics of the MR system's magnetic field.

In the second region (the fringe field), the strong magnetic field strength drops off rapidly as the distance from the magnet increases, producing a large spatial gradient that typically is greatest in regions immediately adjacent to the magnet. Modern day scanners have actively shielded main magnetic fields, which significantly increases the spatial gradient. Metallic objects introduced into this magnetic field gradient experience a translational (attractive) and rotational force. The translation will be in the direction of the higher field strength. The strength of the attractive/translational force will depend on the size of the object and its location within the gradient field and will increase rapidly as the object approaches the magnet. As such, the metallic object will be accelerated along the direction of the spatial gradients in the static field and

## Abstract:

Following MRI safety guidelines is critical in ensuring a successful and safety event-free MRI experience. However, there are unique considerations in adhering to safety guidelines in children compared with as an adult population. The higher use of sedation also makes following MRI safety guidelines challenging.

## Keywords:

Pediatric MRI safety
ACR guidelines

**TABLE 2.1** Principal Mechanisms of Interaction of the Three Main MRI Energy Fields With Tissues and Some Related Effects

| Magnetic Resonance–Related Electromagnetic Field | Mechanism of Interaction | Potential Effects |
|---|---|---|
| Static magnetic field (T) | Polarization/ magnetization | Elevated electrocardiographic T wave and/or transient sensory effects (e.g., vertigo, nausea, phosphenes, and metallic taste) |
| Transient gradient magnetic field (dB/dt) | Induced currents<br>Acoustic noise | Peripheral nerve stimulation<br>Physiologic stress, anxiety, temporary hearing loss |
| Radio frequency field (specific absorption rate) | Thermal heating | Local burns |

*From Bushong SC. Biologic effects of magnetic resonance imaging. In:* MR safety, magnetic resonance imaging: physical and biological principles. *3rd ed. St Louis: Mosby; 2003.*

quickly can become a dangerous projectile. Depending on the size and composition of the metallic object, these attractive/translational effects may begin as soon as the object is introduced into the scan room. Once the object enters the uniform field within the bore of the magnet, acceleration will cease and the object will come to a stop.[25]

The potential hazards associated with the spatial gradients are greatest for high magnetic field strengths and large fringe fields. In general, the forces increase approximately as the square of the field strength but will vary depending on the composition of the object.[30] For example, at 3 T compared with 1.5 T, the force on a paramagnetic material (e.g., a stainless steel scalpel) is 5 times greater, whereas the force on a ferromagnetic object (e.g., a steel wrench) is 2.5 times greater.[30] Finally, even for a given field strength, the magnitude and footprint of the spatial gradients can vary between magnet configurations. For example, it has been reported that short-bore MR systems have significantly higher spatial gradients than long-bore scanners, particularly those operating at 3 T.[31,32] This finding highlights the multiple nuances and factors that must be considered when evaluating and establishing MR safety guidelines and operating procedures for any object before it may be introduced into a specific MRI environment. It is a common misconception that the magnet is only "on" when the images are being acquired. However, the magnet is *always* on, and signage to indicate the "Magnet is ON" should be displayed conspicuously on the door to the MR scan room.

**Missile/Projectile Effect.** The projectile/missile effect, wherein a ferromagnetic object is accelerated toward the isocenter of the magnet, is the most widely recognized and publicized safety hazard associated with MRI. Objects constructed partially or entirely of ferromagnetic materials (e.g., iron, nickel, cobalt, and the rare earth metals chromium, gadolinium, and dysprosium) are strongly attracted to the magnet bore. Steel objects also are highly ferromagnetic, as are some medical grades of stainless steel. Notably, working a metal by machining, molding, and/or bending it, for example, can alter its magnetic properties and, as a result, some forms of nonmagnetic stainless steel can be made magnetic. For this reason, the MR safety of a given metallic object must be evaluated in its final form.[33] If any doubt remains regarding the presence of ferromagnetic material, the object should be checked with a permanent magnet and/or a ferromagnetic wand as a final precautionary measure before it enters the scan room.

Any individual in the path between the object and the center of the magnet (e.g., the patient lying in the magnet bore) can be seriously injured or killed.[34] Numerous instances of MR-related accidents involving objects such as scalpels, scissors, oxygen tanks, intravenous line poles, wheelchairs, transport carts, floor buffers, mop buckets, vacuum cleaners, other medical devices, and even firearms have been documented. Any injuries related to ferromagnetic projectiles must be documented; the necessary forms can be accessed on the FDA website.[35,36] More comprehensive information regarding these online resources is provided in a later section of this chapter.

To prevent potentially devastating MR-related accidents from occurring, it is essential that access to areas that exceed the 5 Gauss line (see next section) must be rigorously restricted and vigilantly supervised at all times. All patients, accompanying family members, and hospital personnel with a demonstrated need to enter the MR environment must be appropriately educated to the potential hazards and rigorously screened for contraindications.

**5 Gauss Line.** Failure to adhere to safe practices within the MR environment has led to most of the MR-related accidents and fatalities. These incidents have involved the inappropriate introduction of metallic objects and/or implanted medical devices into the scan room. Five gauss (G) (1G = 0.0001 T) and below are considered "safe" levels of static magnetic field exposure for the general public.[29] The 5 G line identifies the perimeter around an MR scanner within which the static magnetic fields are higher than 5 G; it is the most commonly recognized MR safety policy.[25] Safety considerations require that this distance from the magnet be determined and that areas with field strength greater than 5 G be identified with appropriate and conspicuous signage. Importantly, the 5 G line extends in three dimensions; thus when the MR area is sited, the extent of the fringe field to the floors above and below the magnet must be considered. Because of the potential hazards, access to this area must be rigorously controlled and supervised.

## Time-Varying Gradient Magnetic Fields

During imaging acquisition, gradient magnetic fields are transiently imposed along the main magnetic field to spatially localize and encode the spins. These gradient magnetic fields (current clinical gradient strengths vary between 30–90 mT/m) are much weaker than the static magnetic field and are generated by gradient coils located inside the magnet bore. Each orthogonal axis (i.e., $x$, $y$, and $z$) has a pair of gradient coils. For a given direction, a linear gradient magnetic field is generated within the main magnetic field by applying electrical current in opposite directions to the coil pair over a short time interval.[27] When this gradient magnetic field is applied, the magnetic field intensity changes rapidly, giving rise to a time-varying magnetic field. The rate of change in a magnetic field (dB) occurs over time (dt) and usually is measured and reported in units of dB/dt expressed in milliteslas per meter per millisecond (mT/m/msec). During the rise time of the magnetic field, an electrical current can be induced in any electrical conductor (e.g., implanted medical device, wire, human body). Notably, the magnitude of the time-varying magnetic field along each of the three spatial directions (i.e., $x$, $y$, and $z$) is zero at the center of the magnet and increases linearly with increasing distance from the isocenter.

Because the human body is a conductor, the rapidly switching magnetic fields can induce electrical fields and current in a patient (as described by Faraday's law of induction) that may lead to the stimulation of muscle and nerve tissues.[27] The mean threshold levels (measured in tesla per second) for various stimulations are 3600 T/sec for the heart, 900 T/sec for the respiratory system, 90 T/sec for pain, and 60 T/sec for the peripheral nerves. However, the exact values differ significantly among individuals.[25] Experience has shown that sufficient dB/dt levels can produce brief muscle twitches and peripheral nerve stimulation (PNS) perceptible as a "tingling" or "tapping" sensation. This sensation can become uncomfortable and/or painful as the gradient magnetic field increases to 50% to 100% above perception thresholds.[37] For these reasons, threshold sensations, when reported, should not be ignored, because they may readily escalate to uncomfortable levels. Although cardiac stimulation is a concern, studies conducted in dogs have shown that the cardiac stimulation threshold for the most sensitive 1% of the population is 20 times, and the mean defibrillation threshold is 500 times, the energy required for PNS.[33] The exceedingly strong and/or rapidly switching gradient magnetic fields necessary to achieve cardiac stimulation threshold levels are more than an order of magnitude greater than those used in commercially available MR systems.[37–39]

In practice, the potential for PNS is greatest for fast imaging (e.g., echo planar imaging [EPI]) acquisitions, particularly when oblique imaging planes are obtained where the combined contributions of gradients from more than one axis result in a higher effective slew and/or when the readout (i.e., frequency encode) lies along the cranio-caudal direction.[25]

Normal imaging sequences (e.g., conventional spin echo and gradient echo) induce currents of a few tens of milliamperes per square meter, a level far below that present in the normal brain and heart tissue. However, as noted previously, PNS is quite possible for the rapid imaging techniques such as EPI and for high-performance gradients. These effects can be controlled by limiting the maximum rate of change in the magnetic field gradients. The current FDA standard is based on the threshold for sensation, rather than a specific numerical value of dB/dt. Specifically, "current FDA guidance limits the time rate of change of magnetic field (dB/dt) to levels which do not result in painful peripheral nerve stimulation."[29] This policy reflects in part the complexity of modeling and calculating the current distribution in the body associated with the pulsed gradient fields. Correspondingly, dB/dt levels below that resulting in painful stimulation are considered a nonsignificant risk by the FDA. It is important to note that dB/dt is a function of the gradient strength and rise time and not of the static field strength. Thus dB/dt is of equal concern for both lower and higher field scanners.

Clinically, two operating modes for the radio frequency (RF) and gradient field levels used for imaging are permissible, normal and first level controlled (Table 2.2). In normal mode, the system output levels are below those that will cause physiologic stress and therefore are appropriate for all subjects. Alternatively, in first level controlled mode, one of the MR system outputs (e.g., dB/dt) may reach a value that may cause physiologic stress and thus may not be appropriate for the most medically compromised patients. Operation in this mode requires authorization by appropriate clinical staff and vigilant medical supervision during the examination. Institutional Review Board approval is required for operation above these levels (second level controlled). In practice, the commercial MR systems monitor dB/dt throughout the examination and generate a warning for the specific protocols for which PNS is likely. For normal operating mode, the dB/dt threshold level is set at 80% of the mean threshold value for PNS stimulation, and it is set at 100% for the first level.[30] In addition, the MR operator should remain in constant verbal contact with the patient and instruct him or her to report any tingling, muscle twitching, or painful sensations that occur during scanning. This contact is not possible for infants and for sedated, noncommunicative, or otherwise compromised patients. Operationally, dB/dt can be reduced by increasing the field of view and/or slice thickness, reducing the matrix size, and decreasing receiver bandwidth.

**TABLE 2.2** International Electrotechnical Commission/Food and Drug Administration Operating Modes for Magnetic Resonance Imaging Diagnostic Equipment

| Operating Mode | Conditions/Qualifications |
|---|---|
| Normal mode | Will not cause stress; suitable for all patients |
| First level controlled mode | May cause stress; requires medical supervision and positive action by operator to enter |
| Second level controlled mode | Institutional Review Board approval required |

## Radiofrequency Fields

### Biologic Effects

One of the primary safety concerns in MRI is tissue heating. The conductivity of tissue allows the absorption of RF energy, which is transformed into heat as a result of resistive losses.[40,41] The heating is greatest at the periphery of the body, and thus the skin is the most prone to this effect.[30] When thermally challenged, the body responds by thermoregulatory mechanisms and attempts to dissipate the heat by means of convection, conduction, radiation, and evaporation. If these attempts are not completely successful, the heat accumulates, resulting in a rise in local tissue and/or systemic core temperatures,[40–42] which has the potential to produce physiologic changes.[27] For humans, the typical skin temperature is about 33°C, whereas core temperature is about 37°C. Experience has shown that, when the body is subjected to significant RF power levels, it immediately attempts to dissipate the heat load through vasodilatation of the blood vessels of the skin, with the skin approaching core temperature. This response mechanism allows the body to reduce heat fairly rapidly and typically is evidenced by flushing of the skin, which in itself is not harmful and usually subsides within several hours.

The dose measure used to describe this energy absorption or heat dose is the specific absorption rate (SAR). SAR is defined in the International Electrotechnical Commission standard as the amount of RF power (measured in watts) absorbed per patient mass in kilograms (W/kg). The MR system software calculates an SAR for each imaging sequence and enforces the limits established by the FDA. Because SAR depends on patient weight, it is important that an accurate value be entered during the patient registration procedure. The amount of RF energy absorbed is dependent on the frequency (as determined by the static magnetic field strength), the RF coil used, the volume (size), composition (conductivity), and configuration of the exposed tissue and the duty cycle and type of RF pulses applied, as well as other factors.[40–44] Notably, SAR increases with the square of the frequency (and hence magnetic field strength) and patient size.[30] Consequently, for a given pulse sequence, doubling the field strength (e.g., 1.5 vs. 3 T) results in a factor of four increase in SAR. SAR can be minimized by decreasing the power and/or duty cycle of the RF pulses. In practice, this minimization can be accomplished by increasing the repetition time (TR), reducing the number of slices, and, when feasible, reducing the RF flip angle (because SAR is proportional to the square of the flip angle). A person's ability to respond to the thermal challenge and effectively dissipate the heat is influenced by the rate at which the energy is deposited and the duration of the exposure. Underlying health conditions such as cardiovascular disease, hypertension, diabetes, fever, old age, obesity, or a compromised ability to perspire can impair a person's ability to tolerate the thermal challenge.[45–49] In addition, certain medications such as diuretics, β-blockers, calcium channel blockers, amphetamines, muscle relaxants, and sedatives can alter the body's thermoregulatory responses significantly, with some medications actually having a synergistic effect with respect to tissue heating caused by RF exposure.[2] Finally, the ability of the subject to dissipate heat is also affected by the ambient temperature, relative humidity, and airflow in the MR scan room.

To prevent excessive heat stress and/or local tissue damage, the FDA has established guidelines to limit allowable whole-body SAR levels to those that produce no more than a 1°C increase in tissue and/or core temperature beyond the normal 37°C.[27] As with dB/dt, two levels of clinical operation are possible for SAR. Note, however, that only the whole-body SAR limit is increased, from 2 W/kg to 4 W/kg, in the advancement from normal to first level controlled operation. The SAR limit for normal and first level controlled operating modes for the head is 3.2 W/kg (1°C maximum temperature increase) averaged over head mass and 10 W/kg temperature over any 10 g of tissue for the torso and extremities.[50] These SAR limits correspond to time-averaged values over a 6-minute interval. Exceptions to the specified FDA guidelines include infants and pregnant women, for whom the FDA recommends that the limits be reduced by a factor of two. Similarly, for patients with thermoregulatory compromise (e.g., cardiovascular impairment, cerebral vascular impairment, and diabetes), the FDA recommends a whole-body SAR limit of 1.5 W/kg.[33] In addition, the SAR limits are reduced when the ambient temperature rises above 24°C (75°F) or if the humidity exceeds 60%.

### Interaction With Other Devices

Additional safety concerns associated with RF irradiation exist when objects made from conductive materials that have an elongated shape or are looped, such as electrodes, monitor leads, guidewires, and certain types of catheters (e.g., catheters with thermistors or other conducting components), are present in the magnet bore.[38,51–56] The rapidly changing magnetic field associated with the RF can induce an electromotive force in the conductor and, hence, current flow, which, because of electrical resistance, will lead to heating of the conductor. If the conductor is in contact with the skin, burns can result. Incidents of first-, second-, and third-degree burns have been reported.[2,25] In addition, because the body is a conductor, inadvertent conductive loops can arise in the absence of any external conductors, when, for example, the patient's hands or calves are in contact to form a closed loop. In such cases, heating can occur at the high-resistance skin-to-skin contact point, which can result in local redness and blistering. To minimize the possibility of RF burns, all conductors (e.g., leads and coils) that are not being used should be removed from the magnet bore. In addition, the integrity of all conductors that must remain in the magnet bore should be verified before the MR examination, and these cables, leads, and/or wires should be kept as straight as possible and run down the center of the bore. In addition, the patient should be thermally and/or electrically isolated (e.g., using pads and/or sheets or blankets) from direct contact with all conductors and all RF body transmitters, as well as surface coils, and skin-to-skin contact should be avoided. The MR operator must be extra vigilant to mitigate the potential heating risks for infants and sedated or other noncommunicative patients. Any metallic object in or on the patient may absorb RF energy, resulting in excessive heating that may lead to thermal damage of surrounding tissue; the potential for this effect is greatest at higher field strengths.[27,33]

## ACOUSTIC NOISE

The predominant and most widely recognized source of MRI-related acoustic noise is the time-varying gradient magnetic field applied during MRI. The rapid pulsed currents within the gradient coils in the presence of the static magnetic field create strong Lorentz forces that produce a torque on the coil itself, causing it to move and/or vibrate against its mounting. This movement, analogous to that of the diaphragm of a loudspeaker, creates the loud chirping, tapping, knocking, and banging noises heard by the subject during MRI.[2,27] Sound levels for MRI are measured in A-weighted decibels (dBA), which takes the frequency response of the human auditory system into account. As a reference, normal conversation is approximately 60 dBA (www.osha.gov), and a difference of 6 dBA represents a doubling of sound intensity. Sound pressure levels (SPL) of 81 to 117 dBA are common for standard 1.5 T MRI examinations[57] and can be as high as 130 dBA for high-speed acquisitions such as echo planar imaging (EPI) and techniques that use nontraditional (i.e., non-Cartesian) k-space trajectories, such as propeller, radial, and spiral sequences. Although many factors influence the intensity of the MR-related acoustic noise (e.g., gradient coil design, gradient amplitude and slew rate, size of patient, location of patient in magnet bore), higher field strength systems tend to be louder.

MRI-related acoustic noise may lead to simple annoyance, difficulties in verbal communication, heightened anxiety, and temporary or potentially permanent hearing loss for both the patient and other persons in or near the MR scan room.[58–70] In addition, the noise may cause confusion and/or extreme anxiety in more vulnerable patients such as children and elderly persons and in persons with psychiatric disorders.[58,60,71] MRI-related noise also has been reported to produce alterations in physiologic parameters in neonates, which may be problematic in light of their immature cardiac physiology and cerebrovascular regulation.[62] Furthermore, the acoustic noise levels may cause discomfort to sedated patients, and certain drugs are known to increase hearing sensitivity.[61] Because exposure duration is one of the most influential factors in determining the effect of noise on hearing, it is unlikely that the noise levels experienced during the relatively short MR examinations will have a long-term negative effect on hearing.[72,73] It is the short-term effects of MR-related acoustic noise that are the primary concern.

The FDA indicates that MR-related acoustic noise levels must be below the level of concern established by pertinent federal regulatory or other recognized standard-setting organizations.[74] Guidelines for acceptable acoustic noise levels associated with MRI are based on Occupational Safety and Health Administration (OSHA) guidelines for industrial workers, which recognize that the risk is a function of its intensity and the duration of exposure.[25] OSHA standards stipulate that, to avoid hearing damage, the peak unweighted SPL cannot exceed 140 dB[27] and the A-weighted root mean square SPL cannot exceed 99 dBA, with hearing protection in place. Because the acoustic noise level for many sequences can exceed 99 dBA, the MR manufacturer must recommend that it is necessary for the MR system operator to provide the patient with hearing protection.[2] Hearing protection should also be given to all other persons who will be present in the scan room during the MR exam.

The Noise Reduction Rating (NRR) is the standard for hearing protection devices established by the Environmental Protection Agency. For a given noise attenuator, the NRR value is the mean attenuation value (in dB) for the device minus two standard deviations, corresponding to the minimum noise reduction achieved by 98% of the population. For MR examinations, adequate hearing protection can be most easily and effectively accomplished with earplugs (≈29–32 dBA NRR) and/or headphones (≈29–49 dBA for adults and 7–12 dBA mini muffs for infants). Notably, the NRR reported for earplugs will not be realized if they are improperly inserted or do not fit snugly, as often may be the case for young pediatric patients. Although the combined use of earplugs and headphones do not produce additive effects in hearing protection per se, they can increase the NRR by 5 to 6 dB (equivalent to approximately half the sound intensity) for frequencies less than or equal to 2000 Hz (http://www.biac.duke.edu/research/

safety/tutorial.asp). At frequencies higher than 2000 Hz, hearing protection is limited by bone conduction, and the combined use of headphones and earplugs is less beneficial. Nevertheless, the harmonic response of MR systems for a wide spectrum of imaging protocols contains a significant amount of energy at or below 2000 Hz so that combined use is still advisable (Fig. 2.1). MR manufacturers are actively working to further decrease noise levels by using methods such as quieter MR sequences, active noise cancellation filters, acoustic hoods,[57] and vacuum packing.[71]

## CLAUSTROPHOBIA

Many patients find the confinement of the MRI bore at least somewhat disconcerting. For some patients, this discomfort is extreme and can result in anxiety that may escalate into panic. In these cases, sedation is required to perform the MR examination. Claustrophobic reactions in the scanner typically are characterized by a fear of suffocation and/or a fear that something will happen while they are confined.[75] Operationally, experience suggests that this reaction can be minimized by maintaining frequent verbal contact with the individual throughout the examination and sufficient airflow (e.g., a bore fan) to reduce heat and mitigate the fear of suffocation. In addition, the individual also should be provided with an emergency panic notification device (e.g., a pneumatic squeeze bulb) to allow him or her to summon help at any time throughout the examination. In fact, such a device should be provided to all nonsedated communicative patients as a means of notifying the MR operator immediately upon any sign of discomfort, including local heating or tugging of ferromagnetic objects (e.g., a belt or shoes).

## MEDICAL IMPLANTS, DEVICES, AND OTHER METALLIC POTENTIAL HAZARDS

### Passive and Electrically Active Medical Devices

The MR environment may be unsafe for persons with certain medical implants or devices that are made out of ferromagnetic materials. For passive implants (i.e., any medical device that serves its function without the supply of power, such as aneurysm clips, shunts, or stents) made of ferromagnetic materials, the primary concern is movement and/or dislodgement,[31,32,35,36,52,76–85] although excessive heating of the implant is also possible (Table 2.3). Several incidents have occurred in which metallic implants were mistakenly introduced into the MR environment and were dislodged within or from the body, resulting in blindness or death.[25] For electrically active implants such as deep brain or vagal nerve stimulators and drug pumps, excessive heating at the lead tips and associated tissue damage is the primary safety concern.[54,86–88] Device malfunction, device heating, induced currents, and movement and/or dislodgement also are potential hazards (see Table 2.3).

When it is known that a patient has an implant (passive or active), the implant should be considered a contraindication for MRI until documented proof of its MR compatibility and safety

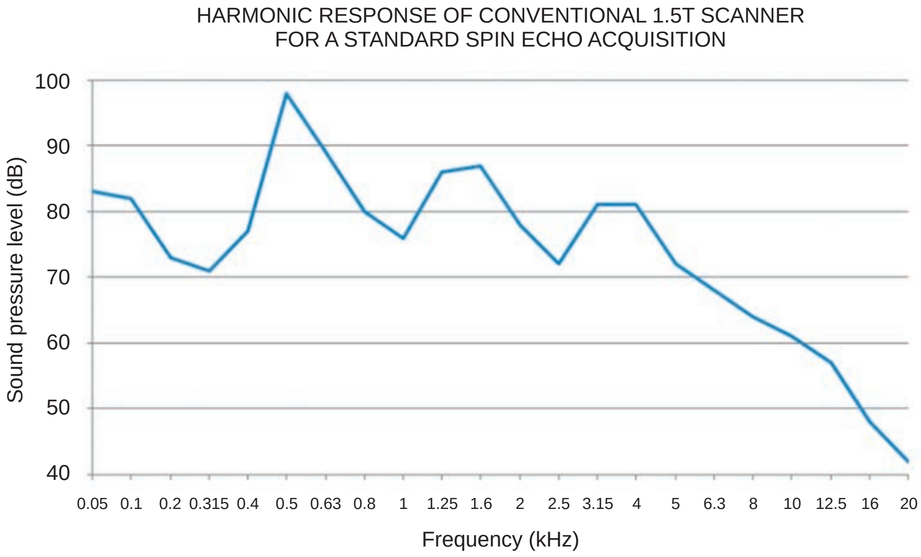

**Figure 2.1.** Harmonic response of a conventional 1.5 T magnetic resonance scanner for a standard spin echo acquisition demonstrating significant energy below 2 kHz. The human auditory range is 20 Hz to 20 kHz.

**TABLE 2.3** Magnetic Resonance Environment Medical Device Concerns

| Component of Magnetic Resonance Environment | Medical Device Concern | Potential Adverse Effect |
|---|---|---|
| Static magnetic field (always on) | Rotational force (torque) on object<br>Translational force on object | Tissue damage as object rotates to align with main field;<br>Tissue trauma as object accelerates toward magnet bore (projectile/missile effect) |
| Gradient magnetic field (pulsed during imaging) | Induced currents due to dB/dt | Device malfunction or failure |
| Radio frequency field (pulsed during imaging) | Radio frequency–induced currents resulting in heating<br>Electromagnetic interference—active | Patient burns (thermal and electrical)<br>Device malfunction, induced noise (monitoring devices) |

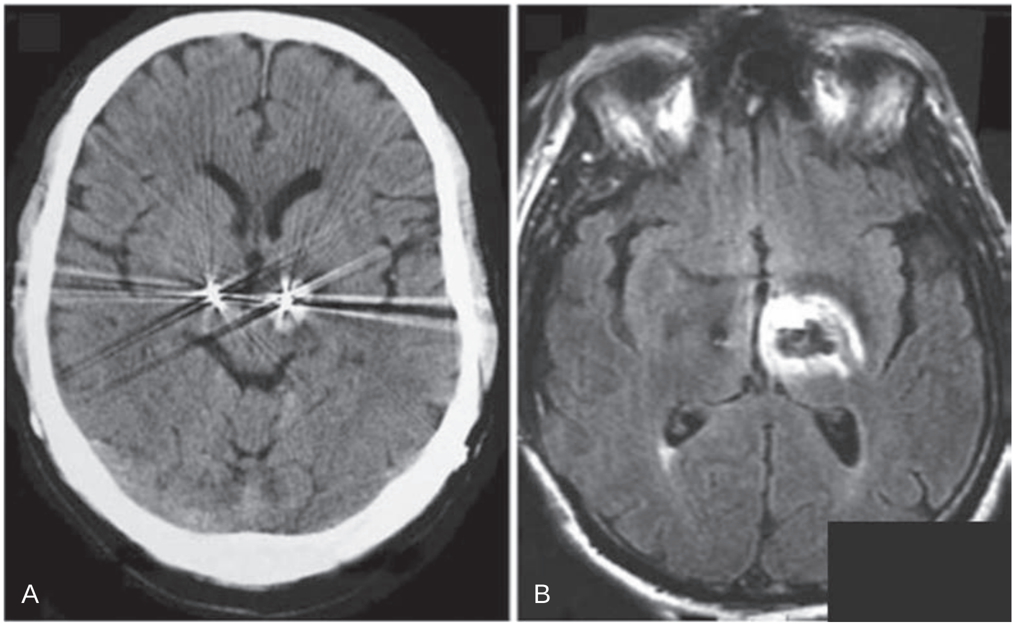

**Figure 2.2. Adverse event due to failure to adhere to medical device product guidelines.** Tissue damage (brain hemorrhage) as a result of radiofrequency heating at the left deep brain stimulator (DBS) lead tip that occurred during a routine MR examination of the lumbar spine. The CT (A) and MRI (B) images of the brain were acquired immediately after a lumbar spine MR scan performed on a 1.0 T MR scanner using the body coil to transmit and a surface coil to receive, and a relatively SAR aggressive imaging protocol. Alternatively, the DBS device manufacturers specified the MR conditions under which MRI can be accomplished safely for patients implanted with this device as a 1.5 T scanner using a transmit receive head coil and head SAR levels at or below 0.1 W/kg. *(From Henderson JM, Tkach JA, Phillips M, et al. Permanent neurological deficit related to magnetic resonance imaging in a patient with implanted deep brain stimulation electrodes for Parkinson's disease: case report.* Neurosurgery. *2005;57:1063.)*

is verified. The documented information must contain the exact model and serial number of the device, which should be recorded in the patient's medical record. If such information is not available, the radiologist or MR technologist should consult the implanting or monitoring physician. Once the device is identified, the associated device documentation typically is available online, posted on the device manufacturer's website. The device labeling should be carefully reviewed for information regarding behavior in the MR environment specific to the exact MR scanner and set of imaging conditions to be used to perform the examination. Salient MR-related information includes system parameters such as field strength(s), magnet types and manufacturers, RF transmit coils, system software versions, and imaging conditions (e.g., RF power levels and gradient slew rates [dB/dt]). In addition, when appropriate, information regarding the configuration of the device itself, such as lead length and routing, that were evaluated and reported in the device labeling must also be considered. Note that the safety information for any implantable medical devices (passive or active) and medical equipment applies only to the magnetic field strengths, MR system configurations, RF coils, and/or imaging conditions evaluated. Safety at 1.5 T does not necessarily imply safety at 3 T, and vice versa. The consequences of failing to strictly adhere to the product information regarding MR safety can be catastrophic to the patient (Fig. 2.2).[86,89]

Several comprehensive reviews of the topic of MR safety and implants have been published,[2,76,90–94] and more than 1,200 objects have been tested for MR safety, with more than 200 evaluated at 3 T or higher.[95] This MR safety information is readily available to the public as published reports, compiled lists online (www.MRIsafety.com), and in the *Reference Manual for Magnetic Resonance Safety, Implants and Devices*, a publication compiled and updated annually.[96]

## Other Metallic Potential Hazards

In addition to implantable devices, it must be documented that the patient has no other form of metal in his or her body, including metal filings, shrapnel, and abandoned leads (e.g., a pacemaker). If the patient indicates that such materials may be present, or if sufficient reason exists to suspect that such materials might be present (e.g., for noncommunicative or pediatric patients), a radiograph must be obtained, and if the presence of such materials is confirmed, the MR examination should not be performed. All of the precautions and considerations previously outlined apply not only to patients but also to any hospital personnel and/or patient family members who may accompany the patient to the MR environment.

Some body piercing jewelry is ferromagnetic, and certain tattoos and permanent cosmetics may contain irregularly shaped iron oxide or other metal-based pigments and therefore may be of concern. In these instances, mild to moderate movement or displacement in the MR environment may occur that, in the case of the tattoos and/or permanent cosmetics, may result in localized swelling and/or irritation. In addition, when the jewelry or pigments are contained within the transmit RF coil, a risk of localized heating also exists. For these reasons, patients and/or individuals should be informed of the potential risks. Body jewelry should be removed before entering the MR environment. If removal is not possible and the individual chooses to proceed, the jewelry should be stabilized (e.g., with application of adhesive tape or a bandage) and, if it is contained within the transmit RF coil, it should be wrapped with gauze or tape to insulate it from underlying skin.[95] Similarly, for tattoos and permanent cosmetics, if any concern exists that heating may occur, an ice pack or cold compress can be applied to the site as a precautionary measure. Adverse events associated with tattoos and/or permanent cosmetics are relatively infrequent, and when they do occur, they are relatively minor and transient.[35,36,95,97] In the opinion of the FDA, "The risks of avoiding an MRI when your doctor has recommended one are likely to be much greater than the risks of complications from an interaction between the MRI and tattoo or permanent makeup. Instead of avoiding an MRI, individuals who have tattoos or permanent makeup should inform the radiologist or technician of this fact in order to take appropriate precautions, avoid complications, and assure the best results."[2,98]

A comprehensive and updated list of reported adverse MR safety-related incidents can be accessed online from the Manufacturer and User Facility Device Experience Database (MAUDE; available at https://www.accessdata.fda.gov/scripts/cdrh/cfdocs/cfmaude/search.cfm)[36] and the Medical Device Report (available at http://www.fda.gov/MedicalDevices/Safety/ReportaProblem/ucm2005291.htm),[35] both of which are compiled and maintained by the FDA Center for Devices and Radiological Health.[95]

## MAGNETIC RESONANCE "SAFETY" LABELING

In response to the severity of the potential hazards of the presence of ferromagnetic objects in the MR environment, the FDA has implemented a well-defined and stringent evaluation and labeling convention. Medical equipment, devices, and/or implants are now classified as "MR safe," "MR unsafe," and "MR conditional."[99,100] These terms replace the previous MR-related evaluation and labeling convention of "MR safe" and "MR compatible."

The replacement of these previous designations and definitions by "MR safe," "MR unsafe," and "MR conditional" was deemed necessary because the earlier designations were confusing and the terms often were used inappropriately. To clarify and prevent misuse, the new set of terms and associated icons was developed (Fig. 2.3).[29,99–101] "MR safe" and/or "MR unsafe" designates an item (e.g., a medical device, equipment, or implant) as unequivocally safe or unsafe in any or all MRI environments (e.g., regardless of field strength, magnet type, and RF coils) and imaging conditions (e.g., RF power levels and gradient slew/switching rates [dB/dt]) and for all configurations of device/object use. "MR safe" objects include nonconducting, nonmetallic, and/or nonmagnetic items such as plastic or gauze tape. "MR unsafe" items include any magnetic object such as a pair of ferromagnetic/metal scissors, scalpel, wrench, or cleaning bucket.[95]

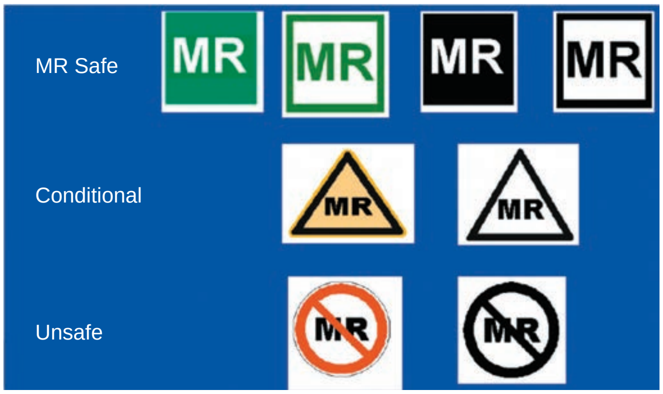

**Figure 2.3. International magnetic resonance safety labeling icons.** US FDA labeling criteria (developed by American Society for Testing and Materials International) for portable objects (e.g., medical devices, implants, medical equipment, oxygen tanks, housekeeping equipment, and tools) that may or may not enter the MR environment. Square/green "MR safe" labels correspond to objects that are totally nonreactive, triangular/yellow labels correspond to objects with "MR conditional" status, and round/red labels identify an object as being "MR unsafe." The use of the new labeling convention has been adopted by the FDA and applied to items prospectively (but not retrospectively), beginning approximately in August 2005. *(From ASTM International.* Standard practice for marking medical devices and other items for safety in the magnetic resonance environment *[designation F203-5], West Conshohocken, PA: ASTM International; 2005.)*

Alternatively, "MR conditional" indicates an item that has no known hazards for very specific combination(s) of MR environment and imaging conditions. When appropriate, additional conditions of use of the item (e.g., routing of leads associated with a neurostimulation system) also are specified. Notably, the use of the new labeling convention has only been applied to items prospectively, beginning approximately as of August 2005.[95] Because it has not been applied by the FDA retrospectively, the labeling for many currently used items may still adhere to the prior definitions of and labeling as "MR safe" and "MR compatible."

## MAGNETIC RESONANCE SAFETY, FACILITY OPERATION, AND PATIENT CARE GUIDELINES

In light of the extreme severity of the potential hazards associated with the improper management of the MR environment, all hospital personnel who may have reason to be in the MR department, patients, and patient family members must be appropriately educated and screened for metallic objects and/or electrically active devices on or within their person well before entering the scan room. The education must include information about the behavior of metallic objects in static magnetic fields and the associated hazards.[95] The importance and necessity of these measures are highlighted by the fact that the majority of adverse MR safety incidents have been due either to deficiencies in and/or failure to enforce screening or MR environment access control procedures and practices, resulting in contraindicated personal items and other potentially problematic objects entering the MR scan room.[35,36]

### Magnetic Resonance Safety Education and Screening

Because of the danger of inappropriately introducing ferromagnetic materials into the MR environment, the following educational and screening procedures have been implemented for facilities and apply to both patient and nonpatient populations. Access to areas that exceed the 5 G line must be vigilantly restricted and supervised at all times.[25] It is important to remind all persons entering the MR facility that the magnet is always "on," even when no examinations are being performed. Screening involves both written documentation and a verbal review. The written screening questionnaire is designed to elicit information about the presence of a medical device, implant, or other ferromagnetic object within or on the individual and/or of the existence of an underlying condition (e.g., pregnancy or disability) that may require special consideration. Once completed, an oral interview is conducted to verify the information reported, and the individual is given the opportunity to express concerns and have any remaining questions about the examination answered before entrance into the MR environment is finally allowed.

The education and screening must be performed by a health care worker specially trained in MR safety who has a comprehensive appreciation and understanding of the potential hazards of the MR environment and procedures and is familiar with the information and implications of the contents of the screening forms for patients and other individuals. Because some of the questions included on the patient screening form may not be relevant for nonpatients, separate screening forms for the patient and nonpatient groups have been compiled. Template screening forms for patients (English and Spanish versions) and a screening form for nonpatient individuals can be downloaded for use at www.MRIsafety.com.[91,92]

The fact that a patient has had a previous MR examination without incident does not ensure the safety of current or future studies. For example, the patient may have undergone a surgical procedure and/or experienced an accident involving a metallic foreign body in the interim that now makes him or her ineligible to enter the MR environment. The exact conditions (e.g., static magnetic field strength of the MR system, RF coil used, orientation of the patient, body part evaluated, or orientation of a metallic implant or object) also can alter the safety profile substantially.[94,102,103] Therefore comprehensive screening must be conducted each time any person prepares to enter the MR environment.

With respect to pregnancy, in 1991, the Safety Committee of the Society for Magnetic Resonance Imaging issued a document entitled "Policies, Guidelines, and Recommendations for MR Imaging Safety and Patient Management,"[2,104] which stated that "MR imaging may be used in pregnant women if other non-ionizing forms of diagnostic imaging are inadequate or if the examination provides important information that would otherwise require exposure to ionizing radiation (e.g., fluoroscopy, CT). Pregnant patients should be informed that, to date, there has been no indication that the use of clinical MR imaging during pregnancy has produced deleterious effects." This policy was adopted by the American College of Radiology (ACR) and remains the current "standard of care"; it is applicable to MR systems operating at static magnetic field strengths up to and including 3 T.[2] Because no deleterious effects of MRI exposure on the fetus have been documented during any stage of development, pregnant women can undergo MRI examinations at any point during their pregnancy, provided that the MRI study is clinically indicated.

## CONTRAST AGENTS

Contrast enhanced MRI (CE-MRI) examinations are widely performed for their ability to provide superior information about the anatomy and physiology. Gadolinium-based contrast agents (GBCA) are widely used for this purpose. It is estimated that around 40% to 50% of all MRIs are performed with GBCAs, and that around 10 million such examinations are performed every year in the United States alone. Contrast agents are never to be used without a physician-prescribed injection in pediatric patients. Qualified MR technologists may start the IV and administer FDA-approved GBCA injections. Certain precautions have to be taken. First, the kidney function of the patient needs to be assessed. The estimate glomerular filtration rate (eGFR) needs to be greater than 30 mL/min/ 1.73 m2. However, precaution should be taken to use the right equation to calculate the eGFR in children. The current accepted equation is the bedside Schwartz equation. Second, the name of the administered contrast agent, the administered dose, and route of administration, as well as any allergic reaction needs to be noted. Third, patients with prior contrast reaction, after careful clinical consideration, can be pretreated with antihistamines and corticosteroids. Also, alternate contrast agent can be considered for repeat studies.

### Magnetic Resonance Facility Operating Procedure Guidelines

In recognition and acknowledgement of the appreciable potential hazards and severe consequences of failure to adhere to safety precautions associated with the MR environment, the ACR formed the Blue Ribbon Panel on MR Safety. First convened in 2001, the panel reviewed and refined the current MR safety practices and guidelines and established new ones when appropriate. The results of this first review were published in 2002[104] and became the de facto industry standards for safe and responsible practice in both clinical and research MR environments. The results of the most recent revisions were published as the "ACR Guidance Document for Safe MR Practices: 2013."[93]

The ACR outlines well-defined methodologies and procedures to ensure and enforce safe and restricted exposure and access to the MR environment most appropriate to the existing state of the MR technology, recognizing that this is continuously evolving. Specifically, in their 2007 publication, the ACR stated that the ACR MR Safe Practice Guidelines document was intended to be used as a template for MR facilities to follow in the development of their own individualized MR safety program.[93] In addition, the ACR recommended that, once established, each site should regularly review, reevaluate, and update its safety program as the field of MR, and MR safety, continues to evolve. The ACR also recommended that each site name an MR medical director whose responsibilities include ensuring that MR safe practice guidelines are established and maintained as current and appropriate for the site.[93]

One of the recommendations is the separation of the general MR facility into four zones of increasing potential MR-related danger.[93] Zone 1 is to include all areas that are freely accessible to the general public, such as outside areas surrounding a freestanding MRI facility or the corridor in an imaging department. Zone 2 is defined as the area controlled and supervised by the MR personnel, such as the reception area and patient preparation area. Zone 3 is the area where there is potential for injury from ferromagnetic objects and equipment. Access to this zone must be vigilantly and strictly controlled and limited by MR personnel. These areas include the operator control room, computer room, and/or any areas immediately adjacent to the MR scan room. Finally, Zone 4 is the MR scan room itself. This zone must be clearly marked with warning signs and notification of high magnetic field strengths within this area, including a sign that the magnet is always on. Access to Zone 4 is strictly limited to persons with a demonstrated need to be there (i.e., patients and medical personnel) and then only after comprehensive education about the MR environment and a rigorous screening.

Also, the 2013 ACR recommendations have listed three pediatric specific guidelines, which are worth studying[93]:

1. Sedation and monitoring issues. Children form the biggest group requiring sedation due to multiple reasons. Sedation protocols, that can be tailored to meet the imaging institution's resources, have to meet the safety guidelines set by the American Academy of Pediatrics, the American Society of Anesthesiologists, and the Joint Commission on Accreditation of Healthcare Organizations.
2. Pediatric screening issues. Children are not reliable historians and have to be screened more vigilantly. It is recommended that older children and teenagers be screened both in the presence of guardians, as well as separately to maximize that possibility of all potential safety issues being disclosed. Extra vigilant screening for hidden MR unsafe objects needs to be performed.
3. MRI safety of accompanying family members. Pediatric patients form the largest group having accompanying family members into Zone 4. These accompanying members are recommended to be limited to one, must be thoroughly screened for safety issues, and given hearing protection.

## CONCLUSION

The potential health hazards associated with MR are directly attributable to the three main electromagnetic fields that make up the MR environment: (1) a strong static magnetic field, including its associated spatial gradient; (2) pulsed gradient magnetic fields; and (3) pulsed RF fields. For a properly operating system, the hazards associated with direct interactions of these fields and the body is negligible. However, it is the interactions of these fields with medical devices and/or ferromagnetic objects inadvertently introduced within the fields that create potential concerns for human safety. To prevent adverse MR safety-related incidents and allow the full benefit of this powerful imaging modality to be realized, it is imperative that the potential safety risks intrinsic to the MR environment be understood and respected by all persons exposed to the MR environment. Comprehensive education and screening to rule out contraindications of both patient and nonpatient groups who enter the MR environment is imperative.

### Mr Safety Websites

**Danger! Flying objects!** (http://simplyphysics.com/flying_objects.html) is an illustrative gallery from the educative "Simply Physics" site, an MRI portal created by Dr. Moriel NessAiver, PhD. The gallery depicts the dangers resulting from common hospital-based ferromagnetic medical equipment.

**ECRI Institute** (https://www.ecri.org) is an independent, nonprofit organization that researches the best approaches to improving the safety, quality, and cost-effectiveness of patient care. ECRI is designated an Evidence-Based Practice Center by the US Agency for Healthcare Research and Quality and is listed as a federal Patient Safety Organization by the US Department of Health and Human Services.

**MRIsafety** (http://www.mrisafety.com), developed and maintained by Dr. Frank Shellock, provides up-to-date information on MRI safety-related topics. Impressively, the latest information regarding screening patients with implants, materials, and medical devices is provided. A key feature of the site is The List, a searchable database that contains more than 1200 implants and devices, including more than 200 objects tested at 3 T for MRI safety. Moreover, the site includes a summary section that is a presentation of more than 100 peer-reviewed articles on MRI bioeffects and safety. Other features include a downloadable Pre-MRI Screening form and safety information.

**ReviseMRI** (http://www.revisemri.com/questions/safety) is designed principally as a revision aid but also may be used as an educational resource. Contents include a detailed question and answer section, web-based animated tutorials, interactive learning tools, and links to resources for further reading in common textbooks and online for nearly every question and answer posed.

**The Institute for Magnetic Resonance Safety, Education and Research** (http://www.imrser.org) is a multidisciplinary professional organization headed by Director Dr. Frank Shellock. It focuses on information and research on magnetic resonance (MR) safety, while "promoting awareness, understanding, and communication of MR safety issues through education and research," and has useful sections, including MRI Safety Guidelines and MR Safety Papers.

**The US Food and Drug Administration** has a **Center for Devices and Radiological Health,** which is an integral part of the Department of Health & Human Services. Online documents available include "A Primer on Medical Device Interactions with Magnetic Resonance Imaging Systems" at http://www.fda.gov/MedicalDevices/DeviceRegulationandGuidance/GuidanceDocuments/ucm107721.htm and "MRI Safety" at http://www.fda.gov/MedicalDevices/Safety/AlertsandNotices/ucm135362.htm.

Two important **MRI accident databases** derived from the Database of Medical Device Related Accidents and Events are available from Maude Accidents Database (http://www.accessdata.fda.gov/scripts/cdrh/cfdocs/cfMAUDE/search.cfm) and the UK Medical Devices Agency (http://www.mhra.gov.uk/index.htm#page=DynamicListMedicines).

**Medicalphysicsweb** (http://medicalphysicsweb.org) is a unique site for the medical physics community. It provides in-depth analysis and incisive commentary on the fundamental research, emerging technologies, and clinical applications that underpin the dynamic disciplines of medical physics and biomedical engineering.

# Complications of Contrast Media

*Gauravi K. Sabharwal*

## ALLERGIC-LIKE REACTIONS

### Introduction

Contrast media (CM) are an essential aid in diagnostic medical imaging. They are used primarily to enhance the visibility of blood vessels, organs, and pathology in the body. CM are considered pharmacologic agents, and, like any other medication, they are not without adverse effects.

### Incidence

Scant data are available regarding the incidence of contrast reactions in children for at least three reasons: (1) few clinical trials with children as subjects have been performed to obtain federal approval of an agent[1]; (2) assessing symptoms, particularly mild ones in very young children, is difficult; and (3) differentiating true contrast reactions from symptoms is difficult because of sedation, synchronous medications, anxiety, and other preexisting diseases.[2]

In children, use of any intravenous (IV) CM is discriminative and exclusive.[3] Administration of nonionic iodinated contrast is associated with a low incidence of adverse effects.[2] Dillman et al.[4] reported a 0.18% incidence of acute allergic-like reactions to IV administration of nonionic iodinated CM in children, similar to 0.23% reported in the adult population.[5] Most of the contrast reactions are mild in both children[4] and adults.[2,5,6] Of all the reported allergic reactions in children, 15% (<0.03% overall) were severe in degree.[4] Fatal reactions are very rare, suggesting the effectiveness of aggressive preventive measures and advancement in management of these reactions.[2]

Gadolinium-based contrast media (GBCM) demonstrate a better safety profile[7] with a lower incidence of allergic-like reactions of 0.04%.[8]

### Risk Factors

As with adults, children need to be appropriately screened before CM are administered. Screening includes a complete and specific history from the accompanying adults. Attempts should be made to identify any variables that may preclude the use of the CM or potentially increase the eventuality of an adverse reaction. Factors that may increase this risk include the following:

1. Known prior reaction to CM.[9-12]
2. Known allergies to food products or medications; minor allergies do not pose a significant risk, but a prior anaphylactic reaction to any substance should heighten awareness of the possibility of a similar reaction to CM administration.
3. A history of asthma.[9,12]
4. Known renal disease; renal function in such patients can worsen after administration of CM.
5. Known heart disease, sickle cell disease, or diabetes mellitus.

Other disease entities, such as pheochromocytoma, dehydration, heart failure, severe hyperthyroidism, and β-blocker therapy, that are known risk factors in adults have not been studied in the pediatric population (Box 3.1).

### Pathogenesis

The exact pathogenesis of untoward events after the administration of CM remains obscure and poorly understood. Most of the symptoms resemble an allergic or anaphylactoid reaction to a medication or allergen. However, definitive evidence is lacking that these reactions are truly allergic reactions because antibodies and the typical allergic cascade to these agents have not been identified.[12]

### Classification of Allergic-Like Contrast Reactions

Based on severity, contrast reactions can be classified as mild, moderate, or severe. Flushing and a sensation of warmth are considered physiologic responses (Box 3.2).

**Mild reactions** are usually of short duration and resolve without the need for any treatment. However, patients should be carefully observed until the symptoms resolve because the symptoms could progress to more severe reactions.

**Moderate reactions** require some form of treatment. More important, close observation is essential until the symptoms resolve. Vital signs should be monitored and IV access should be secured.

**Severe reactions,** which are rare, can be life threatening. They could present a worsening of mild or moderate reactions. Prompt and aggressive treatment may be required. The assistance of a rapid response or code team often may be necessary.

### Management

In the event of any adverse reaction to CM, the IV contrast injection should be discontinued. All reactions and management of the reactions should be documented in the patient care notes, and notation of a contrast allergy should become part of the patient's permanent medical record. The following protocols closely follow the American College of Radiology (ACR) guidelines for management of acute reactions in children.[2] The specific agents used in the management of an adverse reaction are determined by individual institutional pharmacy formulary and policy. Some institutions require the radiology personnel to call for assistance (e.g., a rapid response team) if they administer IV epinephrine for the management of these adverse reactions (given the rare incidence of these events and hence the lack of uniformity in preparedness for these reactions).[13,14] To be prepared for such reactions, weight-based dosages of the medications used for management should be posted in clearly visible areas where CM are administered to children. Regular review of treatment protocols and practice of contrast reaction scenarios should be performed by radiologists and staff. If at any time a patient does not respond to treatment or the situation seems concerning, it is appropriate to seek additional medical support immediately. This support may be sought from another radiologist in the department or through activation of an institutional rapid response or code team.

### Urticaria

Urticaria, the most common reaction to CM, is limited to skin and subcutaneous tissue. Worsening of symptoms can be caused by the accompanying pruritus. Findings on physical examination include the following:

- Red raised wheals that blanch with pressure
- Patchy, symmetric involvement
- Itching, often intense
- Stable vital signs

Mild urticaria is usually self-limiting and does not require treatment.

**BOX 3.1** Risk Factors for Allergic-Like Contrast Reactions

- Prior reaction to contrast media
- Prior anaphylactic reaction
- Moderate to severe allergies to food products or medications
- History of asthma
- Preexisting renal or heart disease
- Diabetes mellitus or sickle cell disease
- Concomitant use of certain medications

**BOX 3.2** Classification of Allergic-Like Contrast Reaction

**MILD**

- Nausea/vomiting
- Mild urticaria
- Pallor

**MODERATE**

- Severe vomiting
- Significant urticaria
- Mild vasovagal reaction
- Mild bronchospasm
- Dyspnea
- Tachycardia and hypotension

**SEVERE**

- Laryngeal edema
- Pulmonary edema
- Moderate to severe bronchospasm
- Cardiovascular collapse
- Bradycardia and hypotension
- Seizures

Close observation for 30 to 60 minutes, or until resolution, is recommended because urticaria may progress to a moderate reaction. Medications may include $H_1$-receptor blockers (such as diphenhydramine) or α-agonists (such as epinephrine). The accompanying parents/responsible adults should be cautioned about the possibility of drowsiness when diphenhydramine is administered. If urticaria is extensive, pay close attention to the patient's blood pressure and watch for signs and symptoms of hypotension, especially orthostatic hypotension.

## Bronchospasm

The patient may present with varying degrees of cough, wheezing, and/or difficulty breathing. It is most important to ensure the presence of an adequate airway. Administer 6 to 10 L/min of oxygen via a face mask. Vital signs should be monitored. Medications may include β-agonists (i.e., bronchodilators), intramuscular epinephrine for mild symptoms, and IV epinephrine for more acute and severe symptoms.

## Facial or Laryngeal Edema

Swelling of the face may be mild without any significant progression. At this time, only observation may be required. An adequate airway and IV access should be secured. However, if the patient presents with other symptoms such as varying degrees of cough, hoarseness, dysphagia, and/or difficulty breathing, more aggressive measures need to be taken. Medications include intramuscular, intramuscular, or IV epinephrine. The patient should be closely monitored.

## Pulmonary Edema

The patient may present with tachypnea, tachycardia, shortness of breath, diaphoresis, agitation, and/or bibasilar rales. Blood-tinged sputum is a late-presenting sign. The airway must be secured and supplemental oxygen should be administered. Medications may include diuretics. Pulmonary edema is a severe response that usually should involve a rapid response or code team.

## Hypotension With Tachycardia (Anaphylaxis)

Anaphylaxis can be a life-threatening response to CM. Symptoms may include difficulty breathing, chest tightness, a thready pulse, a rapid or irregular heart rate, dizziness, hoarseness, and/or loss of consciousness. The rapid response or code team should be called the moment this adverse effect is suspected. Meanwhile, management should be initiated with Trendelenburg positioning, securing of the airway, rapid fluid resuscitation, and administration of IV epinephrine.

## Hypotension With Bradycardia (Vasovagal Reaction)

Patients may present with pallor, a decreased level of consciousness, diaphoresis, and a decreased heart rate. Management should be initiated with Trendelenburg positioning, securing of the airway, hydration, and administration of atropine if bradycardia persists (Box 3.3).

## Delayed Reactions

Delayed reactions appear to occur more frequently than acute/immediate reactions to administration of CM. The incidence ranges from 2% to 12%.[15,16] No definite data are available on the incidence and symptoms of delayed reactions in children. In adults, rash, itching, and other cutaneous manifestations predominate.[16] Other symptoms include fevers, chills, nausea, vomiting, headaches, abdominal pain, drowsiness, and dizziness.[16] These symptoms can manifest any time from 1 hour to 2 days after administration of the contrast agent and usually resolve spontaneously by 7 days.[15-17]

## Prevention

Before any study requiring administration of IV CM is begun, it is imperative to identify patients who would be at high risk for adverse reactions. If risk factors are identified, the need for the examination should be reassessed with the ordering clinician. Other modalities that may offer the same level of diagnosis but do not require administration of contrast agents should be considered. The possibility of performing the same test without the use of CM also should be entertained.

Ultimately, if the examination is considered absolutely necessary, the patient with known risk factors for adverse reactions should be premedicated with a combination of an antihistamine and corticosteroids. The regimen suggested by the ACR[2] is described in Table 3.1.

## Extravasation

Extravasation is a well-recognized complication of contrast-enhanced imaging that occurs in approximately 0.7% of all noniodinated contrast injections.[18-21] The incidence is much lower in GBCM injections. This is believed also to be due to the smaller volume generally administered and the slower injection flow rates.

### Risk Factors

Extravasation is more prone to occur in patients who are unable to verbalize their symptoms, such as infants, younger children, and severely ill and unconscious patients.[22,23] Increased rates also

### **BOX 3.3** Management of Acute Reactions in Children

**URTICARIA**

- No treatment is needed in most cases. However, if symptomatic consider an $H_1$-receptor blocker such as diphenhydramine (Benadryl), PO/IM or via a slow IV push over 1–2 minutes, 1 mg/kg, up to 50 mg.
- For moderate or severe itching or if the urticaria is widely disseminated, consider an $H_1$-receptor blocker such as diphenhydramine (Benadryl), PO/IM or via a slow IV push over 1–2 minutes, 1 mg/kg, up to 50 mg.

**FACIAL EDEMA**

- Secure the airway and administer $O_2$, 6 to 10 L/min (via mask, face tent, or blow-by stream). Monitor electrocardiogram, $O_2$ saturation (pulse oximeter), and blood pressure.
- Administer an α-agonist such as epinephrine (1 : 10,000), 0.1 mL/kg (0.01 mg/kg) via a slow IV push over 1–2 minutes, up to 1 mg total dose (maximum single dose of 1.0 mL or 0.1 mg). Repeat in 5 to 15 minutes as needed.
- Consider administering an $H_1$-receptor blocker such as diphenhydramine (Benadryl), PO/IM or via a slow IV push over 1–2 minutes, 1 mg/kg, up to 50 mg.
- Note: If facial edema is mild and no reaction progression occurs, observation alone may be appropriate. If the patient is not responsive to therapy, call for assistance.

**BRONCHOSPASM**

- Secure the airway and administer $O_2$, 6 to 10 L/min (via mask, face tent, or blow-by stream). Monitor electrocardiogram, $O_2$ saturation (pulse oximeter), and blood pressure.
- Administer an inhaled β-agonist (e.g., a bronchiolar dilator such as albuterol [Proventil or Ventolin]), 2 puffs (90 mcg/puff for a total of 180 mcg) from an inhaler. Repeat up to 3 times.
- If bronchospasm progresses, administer epinephrine IM (1 : 1000), 0.01 mL/kg (0.01 mg/kg), maximum 0.3 mL (0.3 mg) for a total of up to 1 mL (1 mg) or epinephrine IV (1 : 10,000), 0.1 mL/kg (0.01 mg/kg) via a slow IV push over 1–2 minutes, up to 1 mg total dose (maximum single dose of 1.0 mL or 0.1 mg). Repeat in 5 to 15 minutes as needed. If the patient is not responsive to therapy, call for assistance for severe bronchospasm or if $O_2$ saturation <88% persists.

**LARYNGEAL EDEMA**

- Secure the airway and administer $O_2$, 6 to 10 L/min (via mask, face tent, or blow-by stream). Monitor electrocardiogram, $O_2$ saturation (pulse oximeter), and blood pressure.
- Administer epinephrine (1 : 10,000), 0.1 mL/kg (0.01 mg/kg) via a slow IV push over 1–2 minutes, up to 1 mg total dose (maximum single dose of 1.0 mL or 0.1 mg) or epinephrine IM (1 : 1000), 0.01 mL/kg (0.01 mg/kg), maximum 0.3 mL (0.3 mg) for a total of up to 1 mL (1 mg). Repeat in 5 to 15 minutes as needed. If the patient is not responsive to therapy, call for assistance.

**PULMONARY EDEMA**

- Secure the airway and administer $O_2$, 6 to 10 L/min (via mask, face tent, or blow-by stream). Monitor electrocardiogram, $O_2$ saturation (pulse oximeter), and blood pressure.
- Administer a diuretic: IV furosemide (Lasix), 0.5–1.0 mg/kg over 2 minutes for a maximum dose of 40 mg.

**HYPOTENSION WITH TACHYCARDIA (ANAPHYLACTIC SHOCK)**

- Secure the airway and administer $O_2$, 6 to 10 L/min (via mask). Monitor electrocardiogram, $O_2$ saturation (pulse oximeter), and blood pressure.
- Elevate the legs 60 degrees or more (preferred) or use the Trendelenburg position.
- Keep the patient warm.
- Administer a rapid infusion of IV or IO normal saline solution or Ringer's lactate.
- If severe, administer epinephrine (1 : 10,000), 0.1 mL/kg (0.01 mg/kg) via a slow IV push over 1–2 minutes, up to 1 mg total dose (maximum single dose of 1.0 mL or 0.1 mg) or epinephrine IM (1 : 1000), 0.01 mL/kg (0.01 mg/kg), maximum 0.3 mL (0.3 mg) for a total of up to 1 mL (1 mg). Repeat in 5 to 15 minutes as needed. If the patient is not responsive to therapy, call for assistance (e.g., cardiopulmonary arrest response team or 911).

**HYPOTENSION WITH BRADYCARDIA (VAGAL REACTION)**

- Secure the airway and give $O_2$, 6 to 10 L/min (via mask). Monitor electrocardiogram, $O_2$ saturation (pulse oximeter), and blood pressure.
- Elevate the legs 60 degrees or more (preferred) or use the Trendelenburg position.
- Keep the patient warm.
- Administer a rapid infusion of IV or IO normal saline solution or Ringer's lactate. Caution should be used to avoid hypervolemia in children with myocardial dysfunction.
- Administer atropine IV, 0.2 mL/kg of 0.1 mL solution (0.02 mg/kg) if the patient does not respond quickly to above steps. Use a minimum single dose of 0.1 mg. Maximum single dose of 0.6–1.0 mg. Maximum total dose: 1 mg for infants and children; 2 mg for adolescents. If the patient is not responsive to therapy, call for assistance.

are noted in patients receiving chemotherapy, likely because of increased friability of the vein wall.[23-25]

Other risk factors include the site of injection, IV access type, and the method of injection.[23] Although the antecubital fossa is the single most common extravasation site, most of these events occur in patients with venous access elsewhere.[18] Increased incidents have been noted with injections at the dorsum of the hand.[26] Other risk factors also include venous thrombosis, extremity edema, multiple venous access attempts, and use of a tourniquet.[2,22,23] Extravasations are more frequent where preexisting catheters are used as access sites for administration of the CM.[24] At least two studies did not note any significant difference in the incidence of extravasation with the use of power injectors (Box 3.4).[26,27]

**BOX 3.4** Risk Factors for Intravenous Contrast Extravasation

Infants, young children, severely ill patients, and unconscious patients
Patients with friable veins
Presence of venous thrombosis or extremity edema
Injection sites other than antecubital fossa
Large volume of contrast medium
Injection through indwelling catheters
Multiple venous access attempts
Use of a tourniquet

**BOX 3.5** Signs and Symptoms of Contrast Extravasation

Pain, erythema, burning and/or tingling, tightness, swelling at the affected extremity
Blisters, skin ulceration, soft tissue necrosis
Compartment syndrome
Altered tissue perfusion
Paresthesia
Diminished arterial pulses

### Presentation

The immediate symptoms of extravasation can be quite variable. Some patients present with a burning sensation, whereas others remain asymptomatic. Close attention should be paid to young children and unconscious patients because they may not be able to express these sensations. On physical examination, the extravasation site may be red, swollen, and tender.[2]

Most incidents are self-limiting and resolve spontaneously within 1 to 2 days. These incidents usually are restricted to the skin and subcutaneous tissue.[2] The injuries can range from transient tightness of the skin to tissue ulceration and necrosis to acute compartment syndromes. Severe reactions have been observed with both small and large volumes of extravasated contrast. However, the majority of severe reactions have been observed with larger volumes (Box 3.5).[28]

### Management

A definite treatment approach has not been accepted because of a lack of consensus on the appropriate management of extravasation.[22,29,30] Minor symptoms can be treated with elevation of the affected extremity above the level of the heart to help reduce edema by promoting resorption of the fluid.[2,23] Sufficient data are lacking to support either warm or cold compresses over the affected limb.[2] Hyaluronidase injected subcutaneously may help speed resorption, but insufficient evidence exists to suggest routine use. Regardless, close monitoring of the patient is warranted. These events should be documented in the patient's medical records and appropriate directions should be provided to seek medical attention in the event of worsening symptoms.

Severe extravasation injuries require a surgical consultation. Such injuries may present as worsening of pain or swelling, skin blistering, decreased capillary refill, diminished pulses, and a change in sensation of the affected extremity.[2,22] Compartment syndrome can develop even with less than 100 mL of extravasated fluid.[18] Thus it is prudent to conclude that signs and symptoms, rather than the volume extravasated, should be used as a scale for seeking surgical consultation (Box 3.6).

**BOX 3.6** Management of Contrast Extravasation

Elevation of extremity
Cold/warm compresses
Frequent monitoring of capillary refill, arterial pulses
Frequent questioning for progression of symptoms
Surgical consultation

## Contrast-Induced Nephropathy

Limited data are available on the nephrotoxic effects of iodinated CM in children. The ACR recommends following the principles used for adults in the prevention and management of contrast-induced nephropathy (CIN).[2] Risk factors include preexisting renal insufficiency, diabetes mellitus, and multiple CM administrations during the same day.

CIN has been described as either an absolute increase in serum creatinine by at least 0.5 mg/dL within 48 hours of contrast injection[31] or an increase of more than 25% within 72 hours of contrast administration.[32] However, serum creatinine cannot be reliably used as a measure of renal function in this setting in the pediatric population.[2] The estimated glomerular filtration rate (GFR) is used widely for this purpose. The National Kidney Disease Education Program has provided information regarding the measurement of GFR at its website (http://www.nkdep.nih.gov/lab-evaluation/gfr-calculators.shtml) and advocates use of the bedside isotope dilution mass spectrometry–traceable Schwartz GFR calculator for children equation[33]:

$$\begin{aligned}&\text{GFR}\ (\text{mL/min/1.73 m}^2)\\&\quad = (0.41 \times \text{Height [cm]})/\text{Creatinine (mg/dL)}\end{aligned}$$

A GFR of less than 30 mL/min is associated with an increased risk of CIN. Cystatin C, a protein that is produced by all nucleated cells and is exclusively eliminated by glomerular filtration, has been suggested as a better indicator of GFR than serum creatinine.

No significant studies have been conducted to understand the nephrotoxic effects, risk factors, or prevention of CIN in children. Hence when CIN is a concern for a pediatric patient, the clinician ordering the test and the radiologist must carefully consider the need for the study and the potential use of other modalities or unenhanced imaging.

## Nephrogenic Systemic Fibrosis

Nephrogenic systemic fibrosis (NSF) is a disease characterized primarily by skin fibrosis, but it may involve multiple organs. Its association with GBCM was first documented in 2006.[34] Very few cases of NSF have been reported from various data sources.[35] Not enough data exist in the pediatric population to provide guidelines for the prevention of NSF in children. The ACR[2] recommends following adult guidelines for identifying patients at risk and the use of GBCM. Risk factors include decreased renal function with GFR less than 30 mL/min, high doses of administered gadolinium, and postsurgical status.[34,36,37] Discreet use of GBCM in accordance with guidelines by various European and US agencies has resulted in a significant decline in the number of cases encountered. Gadolinium agents should be used with caution in infants and preterm babies because their renal function is immature.[38]

## Gadolinium Deposition and Toxicity

There have been recent reports of intracranial gadolinium deposition (predominantly in the dentate nuclei, but also in globus pallidus and thalamus)[39-41] after multiple injections of GBCM over varying periods in children. The clinical significance of this accumulation remains uncertain. However, until a better understanding of the clinical implications is achieved, clinicians and radiologists should use discretion and caution in administering linear GBCM[39] to children.

## Gadolinium and Serum Calcium Levels

Interference with laboratory test of serum calcium is noted with certain linear nonionic GBCM.[42-44] This transient and pseudo hypocalcemia is also attributed to higher doses of GBCM and to impaired renal function.[42]

### KEY POINTS

- Although allergic-like reactions are rare, they sometimes happen after injection of iodinated contrast media; thus screening for risk factors is important.
- A guide describing management and weight-based doses of the medications should be within reach of every radiologist and should be posted in every room where a contrast injection occurs.
- The GFR should be calculated for all children before the injection of iodinated contrast material.
- All reactions and the management provided should be documented in the medical record.
- Patients with extravasation (any volume) should be closely monitored for worsening of pain and development of other symptoms suggesting compartment syndrome or tissue necrosis.
- Gadolinium should be used with caution in infants because of the immaturity of their renal function.

## EMBRYOLOGY OF THE EYE

Development of the eye originates from neuroectoderm, surface ectoderm, and neural crest cells.[1–3] The neuroectodermal layer gives rise to the retina, iris, and optic nerve; the surface ectoderm gives rise to the lens; the neural crest cells are responsible for vascular structures, sclera, choroid, and mesenchymal tissue from which the adnexal structures, bony orbit, fat, and nerve sheaths arise.[4,5]

The prime regulatory gene for human eye development is *PAX6*, a member of the PAX (paired box) family of transcription factors. This gene initially is expressed in a band contained in the anterior neural ridge of the neural plate before the process of neurulation.[6] A single eye field is present at this stage, which then separates into two primordial optic structures under the direction of sonic hedgehog *(SHH)*, which belongs to a family of vertebrate genes involved with encoding inductive signals during embryogenesis and is part of a vast signaling network that affects development of many tissues and organs.[6]

The earliest sign of embryonic eye development is at day 22 with the appearance of a pair of shallow grooves evaginating on either side of the prosencephalon or forebrain.[6] The grooves form the optic vesicles in contact with surface ectoderm. Invagination of the optic vesicle leads to formation of a double-walled optic cup. This cup has two layers that become the retina, separated by the intraretinal space. The outer layer contains pigment granules that appear during the fifth week of development. The inner layer has two parts. The pars optica retinae occupies the posterior four-fifths and contains cells that ultimately differentiate into the rod and cone cells responsible for light reception. The pars ceca retinae, within the anterior fifth of the inner layer, divides into the pars iridica retinae, which will form the inner layer of the iris, and the pars ciliaris retinae, which will be involved with formation of the ciliary body. The central retinal artery results from the residuum of the embryonic hyaloid artery, which regresses by 4 months of gestation. The lips of the choroid fissure fuse during the seventh week; the mouth of the optic cup becomes the future pupil.

Elongation of surface ectoderm cells in contact with the optic vesicle results in formation of the lens placode, which develops into the lens vesicle. The lens vesicle becomes located in the mouth of the optic cup (Fig. 4.1). Cells located in the posterior wall of the vesicle elongate, forming long fibers that fill the lumen of the vesicle, reaching the anterior wall of the lens vesicle by the seventh week of development. The vascular capsule is a mesenchymal condensation that covers the lens. The hyaloid artery supplies the lens, forming a plexus on its posterior surface.[7]

The primary vitreous develops from mesenchyme within the optic cup, which has an embryonic fissure, known as the *canal of Cloquet*. The hyaloid artery reaches the globe through this canal.

The hyaloid artery and its branches are a transient vascular system that nourishes structures of the eye, subsequently involuting by the 35th week of gestation.[5]

The choroid and sclera are formed from mesenchyme surrounding the optic cup. The ciliary body and ciliary processes are formed from the anterior portion of the choroid.[7]

The optic cup and brain are connected by the optic stalk. The choroid fissure is a groove on the ventral surface of the optic stalk, wherein lie the hyaloid vessels. The fissure closes at 7 weeks' gestation, during which time a narrow tunnel is formed inside the optic stalk. The inner and outer walls of the stalk fuse, becoming the optic nerve. The center contains a portion of the hyaloid artery, the central artery of the retina. The exterior of the optic nerve is covered by a continuation of the choroid and sclera, along with the pia, arachnoid, and dura.[6]

Development of the eye continues into postnatal life. The fovea centralis of the retina becomes differentiated by 4 months after birth. The cones remain poorly developed until 4 months after birth.[8] The infant globe and orbit reach 80% of adult size during the first few years of life, with full size reached by approximately 13 years of age.

## NORMAL ANATOMY OF THE ORBIT AND EYE

The orbits are cone-shaped cavities containing the globes, extraocular muscles, blood vessels, nerves, retrobulbar fat, and lacrimal glands. Each orbit is bounded by the floor of the anterior cranial fossa superiorly, the maxillary sinus inferiorly, the ethmoid sinus medially, and the temporal bone and middle cranial fossae anterolaterally and posterolaterally (Figs. 4.2 and 4.3).

The orbital septum is a thin connective tissue membrane that arises from the peripheral periosteum of the anterior osseous orbit and attaches to the tarsal plates of the eyelids. The septum divides the orbit into an anterior preseptal space and a deeper postseptal space. The postseptal space is divided by the extraocular muscle cone (consisting of the four rectus muscles) into intraconal, conal, and extraconal compartments. The lacrimal gland lies in the superolateral quadrant of the orbit.

The globe occupies about 20% of the orbital cavity. It is divided by the lens into an anterior chamber filled with aqueous humor and a posterior chamber containing vitreous humor found between the lens and retina. The globe contains the retina, uveal layer, and sclera. The sclera is covered anteriorly by the conjunctiva, continuous with the mucous membrane of the eyelid (Fig. 4.4). Tenon fascia separates the globe and extraocular muscle insertions from the orbital fat.

The retrobulbar space extends from the orbital septum anteriorly to the orbital apex posteriorly. The space contains six extraocular muscles (the superior, inferior, lateral, and medial rectus muscles

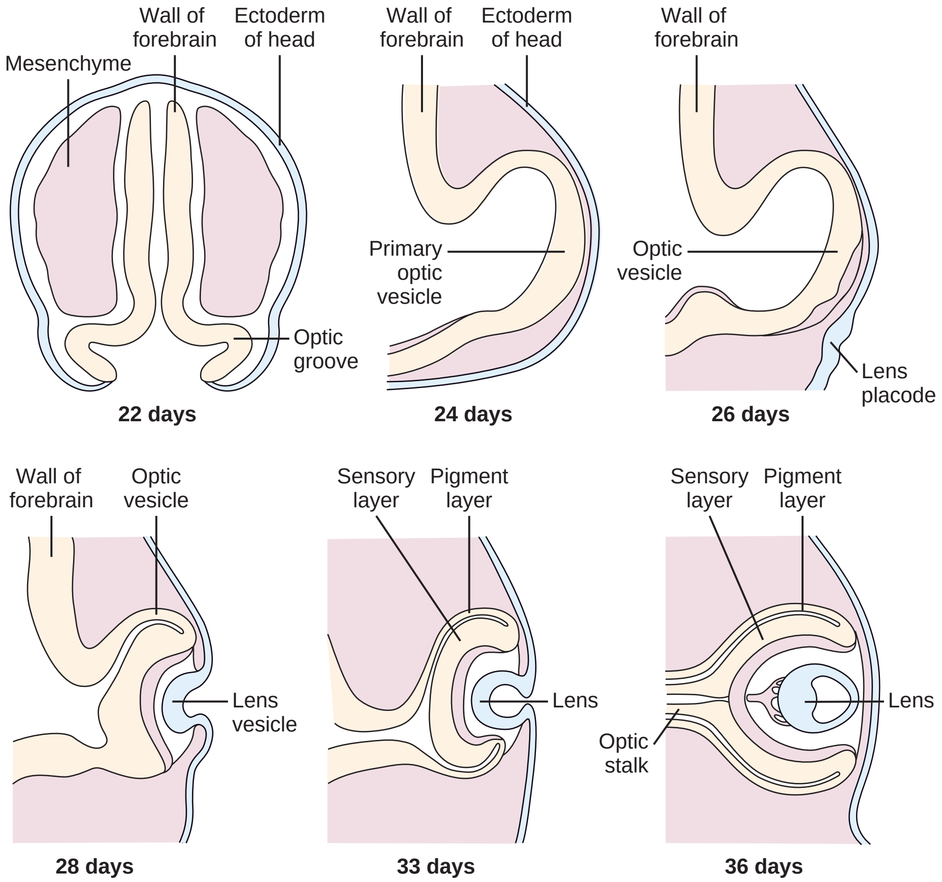

**Figure 4.1. Early development of the human eye.** *(From Carlson BM.* Human Embryology and Developmental Biology*, 2nd ed. St. Louis: Mosby; 1999.)*

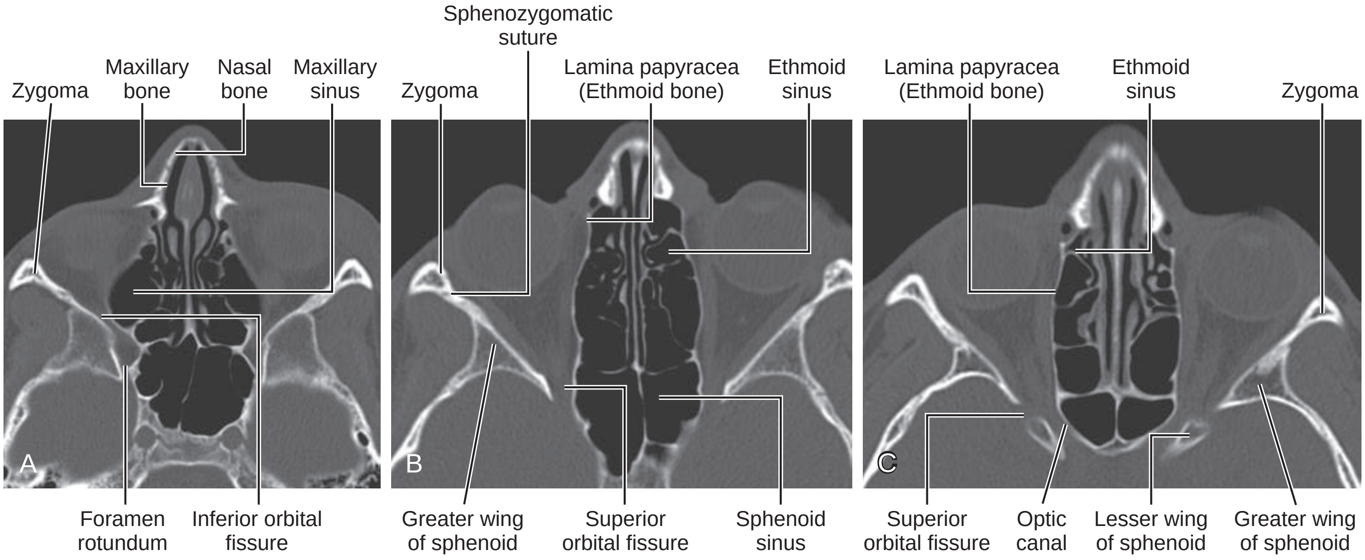

**Figure 4.2. Axial anatomy of the bony orbit.** (A–C) Axial noncontrast computed tomography images from inferior to superior location.

and the inferior and superior oblique muscles), vascular structures, and the optic nerve, surrounded by fat.

The optic nerve is divided into four segments: (1) an intraocular segment penetrating the sclera, (2) an intraorbital segment in the intraconal space, (3) an intracanalicular segment in the optic canal, and (4) an intracranial segment extending from the optic canal to the optic chiasm. It is fully myelinated by 7 months of age. It continues to increase in thickness for the first 8 years of life.

Optic nerve sheath diameter in children as measured on magnetic resonance imaging (MRI) is 3.1 mm in the 0- to 3-year

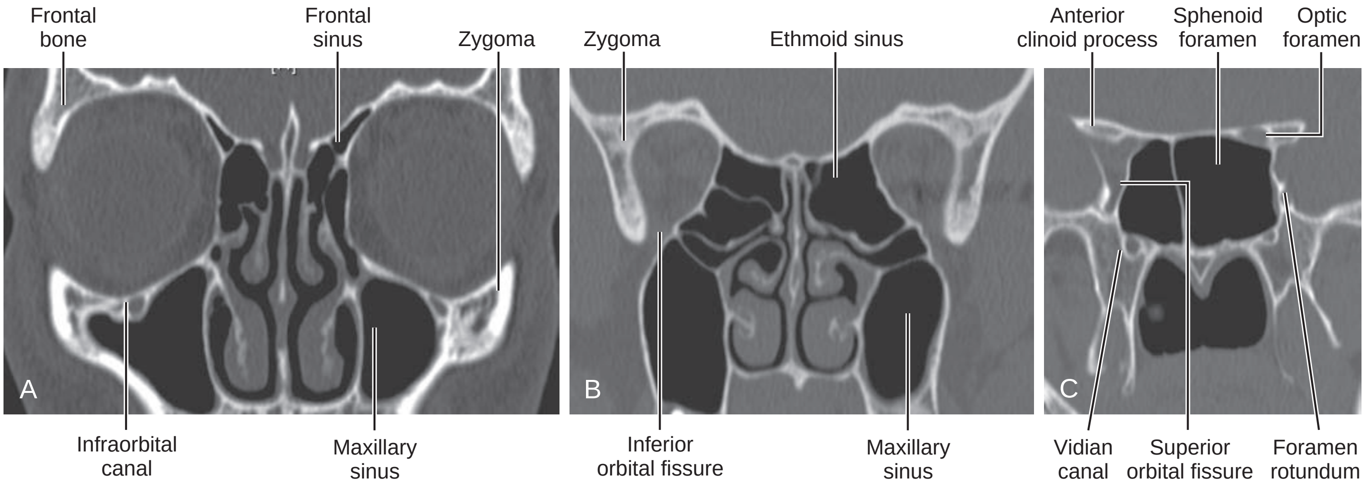

**Figure 4.3. Coronal anatomy of the bony orbit.** (A–C) Coronal noncontrast computed tomography images from anterior to posterior location.

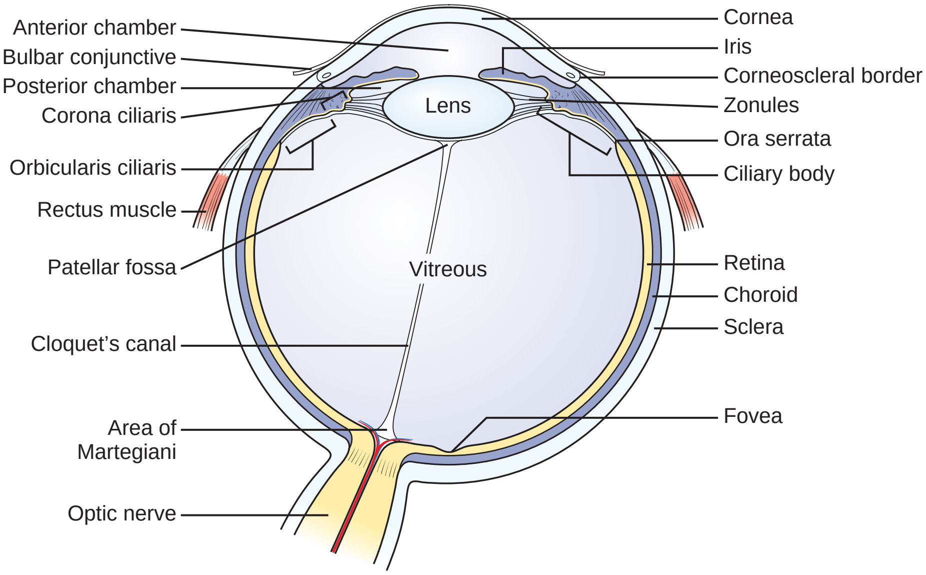

**Figure 4.4. Normal anatomy of the eye.** *(From Jakobiec FA, Ozanics V. General topographic anatomy of the eye. In Jakobiec FA, ed.* Ocular Anatomy, Embryology and Teratology, *New York: Harper & Row; 1982.)*

age group, 3.41 mm between 3 and 6 years, 3.55 mm between 6 and 12 years, and 3.56 mm in the 12- to 18-year age group.[9]

## IMAGING TECHNIQUES

Computed tomography (CT) and MRI are the main imaging modalities for the orbit and optic pathway. Ultrasonography may be useful for specific indications.

### Ultrasound

Ultrasound is extremely beneficial in infants and children because it does not use ionizing radiation, it is widely available, and the need for sedation is rare. The primary indications are disease or conditions of the anterior chamber preventing fundoscopic examination of the remainder of the eye, such as hyphema and trauma, nonneoplastic leukocoria, assessment of vascular integrity of the retina or an underlying lesion, and follow-up of neoplastic causes of leukocoria after treatment.[10] Secondary indications include further elucidation of intraconal and extraconal lesions and assessment of lacrimal masses.[7] Ultrasound is less helpful in showing osseous abnormalities of the orbit.

The procedure is performed with the patient supine. Initially a small amount of gel is placed over the upper eyelid. Images are obtained using a high-resolution (7.0–18.0 MHz) linear-array transducer with color Doppler capability.[10] Power output must be decreased to avoid mechanical or thermal injury. Scanning is usually performed in the axial plane; however, other planes also may be used to evaluate the entire globe (Fig. 4.5A).[10]

Color Doppler imaging is an important component of the ultrasound examination because it permits demonstration of the ophthalmic artery and vein, the central artery of the retina, the retinal vein, ciliary and lacrimal arteries and accompanying veins, and the superior ophthalmic vein (Fig. 4.5B).[10]

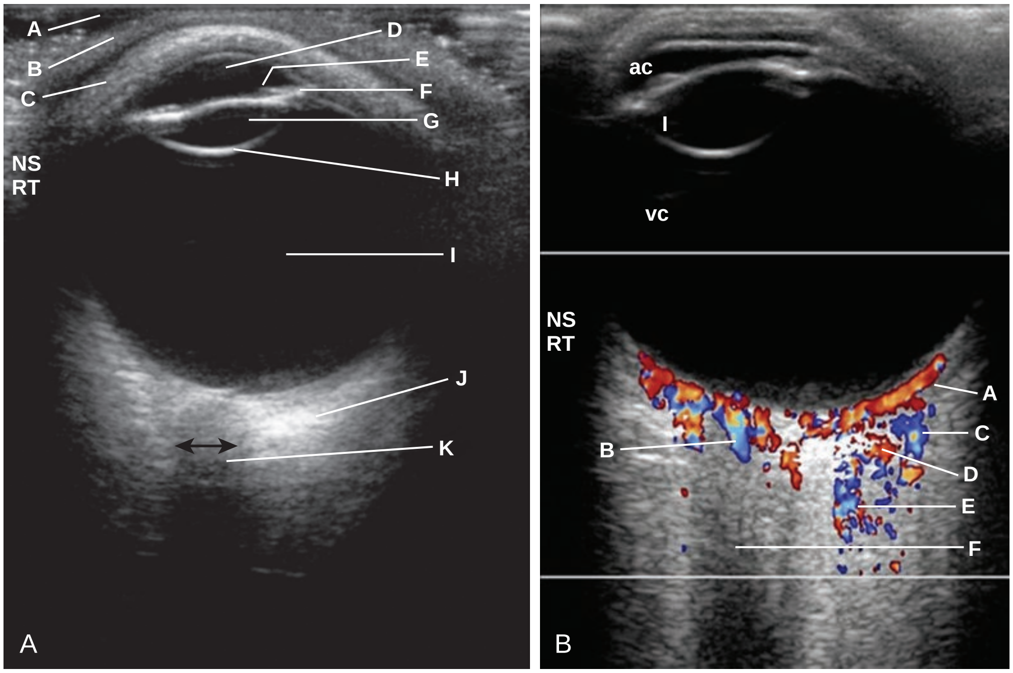

**Figure 4.5. Normal ophthalmic axial ultrasound of a teenager.** (A) Using a broadband, high-resolution linear-array transducer (5–17 MHz extended-frequency range), sterile gel *(A)* is placed on the skin *(B)* over the upper eyelid *(C),* which remains shut throughout the examination. The anechoic anterior chamber *(D),* the iris *(E),* the ciliary apparatus *(F),* the anechoic lens *(G)* with the posterior reflective echo *(H),* the anechoic vitreous chamber *(I),* and the hypoechoic optic nerve *(J)* are demonstrated and the optic nerve width *(double-ended black arrow)* can be measured. (B) Normal color Doppler examination of the eye in the same patient. Color Doppler imaging shows very good flow in the choroidal vessels *(A),* central retinal artery *(B),* lacrimal vein *(C)* and artery *(D),* as well as in the ophthalmic artery *(E)*. The anterior chamber *(ac),* lens *(l),* and vitreous chambers *(vc)* are again noted. Different parts of the eye can be examined by having the patient move the eye as instructed. *(Courtesy Faridali Ramji, MD.)*

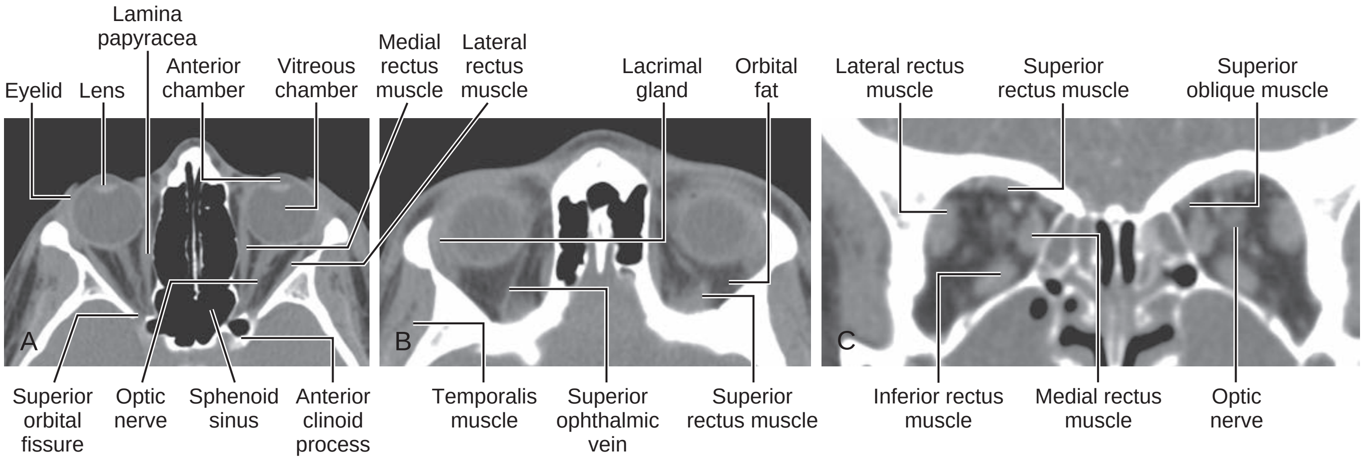

**Figure 4.6. Orbital anatomy on CT.** (A) Axial. (B) Axial more cephalad than A. (C) Coronal (after administration of contrast material).

## Computed Tomography

CT is ideal for showing osseous abnormalities, calcification, and foreign bodies. Excellent anatomic detail is obtained rapidly, with high contrast of orbital tissues. Rapid scan times also decrease the need for sedation in many patients. Common indications include orbital trauma, evaluation of orbital cellulitis, and orbital masses. It is also the imaging modality of choice when intraorbital foreign body is suspected.[11] Disadvantages of CT include use of ionizing radiation, limited imaging planes compared with MRI, beam-hardening artifact, and the potential risk from iodinated contrast media.

High-resolution, thin-section scans with a slice thickness of 2 to 3 mm are obtained in the axial planes with subsequent coronal and sagittal reformatted images, which eliminate further radiation to the patient (Fig. 4.6). The axial plane is usually parallel to the

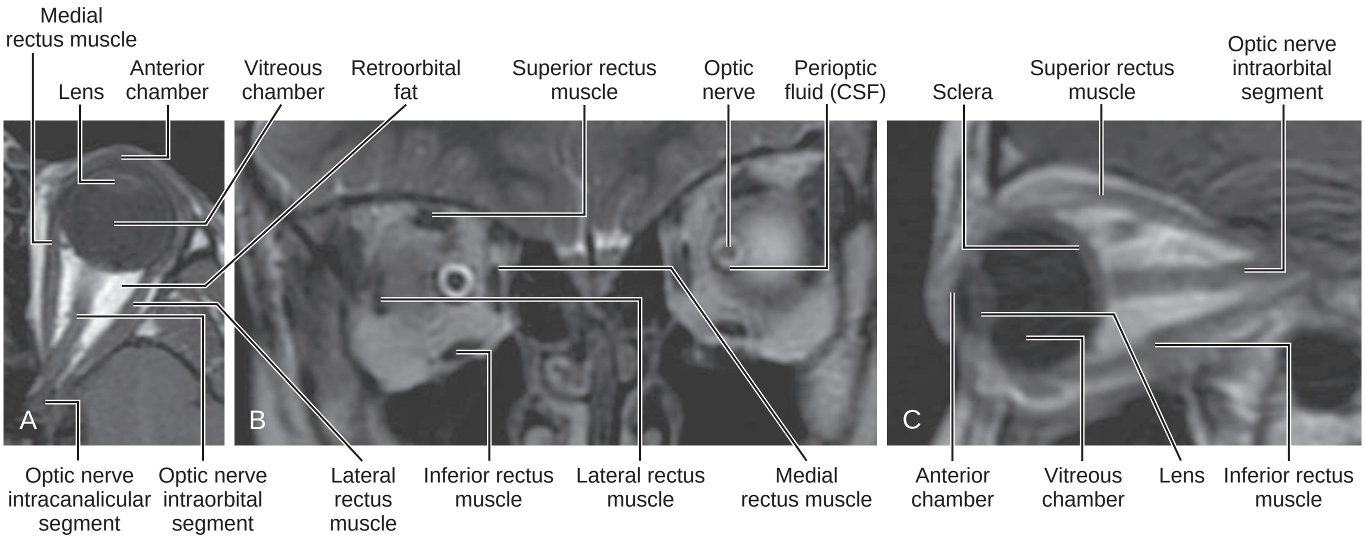

**Figure 4.7. Orbital anatomy on MRI.** (A) Axial T1-weighted image. (B) Coronal T2-weighted image. (C) Sagittal oblique T1-weighted image. *CSF*, Cerebrospinal fluid.

canthomeatal line. Thinner images, especially in the coronal plane, may be obtained when indicated, such as visualization of the orbital floor for a blow-out fracture.

## Magnetic Resonance Imaging

MRI is ideal for imaging the soft tissue abnormalities of the orbit. Orbital MRI involves high-resolution imaging with thin sections (Fig. 4.7); MRI of the brain often is performed concomitantly. Common indications include orbital benign and malignant tumors, infectious or inflammatory etiologies such as optic neuritis, vascular malformations, and congenital anomalies. Although the lack of ionizing radiation is appealing in infants and children, MRI requires a longer scan time than other modalities, and it is less helpful in detecting calcifications, although high-resolution susceptibility weighted imaging could be helpful.

For purely orbital pathology, T1-weighted and fast spin echo (FSE) T2-weighted images with fat saturation or short-tau inversion recovery (STIR) images that suppress the orbital fat are used. Axial and coronal T1-weighted images usually are obtained in an oblique plane parallel to the optic nerve with thin sections with a small field of view (e.g., 20 cm) and a high-resolution matrix (512 × 192). Axial and coronal FSE inversion recovery images are performed through the orbit and chiasm. FIESTA (fast imaging employing steady-state acquisition) and CISS (Constructive Interference Steady State ) are sequences that provides high-resolution images with excellent image contrast and high signal-to- noise ratio. High-resolution 3D FIESTA or CISS images through the orbits can be used to best delineate optic papilla protrusion in cases of increased intracranial pressure. Diffusion weighted imaging (DWI) can help with restricted diffusion seen in epidermoid, tumors with high cellularity, and abscess. Susceptibility weighted images through the orbits can depict retinal hemorrhages in selected cases such as nonaccidental trauma, though gold standard is ophthalmoscopic examination.[12]

Contrast material is administered intravenously for ocular and orbital disease, such as neoplasms, inflammatory and infectious processes, and vascular malformations, with T1-weighted imaging performed with fat saturation in the axial and coronal planes. In some centers, small surface coils are used, which may provide better spatial resolution but are not useful for imaging apical lesions or intracranial disease extension.

Contrast-enhanced MRI of the orbit and brain, using a head coil, is recommended for the evaluation of suspected retinoblastoma, possible subarachnoid seeding of retinoblastoma, and bilateral retinoblastoma. Early detection is made possible for intraocular extension and optic nerve involvement as well as assessment of extraocular and intracranial extension and leptomeningeal spread.[14]

### KEY POINTS

- The globe reaches its full size by 13 years.
- The orbital septum divides the orbit into an anterior preseptal space and a deeper postseptal space.
- CT is used in acute setting for indications such as trauma, orbital cellulitis, and suspected intraorbital foreign body, and provides the best images of the bony orbit.
- MRI is the modality of choice for demonstrating the soft tissues and adjacent intracranial structures.

*Ashley James Robinson, Angela Byrne, and Susan Blaser*

Assessment of the orbits is part of a detailed fetal sonographic or magnetic resonance imaging (MRI) scan, particularly in the setting of suspected central nervous system malformation. When further assessment is performed by fetal MRI, obvious ocular pathologies can be missed, particularly if they are bilateral and symmetric. Diagnoses can be further honed or even altered completely when a coexisting ocular pathology is found.

Ocular evaluation comprises assessment for the presence or absence of eyes, the morphology of the lens and vitreous, and ocular biometry.[1]

## PRESENCE OR ABSENCE OF THE EYES

### Anophthalmia and Microphthalmia

The only way that anophthalmia and microphthalmia truly can be differentiated is pathologically, with anophthalmia being complete absence of the globe but the presence of the ocular adnexa (i.e., eyelids, conjunctiva, and lacrimal apparatus).

#### Primary Anophthalmia

With primary anophthalmia, ocular tissue in the orbit is completely absent because no development of the eyes has occurred. Primary anophthalmia usually is associated with chromosomal abnormalities such as trisomy 13 or genetic syndromes such as CHARGE syndrome, incontinentia pigmenti, Norrie disease, *SOX2*-related eye disorders, Walker-Warburg syndrome, and oculo-auriculo-vertebral spectrum.[2-7]

#### Secondary Anophthalmia

Loss of ocular tissue caused by an insult during development results in secondary anophthalmia. Etiologies include infection (e.g., rubella), a vascular event (e.g., Goldenhar syndrome), or a toxic or metabolic event (e.g., low or high vitamin A levels). The ocular diameter is below the fifth percentile.[8]

Matthew-Wood syndrome (also known as Spear syndrome, PMD, or PDAC syndrome) is composed of pulmonary hypoplasia/agenesis, diaphragmatic hernia/eventration, anophthalmia/microphthalmia, and cardiac defect.[9] In a case of congenital diaphragmatic hernia, associated abnormal orbital morphology and biometry and cardiac anomalies can allow this diagnosis to be made antenatally (e-Fig. 5.1).

Walker-Warburg syndrome, a type of congenital muscular dystrophy, also can be diagnosed antenatally through the association of Dandy-Walker spectrum, along with a Z-shaped brainstem on midline sagittal MRI views, an occipital cephalocele, and ocular asymmetry (Fig. 5.2 and e-Fig. 5.3).

Aicardi syndrome is a rare genetic malformation syndrome that can be diagnosed antenatally by the association of partial or complete absence of the corpus callosum, ocular abnormalities, and a posterior fossa cyst. Aicardi syndrome is thought to be caused by a defect on the X chromosome because it has only been seen in girls and in boys with Klinefelter syndrome (Fig. 5.4 and e-Fig. 5.5).

## MORPHOLOGY OF THE LENS AND VITREOUS

On ultrasound examination, the lens and vitreous are equally hypoechoic; however, the outline of the lens can be seen as a thin hyperechoic ovoid anteriorly within the globe. Typically, however, the only reflection from the lens is from the surfaces perpendicular to the insonating beam, and it can be difficult to see (Fig. 5.6).

On T2-weighted MRI, the entire lens has a low signal compared with the high signal of the vitreous (Fig. 5.7). By endovaginal ultrasound, the lens is visible by 14 weeks as a thin echogenic rim with an anechoic center. The hyaloid artery can be seen as an echogenic line bisecting the vitreous, which, during conversion of the primary vitreous to mature secondary vitreous, gradually becomes beaded as it involutes, a process that should be completed by 30 weeks of menstrual age.[10,11] The remnant channel through the vitreous is known as the Cloquet canal. On MRI, nonspherical globe morphology can be normal up to 29 weeks.[12]

### Persistent Hyperplastic Primary Vitreous

Failure of involution of the hyaloid artery results in a spectrum of abnormalities known as persistent hyperplastic primary vitreous, which is seen frequently with trisomy syndromes and other forms of abnormal brain development.[13,14] It is usually unilateral. Clinically the presentation is variable and includes leukocoria, vitreous hemorrhage, retinal detachment, microphthalmos, and lens opacification.

The diagnosis can be made antenatally or by ultrasound, computed tomography (CT), or MRI postnatally. Ultrasound can detect the hyaloid vessel. A cone-shaped retrolental density is the characteristic finding on CT and MRI. CT findings include a small irregular lens with a shallow anterior chamber; intravitreal densities of variable shape, suggesting the persistence of fetal tissue in the Cloquet canal; and enhancement of abnormal intravitreal tissue after intravenous administration of contrast media. On MRI the appearance is that of low-signal-intensity linear plaques extending from the posterior part of the lens to the optic nerve head. Calcification is unusual (Fig. 5.8 and e-Fig. 5.9).

### Cataracts

Cataracts are seen in a variety of metabolic, infectious, genetic, and chromosomal abnormalities that affect the fetus, including toxoplasmosis; x-irradiation; in vitro fertilization; persistent hyperplastic primary vitreous; PHACE, Nance-Horan, Adams-Oliver, Walker-Warburg, and Neu-Laxova syndromes; rhizomelic chondrodysplasia punctata; trisomy 17 mosaicism; and trisomy 21 (Fig. 5.10).[5,15-26]

### Optic Nerve Hypoplasia

Optic nerve hypoplasia is usually sporadic and difficult to detect prenatally; however, it has a number of associations that potentially can be diagnosed prenatally because of associated structural abnormalities, several of which are discussed in this chapter (Box 5.1 and Fig. 5.11).

Septo-optic dysplasia can be extremely difficult to diagnose antenatally and is usually suspected because of the absence of the cavum septi pellucidi. Associated optic nerve hypoplasia potentially can be detected by measurement of the transverse diameter of the optic chiasm, the normal growth of which has been described by ultrasound[27-29] and can, with some difficulty, be assessed by MRI.[30]

## Coloboma, Morning Glory Disc, and Peripapillary Staphyloma

Coloboma, morning glory syndrome, and peripapillary staphyloma are all congenital anomalies that are excavations of the optic disc and can significantly impair visual function.[31]

Coloboma is a unilateral or bilateral congenital condition caused by incomplete closure of the embryonic fissure. Clinical features include visual field defects. On examination, coloboma appears as an enlarged, sharply circumscribed, deeply excavated optic disc, usually occurring inferiorly with increased risk of macular detachment. Other associated ocular findings include microphthalmos with an orbital cyst, a persistent hyaloid artery, and retinal dysplasia. Coloboma also may be part of the CHARGE syndrome (i.e., coloboma, heart defects, choanal atresia, growth retardation, and genital and ear abnormalities), and it may be associated with numerous other syndromes. Coloboma can be detected by fetal MRI (Fig. 5.12).[32]

Morning glory syndrome is a congenital anomaly of the optic disc in which there is a funnel-shaped excavation of the posterior fundus incorporating the optic nerve, surrounded by an elevated annulus of chorioretinal pigment. It is named for the ophthalmoscopic resemblance to the morning glory flower. Morning glory syndrome occurs more frequently in females and presents with poor vision, amblyopia, and strabismus with leukocoria. In the first months of life there is an increased risk of retinal detachment and associated cerebral abnormalities, including moyamoya disease (e-Fig. 5.13).

Staphyloma occurs as a result of weakening of the outer layer of the eye (cornea or sclera) by an inflammatory or degenerative condition and is an abnormal protrusion of uveal tissue caused by sclero-uveal ectasia. It is most commonly unilateral and nonhereditary.

## Coats Disease

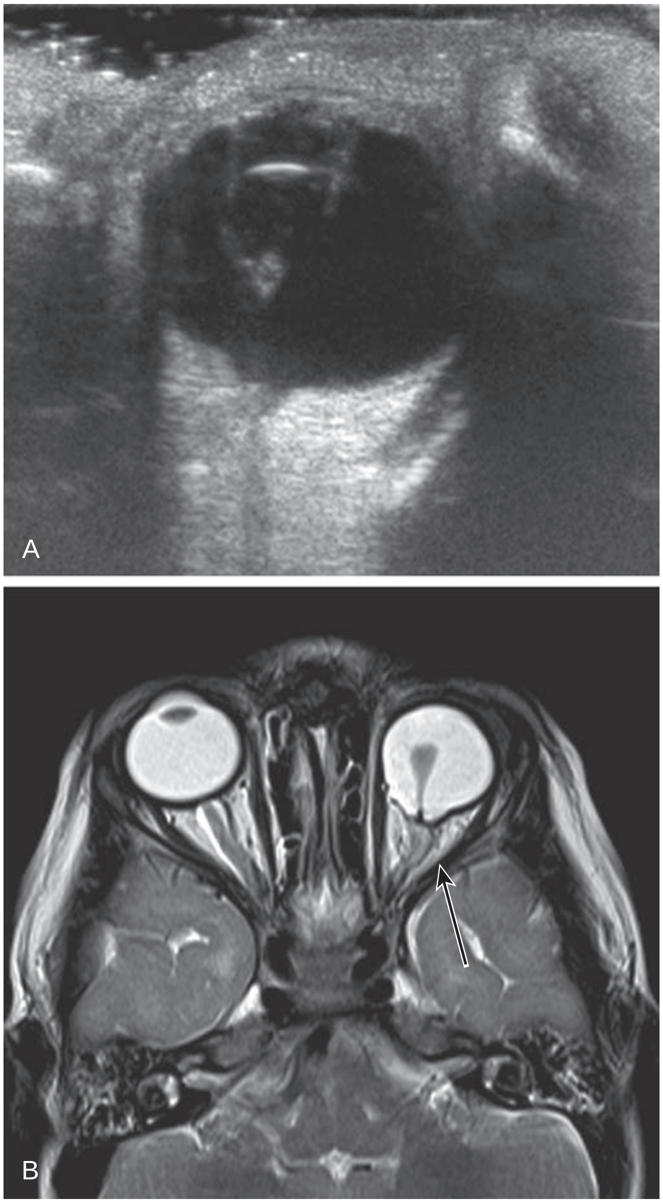
Coats disease is a rare, congenital, nonhereditary disorder characterized by retinal telangiectasia resulting in massive intraretinal and subretinal lipid accumulation, exudative retinal detachment, and blindness. It is usually isolated, unilateral, and occurs predominantly in young males, with the onset of symptoms occurring in the first decade of life. It appears as a hyperechoic mass on ultrasound without posterior acoustic shadowing. Vitreous and subretinal hemorrhage may be present. On CT, the globe is hyperdense and enhancement of the subretinal exudate is seen. This exudate is hyperintense on T1- and T2-weighted MRI sequences (Fig. 5.14). It is important to differentiate this entity from retinoblastoma, which usually presents as a calcified mass and may require enucleation of the globe.

## Norrie Disease

Norrie disease is an X-linked recessive disorder caused by mutations in the *NDP* gene that leads to congenital blindness in male infants. The ocular findings are characterized by retinal dysplasia and the development of a white, vascularized, retrolental mass that may lead to phthisis bulbi. Cataracts and leukocoria also may be present. Norrie disease is associated with progressive hearing loss in one-third of patients, and up to 50% of patients have developmental delay, movement disorders, psychotic features, or behavioral problems. CT demonstrates dense vitreous chambers as a result of vitreous or subretinal hemorrhage, microphthalmia, optic nerve atrophy, a retrolental mass, and retinal detachment.

# BIOMETRY

Growth charts for the fetal lens and orbit,[33-35] orbital total axial length (TAL),[36] eye volume,[37] and the measurements of binocular distance (BOD) and interocular distance (IOD) have been determined sonographically.[38-40] The orbits are measured according to the bony landmarks of the medial and lateral orbital walls. The orbital measurements ideally are made in the axial plane, with both orbits of equal and largest possible diameter.[8] The BOD is measured between the two malar margins, and the IOD is measured between the two ethmoidal margins of the bony orbits. These bony landmarks are difficult to see with fetal MRI and therefore standard sonographic growth charts cannot accurately be applied to fetal MRI studies.



**e-Figure 5.13. Morning glory disc.** (A) Ultrasound of the left eye shows bandlike echogenicity extending to the defect in the retina in a morning glory disc. (B) Axial T2-weighted MRI shows funnel-shaped excavation of the posterior fundus in keeping with a morning glory disc *(arrow).*

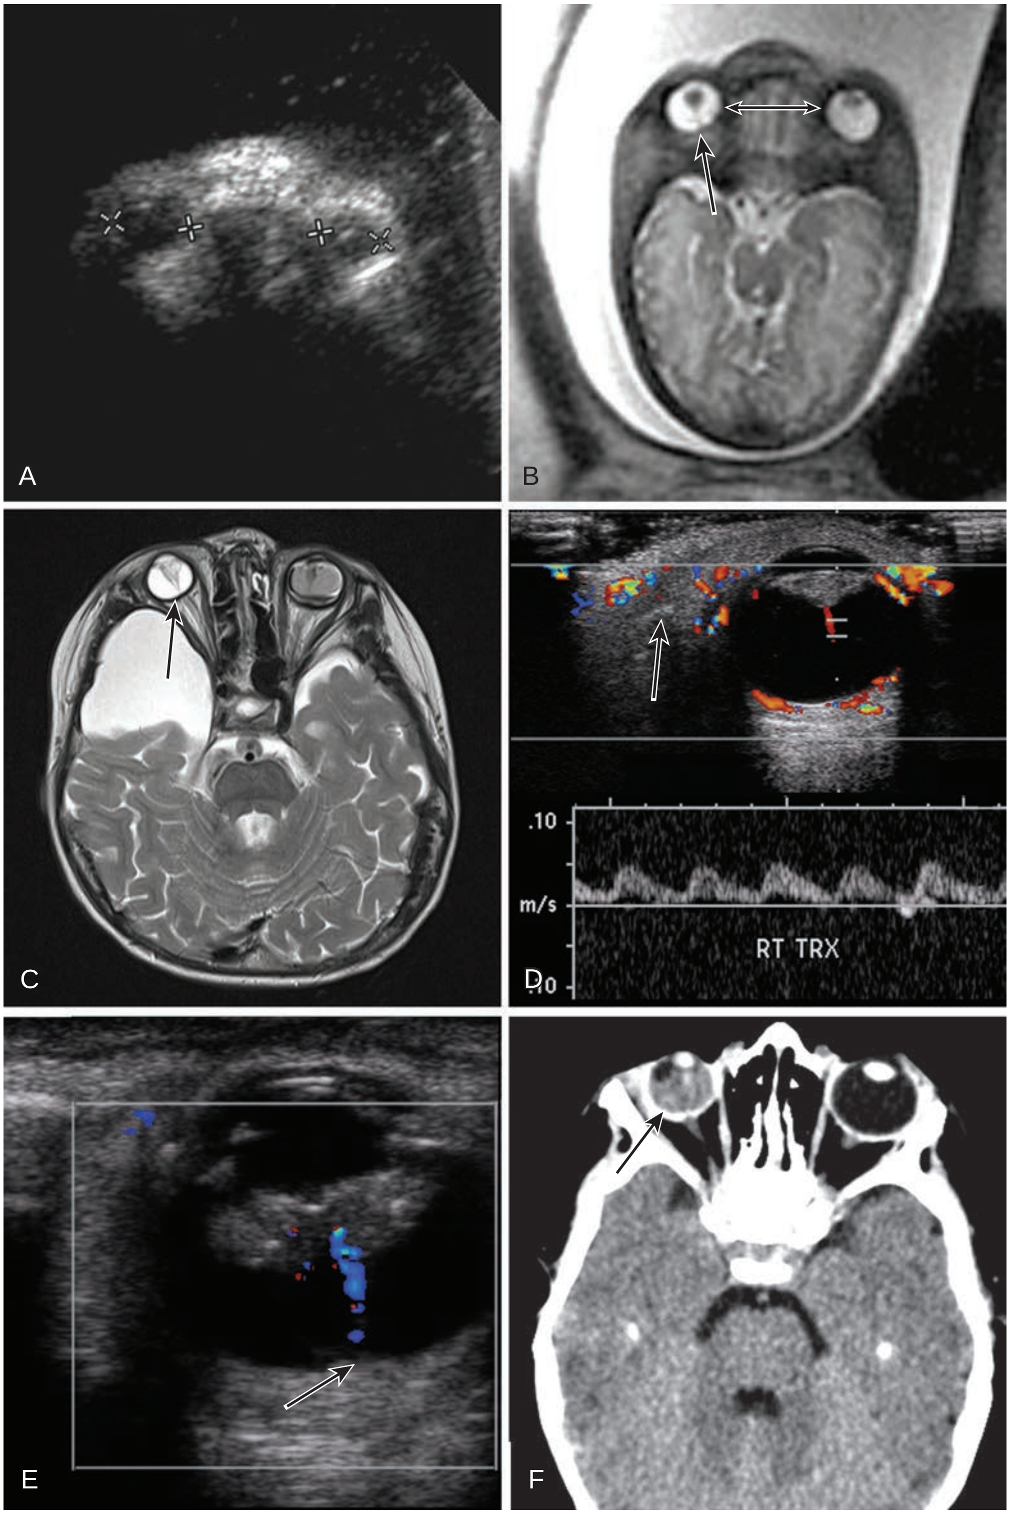


**Figure 5.8. Persistent hyperplastic primary vitreous.** (A) Fetal ultrasonography shows the absence of normal anatomy and ocular hyperechogenicity. (B) Fetal MRI shows hypertelorism *(double-headed arrow)* plus a persistent hyaloid artery *(large arrow)* and a triangular-shaped lens. (C) Postnatal axial T2-weighted MRI demonstrates a low funnel-like signal extending from the right posterior lens to the optic nerve head *(arrow).* A similar low signal is noted on the left with associated vitreous hemorrhage. Note the incidental right middle cranial fossa arachnoid cyst. (D) Doppler ultrasound reveals an arterial waveform within the hyaloid artery *(arrow).* (E) Ultrasound shows thickening of the soft tissues posterior to the lens and a hyaloid vessel *(arrow).* (F) Axial noncontrast CT image shows increased attenuation in the right posterior chamber in keeping with vitreous hemorrhage *(arrow)* with linear high density centrally in persistent hyperplastic primary vitreous.

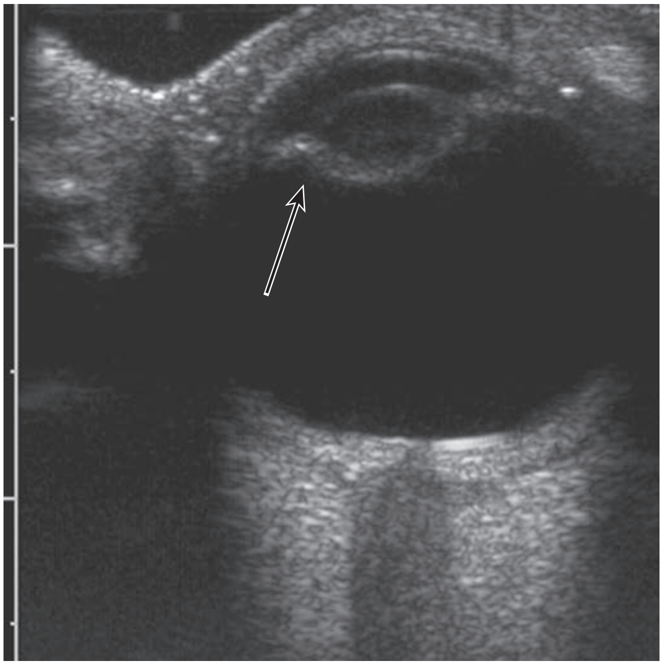

**Figure 5.10. Cataract.** Transverse ultrasound of the left eye shows increased echogenicity of the lens *(arrow)* indicating a cataract.

On MRI the BOD and IOD measurements can be made in any plane from true axial to true coronal, provided both eyes can be seen in the same image and have the most equal and largest possible transverse diameters. The BOD and IOD are respectively measured between the two malar or ethmoidal margins of each vitreous (Fig. 5.15). These measurements can be plotted against gestational age (Table 5.1).[1] Other available nomograms also include orbital volume,[41] measurements of the anteroposterior globe diameter,[42] and the diameter of the lens.[43]

## Hypotelorism

Hypotelorism is defined as an IOD below the fifth percentile.[8]

### Primary

During normal embryologic development, the opening for the eye forms during development of the face, when the paired nasal swellings on either side migrate medially and inferiorly and fuse with the midline frontal swelling to form the nose. Overmigration results in primary hypotelorism; the two halves of the face (and more often than not the underlying halves of the brain) lie too close together ("the face predicts the brain"),[44] and both the BOD and IOD therefore are decreased. This scenario most commonly results in an anomaly within the spectrum of holoprosencephaly,[45] which in around 55% of cases is associated with a variety of chromosomal abnormalities, most commonly trisomy 13 (Fig. 5.16 and e-Fig. 5.17).[38]

### Secondary

Secondary hypotelorism is usually the result of abnormalities of the bony skull, such as microcephaly, plagiocephaly, and metopic synostosis (e-Fig. 5.18).[8]

## Hypertelorism

Hypertelorism is defined as an IOD above the 95th percentile.[8]

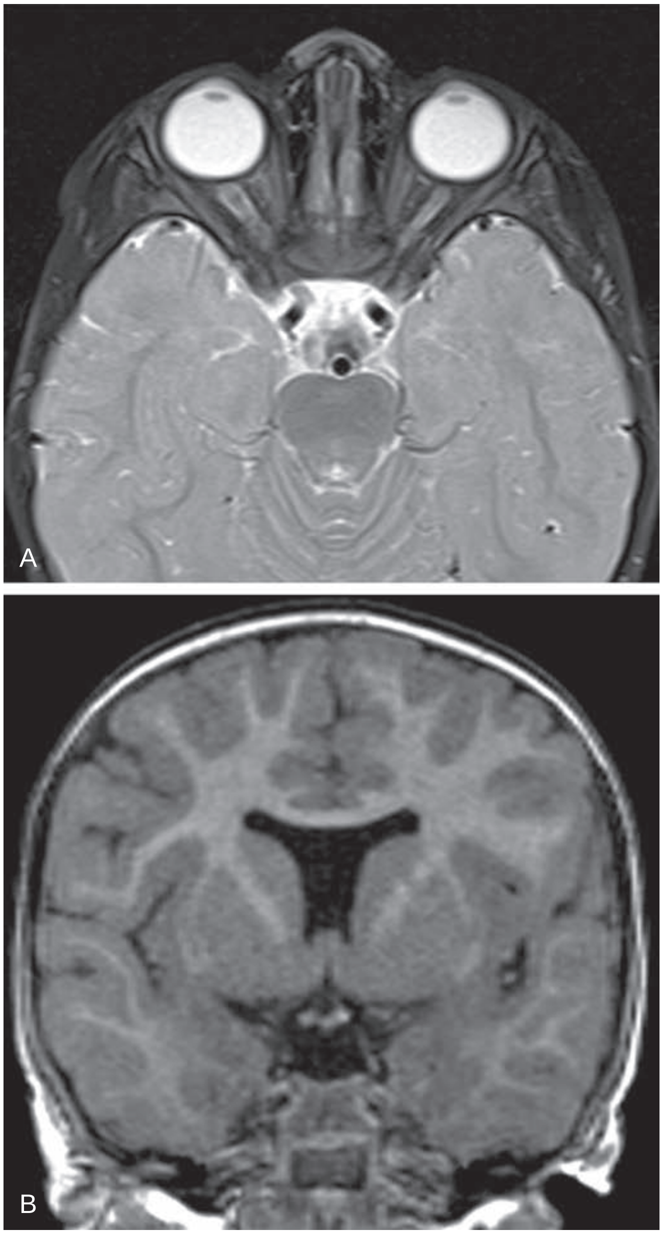

**Figure 5.11. Optic nerve hypoplasia/septo-optic dysplasia.** (A) Axial T2-weighted fat-saturated MRI of the orbits shows bilateral optic nerve hypoplasia. (B) Coronal T1-weighted MRI demonstrates an associated small chiasm and absent cavum septi pellucidi.

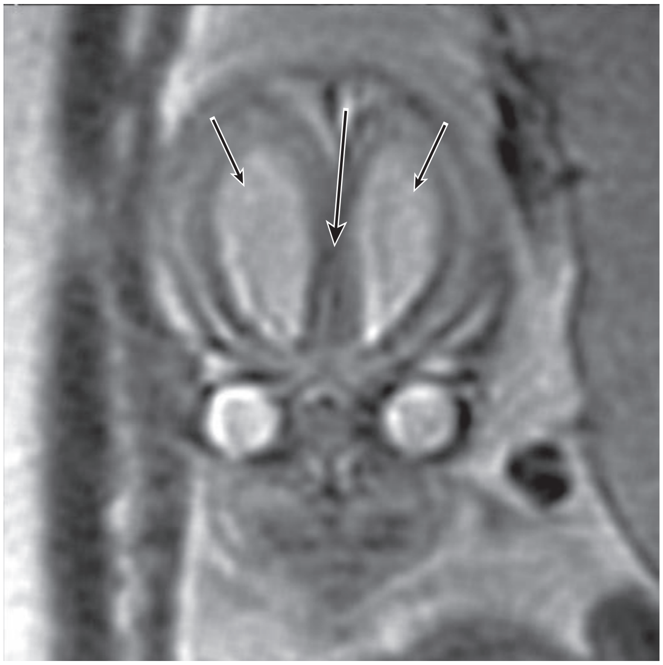
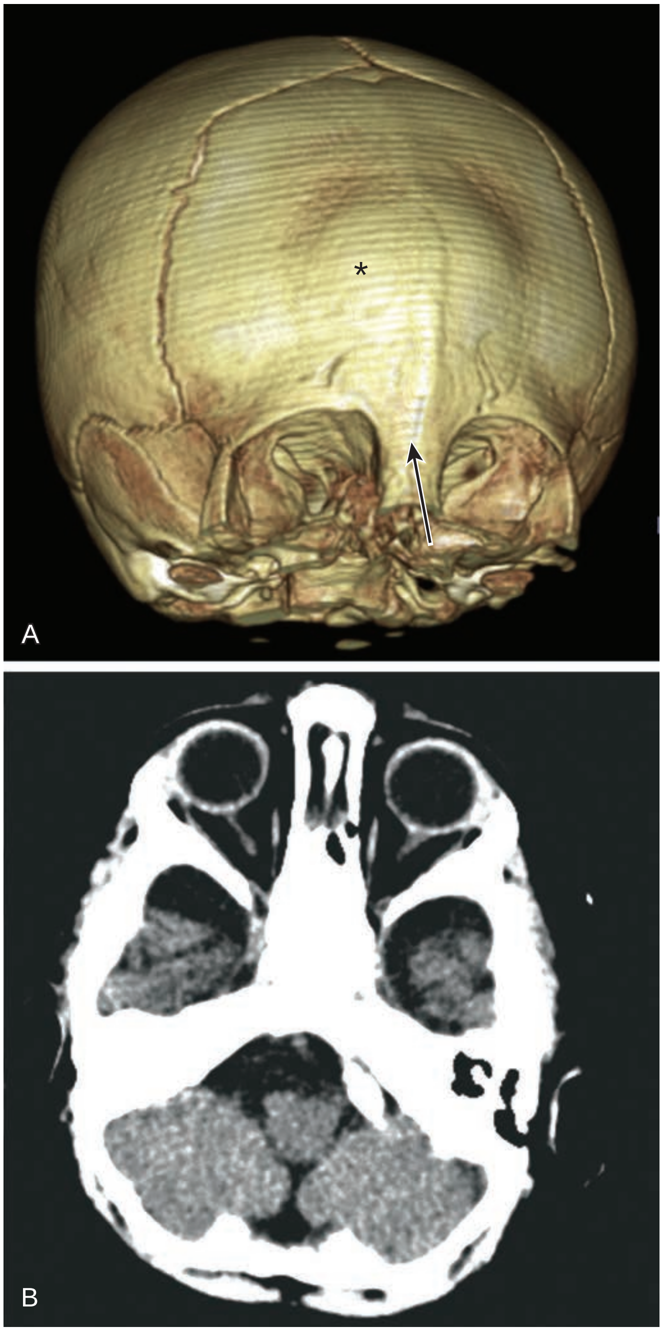
### Primary

During fetal development, if the nasal swellings do not migrate medially and inferiorly far enough that they fuse with the midline frontal swelling, the result is primary hypertelorism, in which the two halves of the face (and often the underlying halves of the brain) lie too far apart. Primary hypertelorism can result from many chromosomal anomalies and syndromes,[2] including median facial cleft syndrome, also known as frontonasal dysplasia (Fig. 5.19 and e-Fig. 5.20). This median facial cleft syndrome is composed of hypertelorism, facial clefting, and as a result of the two cerebral hemispheres "being too far apart," callosal agenesis. IOD may be the most reliable means of making the diagnosis of hypertelorism, because by ultrasound this measurement is usually more than 2

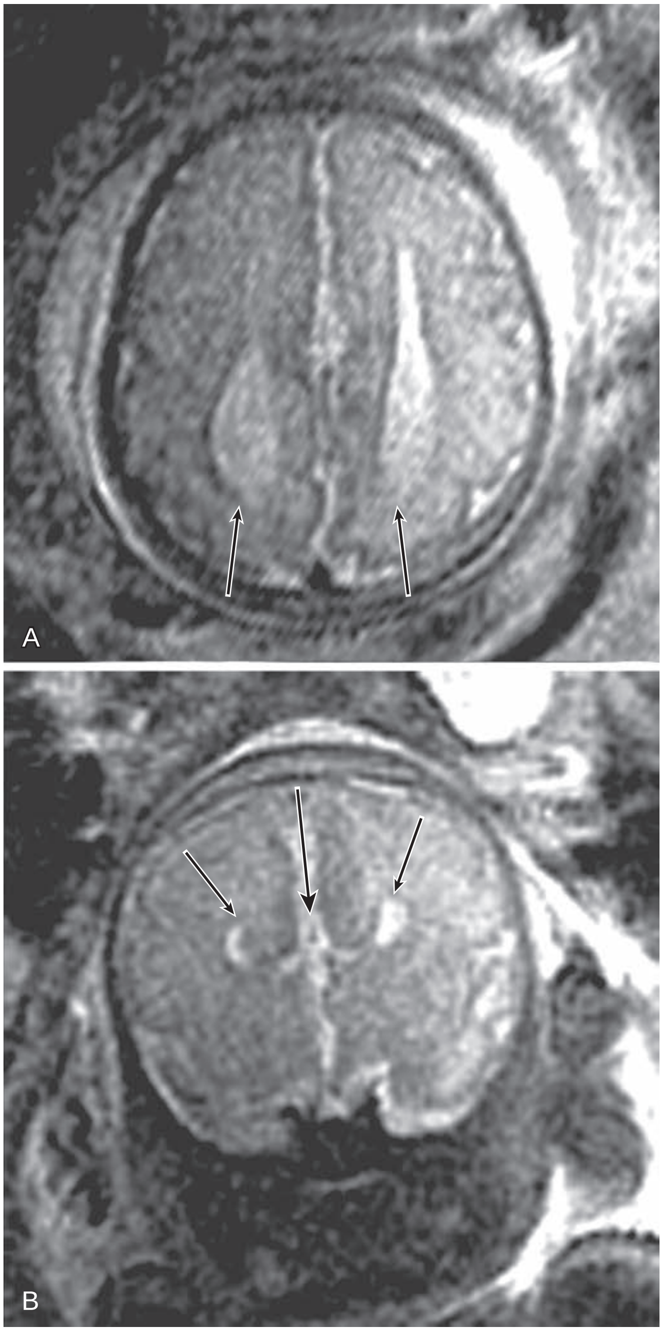
*Text continued on p. 36*



**e-Figure 5.17. Holoprosencephaly.** Coronal fetal MRI shows mild hypotelorism, but not below the 5th percentile. In addition, the cavum septi pellucidi *(large arrow)* and corpus callosum are absent, and ventriculomegaly is present *(small arrows). (From Robinson AJ, Blaser S, Toi A, et al. Magnetic resonance imaging of the fetal eyes—morphologic and biometric assessment for abnormal development with ultrasonographic and clinicopathologic correlation.* Pediatr Radiol. *2008;38:971–981.)*



**e-Figure 5.18. Metopic synostosis.** (A) Three-dimensional CT reconstruction of the skull showing metopic synostosis *(arrow)* and associated bowing of the adjacent frontal bone *(asterisk).* (B) Axial CT scan in the same patient shows hypotelorism.



**e-Figure 5.20. Frontonasal dysplasia.** (A) Axial fetal MRI shows colpocephaly *(arrows)*. (B) Coronal fetal MRI shows "longhorn steer" configuration of the lateral ventricles *(small arrows)* and third ventricle continuous with an interhemispheric fissure *(large arrow)*.

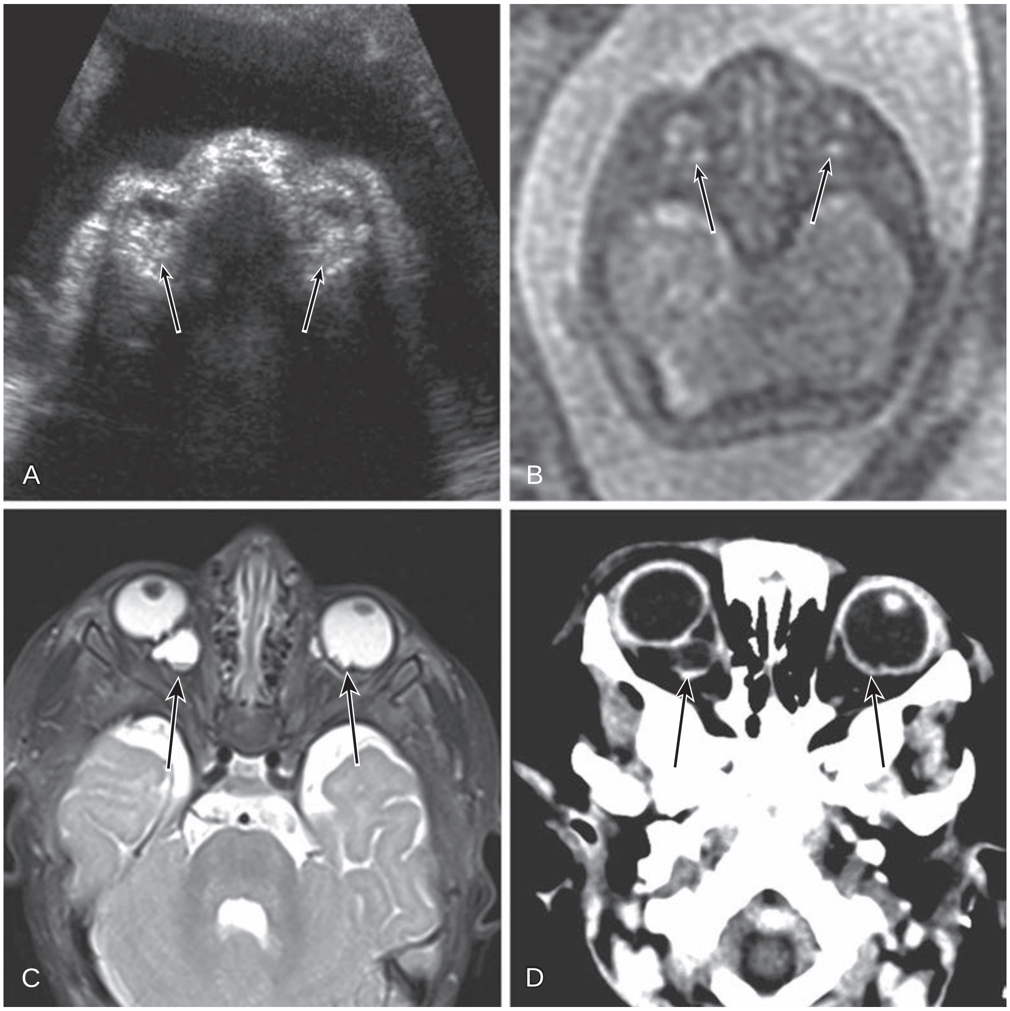


**Figure 5.12. Coloboma.** (A) Prenatal ultrasound image demonstrates abnormal echogenicity of the globes *(arrows),* but the lenses appear relatively normal. (B) Axial fetal MRI shows bilateral, symmetric, abnormal globes with mixed low- and high-signal vitreous *(arrows)* and no definite lens structures. (C) Postnatal axial T2-weighted MRI shows bilateral cystic colobomata *(arrows).* (D) Noncontrast CT image showing cystic coloboma of the posterior right orbit *(arrows). (*B, *From Robinson AJ, Blaser S, Toi A, et al. Magnetic resonance imaging of the fetal eyes—morphologic and biometric assessment for abnormal development with ultrasonographic and clinicopathologic correlation.* Pediatr Radiol. *2008;38:971–981.)*

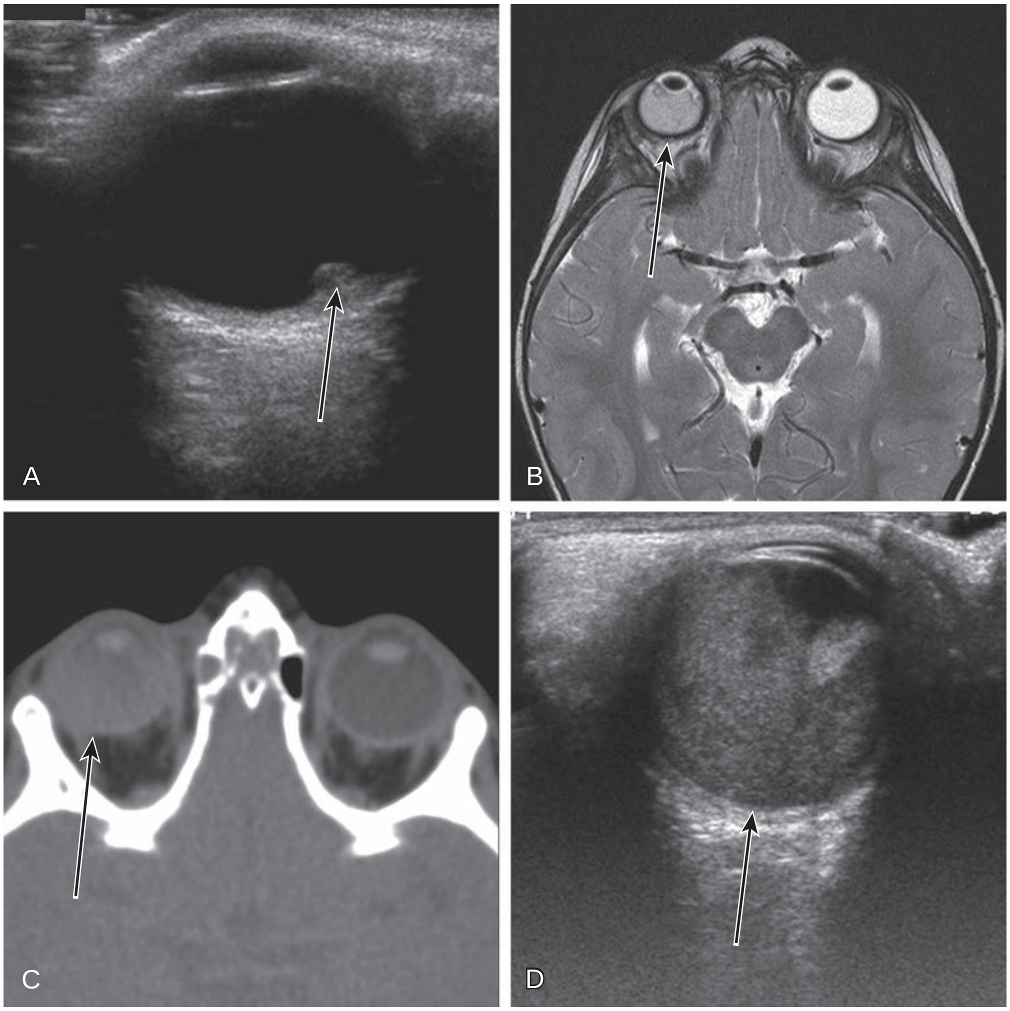

**Figure 5.14. Coats disease.** (A) Ultrasound shows a hyperechoic mass in the posterior vitreous *(arrow)* without posterior acoustic shadowing. (B) Axial T2-weighted MRI shows intermediate signal within the right vitreous *(arrow)* in keeping with proteinaceous exudate. (C) Unenhanced orbital CT demonstrates homogenous hyperattenuation of the right globe *(arrow)* and a normal left globe. (D) Ultrasound of the right eye shows hyperechogenicity within the vitreous *(arrow)* and a more focal area of increased echogenicity anteriorly.

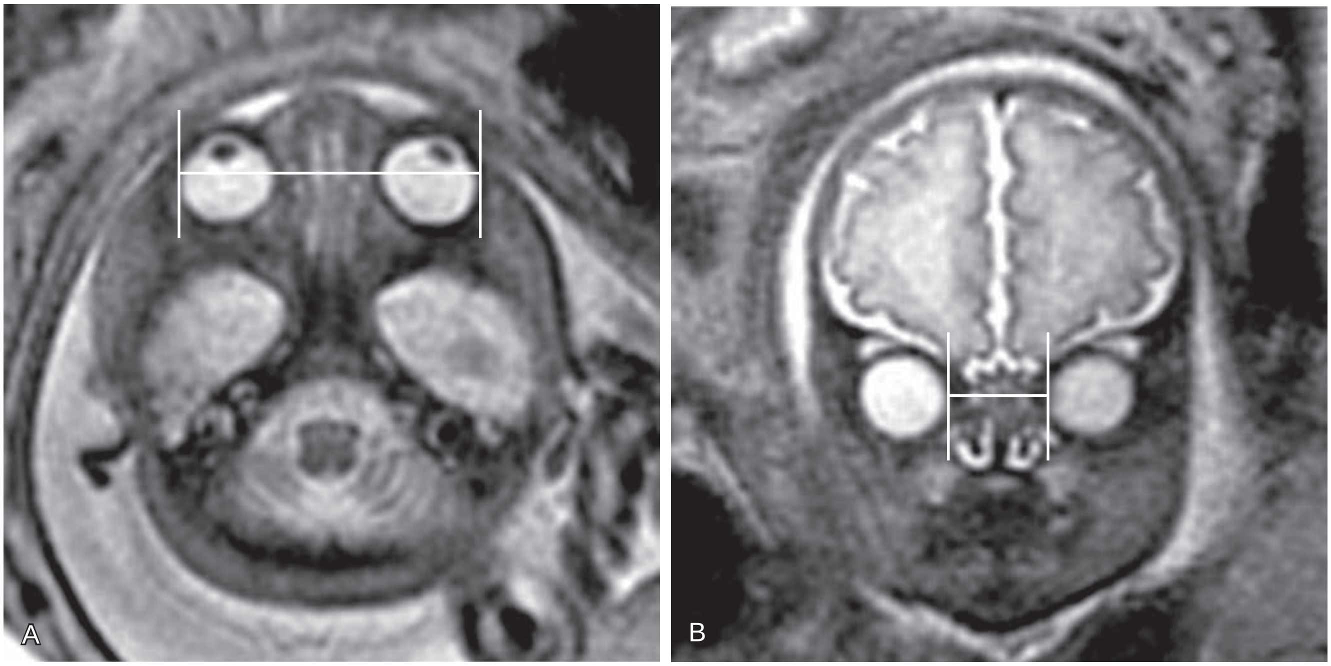

**Figure 5.15. Ocular biometry measurements by MRI.** (A) The binocular distance is measured between the two malar margins of each high-signal vitreous. The measurements can be made in any plane orthogonal to the sagittal plane. (B) The interocular distance is measured in the coronal plane between the two orbital margins of each high-signal vitreous. *(From Robinson AJ, Blaser S, Toi A, et al. Magnetic resonance imaging of the fetal eyes—morphologic and biometric assessment for abnormal development with ultrasonographic and clinicopathologic correlation.* Pediatr Radiol. *2008;38:971–981.)*

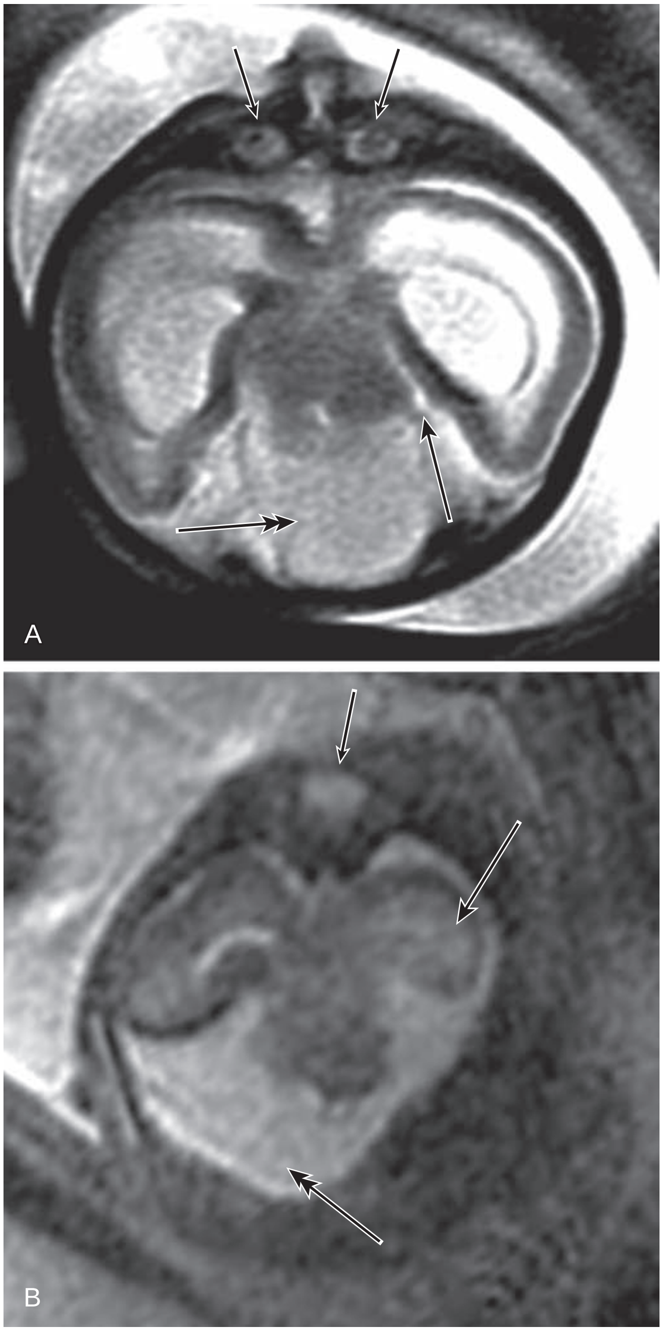

**Figure 5.16. Holoprosencephaly.** (A) Axial fetal MRI shows severe hypotelorism and microphthalmia *(small arrows).* A dorsal interhemispheric cyst is present *(double arrow),* and the hippocampus touches the brainstem at the ambient cistern *(long arrow)* in keeping with lobar holoprosencephaly. (B) Axial fetal MRI shows a single small midline globe *(small arrow).* The hippocampus is not touching the brainstem *(long arrow),* and wide communication of the ambient cistern with the dorsal interhemispheric cyst is present *(double arrow)* in keeping with alobar holoprosencephaly. *(From Robinson AJ, Blaser S, Toi A, et al. Magnetic resonance imaging of the fetal eyes—morphologic and biometric assessment for abnormal development with ultrasonographic and clinicopathologic correlation.* Pediatr Radiol. *2008;38:971–981.)*

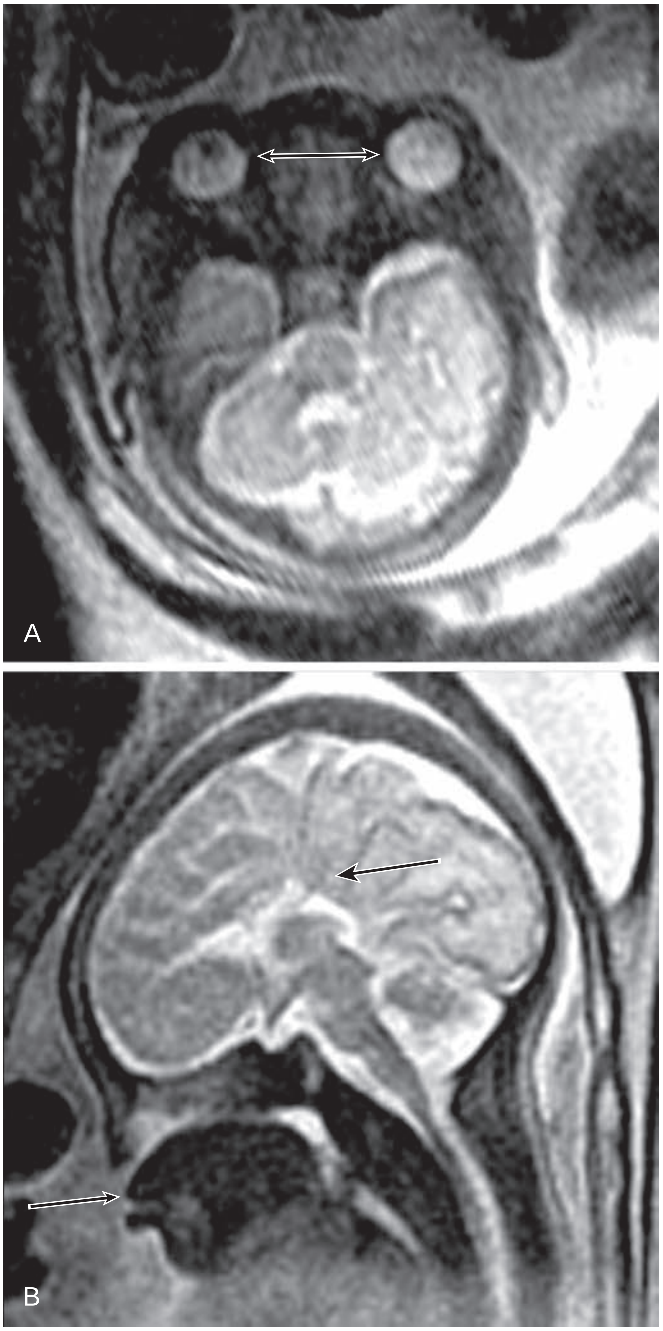

**Figure 5.19. Frontonasal dysplasia.** (A) Axial fetal MRI shows hypertelorism *(double-headed arrow).* The binocular distance and interocular distance were both greater than the 95th percentile for gestational age. (B) Midline sagittal fetal MRI shows absence of the corpus callosum *(large arrow)* and a facial defect with absence of the hard palate separating the nasal and oral cavities, with the tongue protruding through the defect *(small arrow).* (A, *From Robinson AJ, Blaser S, Toi A, et al. Magnetic resonance imaging of the fetal eyes—morphologic and biometric assessment for abnormal development with ultrasonographic and clinicopathologic correlation.* Pediatr Radiol. *2008;38:971–981.)*

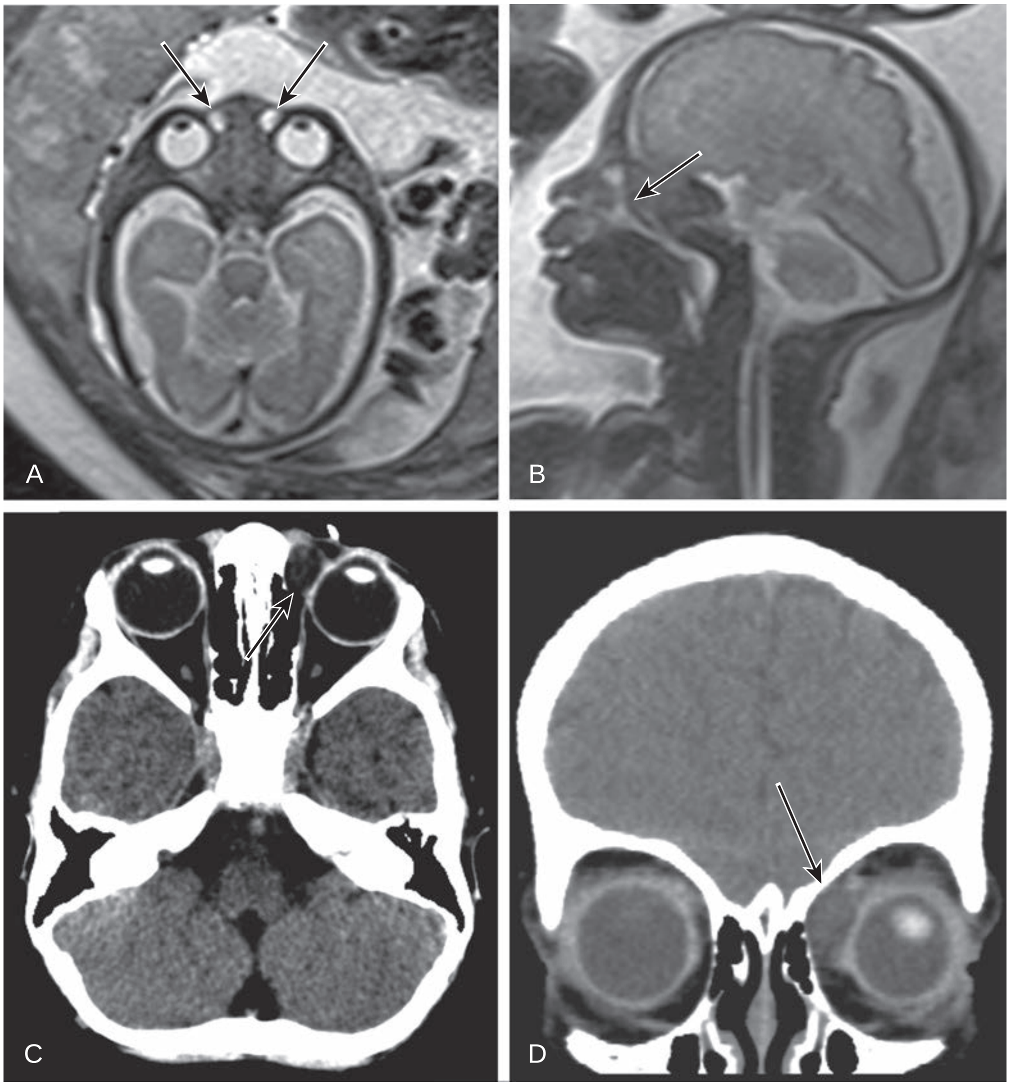

**Figure 5.23. Dacryocystocele.** (A) Axial fetal MRI shows bilateral cysts in the medial canthi *(arrows).* (B) Sagittal fetal MRI showing a dilated nasolacrimal duct *(arrow).* (C) Axial noncontrast CT shows a well-circumscribed low attenuation in the region of the left nasolacrimal duct *(arrow).* (D) Coronal CT shows a left dacryocystocele *(arrow).*

standard deviations from the mean, whereas the BOD remains at the upper limit of normal.[8]

### Secondary

Secondary hypertelorism typically results from abnormalities of the skull, the most common being anterior cephalocele and craniosynostoses (e-Figs. 5.21 and 5.22).[2,45,46]

## OTHER ORBITAL ABNORMALITIES

### Fetal Eye Movements

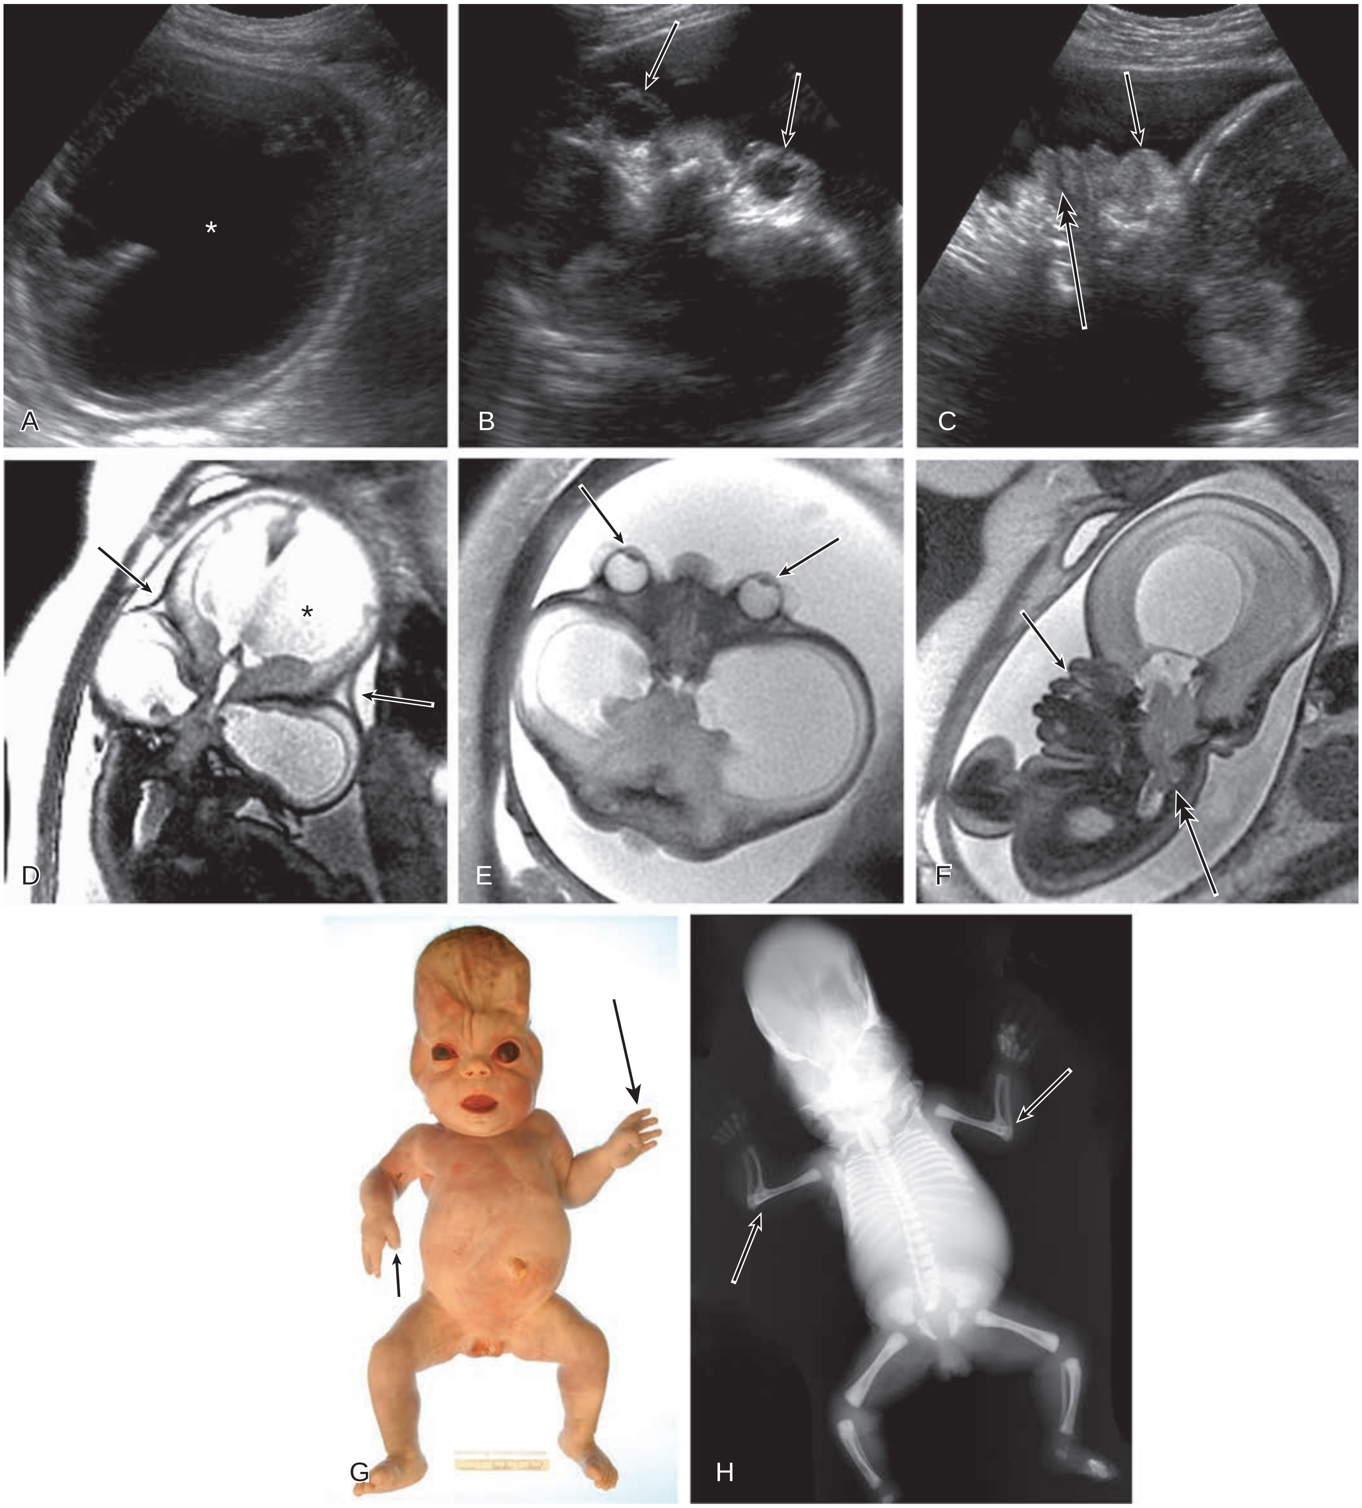
On ultrasound, fetal eye movements can be seen from 14 weeks. The incidence, pattern, and frequency are increasingly being used in the evaluation of development of the fetal brainstem and functional networks.[47-51]

### Dacryocystocele

Congenital dacryocystocele is a distention of the nasolacrimal duct, usually as a result of obstruction at its distal end at the valve of Hasner. Prenatal ultrasound and MRI can be used to make the diagnosis (Fig. 5.23).[52,53] The incidence on prenatal MRI studies has been reported to be between 0.7% and 2.7%, but only 50% of affected eyes are symptomatic postnatally. Congenital dacryocystocele is not expected to be seen before 24 weeks of gestation because nasolacrimal duct canalization is incomplete, and even normal fluid-filled nasolacrimal ducts can only be seen by MRI after 24 weeks of gestation. Dacryocystoceles also can resolve spontaneously before delivery as a result of rupture of the valve of Hasner.[54,55]

KEY POINTS

- Routine assessment of the orbit should include the presence or absence of the eyes, morphology of the lens and vitreous, and ocular biometry.
- Detection of orbital abnormalities often can be a critical step in diagnosing fetal dysmorphology.
- The existing sonographic growth charts for ocular biometry cannot be directly applied to fetal MRI; dedicated MRI nomograms should be used.



**e-Figure 5.21. Craniosynostosis and hypertelorism.** (A) Fetal ultrasound shows severe ventriculomegaly *(asterisk).* (B) Axial transorbital ultrasound image shows severe hypertelorism and exophthalmos *(arrows).* (C) Sagittal ultrasound shows midface hypoplasia *(small arrow)* and protruding lips *(double arrow).* (D) Coronal fetal MRI shows ventriculomegaly *(asterisk)* and a cloverleaf skull *(arrows).* (E) Axial fetal MRI shows severe ventriculomegaly, exorbitism *(arrows),* and hypertelorism. (F) Sagittal fetal MRI shows midface hypoplasia *(arrow)* and protrusion of posterior fossa contents into the cervical canal *(double arrow).* (G) The gross pathologic specimen shows hypertelorism, broad thumbs *(small arrow),* and syndactyly *(long arrow).* (H) Specimen radiograph showing bilateral elbow ankylosis (*arrows*), characteristic of Pfeiffer syndrome. *(*B, E, *and* G, *From Robinson AJ, Blaser S, Toi A, et al. # Orbit Infection and Inflammation

Benita Tamrazi

A wide variety of disease processes can cause inflammatory changes in the orbit, including infection, idiopathic inflammation, granulomatous disease, thyroid-related disease, optic neuritis, and sickle cell disease. Additionally, metabolic diseases can also affect the optic nerves, leading to vision loss. Many of these disease processes can share a similar imaging appearance, and consequently a good understanding of their pathophysiology and clinical presentation is needed to formulate a useful differential diagnosis.

## PERIORBITAL AND ORBITAL CELLULITIS

***Etiologies, Pathophysiology, and Clinical Presentation.*** Infections of the orbit account for more than half of primary orbital disease processes.[1] An orbital infection is described by its location with respect to the orbital septum, specifically as either preseptal (periorbital) or postseptal (orbital). The orbital septum—the anterior reflection of the periosteum of the orbital wall onto the tarsal plate of the eyelid—divides the orbit into preseptal and postseptal compartments. *Periorbital cellulitis* refers to infection anterior to the orbital septum involving the eyelid and ocular adnexa. *Orbital cellulitis* refers to infection posterior to the orbital septum. This distinction is important because orbital cellulitis carries the risks of abscess, blindness, venous thrombosis, intracranial extension, and death. Defects in the orbital septum, direct extension from sinus infection, and valveless veins provide infection access to the postseptal orbit. Sinusitis is the most common cause (60%–85%), with stye, dacryoadenitis/cystitis, dental abscess, skin breaks, and hematogenous seeding being less common.[2,3] *Staphylococcus aureus*, *S. epidermidis*, and *S. pyogenes* account for ~75% of infections; rates of *Hemophilus influenzae* and streptococcal pneumonia are declining as a result of immunization.[2] Patients present with erythema, swelling, warmth, and tenderness of the eyelid. Although ophthalmoplegia and proptosis predict postseptal involvement and abscess, approximately 50% of patients with an abscess do not have these symptoms. As a result, the guidelines for imaging are unclear and vary: edema preventing a complete examination, signs of central nervous system involvement, deteriorating vision, proptosis, ophthalmoplegia, and/or deterioration after 24 to 48 hours of treatment.[4–6]

***Imaging.*** Periorbital cellulitis presents with eyelid swelling and thickening of the preseptal soft tissues on computed tomography (CT) (Fig. 6.1A) and with T2 hyperintensity on magnetic resonance imaging (MRI).[3,7,8] In orbital cellulitis, similar inflammatory changes of the extraconal and/or intraconal orbital fat are present. The most common complication of orbital cellulitis is subperiosteal abscess, frequently involving the lamina papyracea, and directly extending from ethmoid sinus disease (Fig. 6.1B).

***Treatment.*** Treatment consists of oral antibiotics covering staphylococcus and streptococcus for periorbital cellulitis and admission to the hospital with administration of intravenous (IV) antibiotics for orbital cellulitis. Surgical intervention for drainage of an abscess is required in only 12% of admitted patients,[4] and an orbital abscess can be treated with IV antibiotics if it is small or appears in a young child.[9,10]

## SUPERIOR OPHTHALMIC VEIN THROMBOSIS

Superior ophthalmic vein (SOV) thrombosis is a complication of orbital cellulitis that results from inflammatory thrombophlebitis or direct venous invasion by infection; 33% to 75% of isolated SOV thrombosis leads to cavernous sinus thrombosis, which carries a mortality rate of 20%.[11,12] Imaging with CT or MRI demonstrates an enlarged S-shaped SOV below the superior rectus muscle with a filling defect and peripherally enhancing vasa vasorum on postcontrast images, with thrombus sometimes also seen in the ipsilateral cavernous sinus (Fig. 6.2).[13] Restricted diffusion of the SOV also has been reported, facilitating identification.[14] Treatment consists of aggressive use of antibiotics with or without corticosteroids and anticoagulation, which are not proven therapies.[11,12]

## DACRYOCYSTITIS

Dacryocystitis is inflammation and dilatation of the lacrimal sac, a structure located along the inner canthus.[15] In neonates, dacryocystitis can complicate 33% to 65% of cases of congenital dacryocystocele caused by incomplete canalization of the distal nasolacrimal duct.[16,17] In older children, dacryocystitis can result from other causes of nasolacrimal duct obstruction, including rhinitis/sinusitis, tumor, or trauma/fracture. CT or MRI demonstrates a cystic medial canthus mass with adjacent inflammatory changes (e-Fig. 6.3).[18–20] Treatment typically consists of antibiotics and dacryocystorhinostomy.

## OCULAR TOXOCARIASIS

Ocular toxocariasis refers to infection of the globe by the nematodes *Toxocara canis* or *Toxocara cati* and is most common in the southeastern United States in children 6 to 12 years of age as a result of ingestion of food or soil contaminated by the feces of dogs or cats. It presents with painless unilateral vision loss, strabismus, and leukocoria.[21]

CT and MRI demonstrate an intravitreal enhancing mass with or without adjacent uveoscleral thickening and retinal detachment. A normal-sized globe containing a mass without calcification differentiates toxocariasis from other common causes of leukocoria (e.g., retinoblastoma, persistent hyperplastic primary vitreous, Coats disease, and retinopathy of prematurity).[22,23]

## ORBITAL PSEUDOTUMOR (IDIOPATHIC ORBITAL INFLAMMATION)

***Etiologies, Pathophysiology, and Clinical Presentation.*** Idiopathic orbital inflammatory syndrome, also known as orbital pseudotumor (OP), is an inflammatory, nongranulomatous process with unknown underlying cause. Essentially, this is a diagnosis of exclusion for patients presenting with exophthalmos. Pediatric OP is rare, accounting for only 7% to 16% of cases of OP.[24,25] Children present similarly to adults with pain, proptosis, a mass, swelling, and motility restriction; however, children more frequently demonstrate ptosis and bilateral or intraocular involvement.

***Imaging.*** Both CT and MRI are useful in evaluating OP.[26–28] Lacrimal gland involvement is most common, with enlargement and adjacent inflammatory change. Myositis also occurs frequently, typically with unilateral tubular thickening of extraocular muscles and tendons (compared with Graves orbitopathy, which tends to be bilateral with tendon sparing). OP may involve the uvea and

## Abstract:

Imaging findings of orbital infection and inflammation are provided with a wide differential diagnosis presented for review, including infection, idiopathic inflammation, granulomatous disease, thyroid-related disease, optic neuritis, and sickle cell disease. The imaging findings, clinical presentation, and treatment are reviewed.

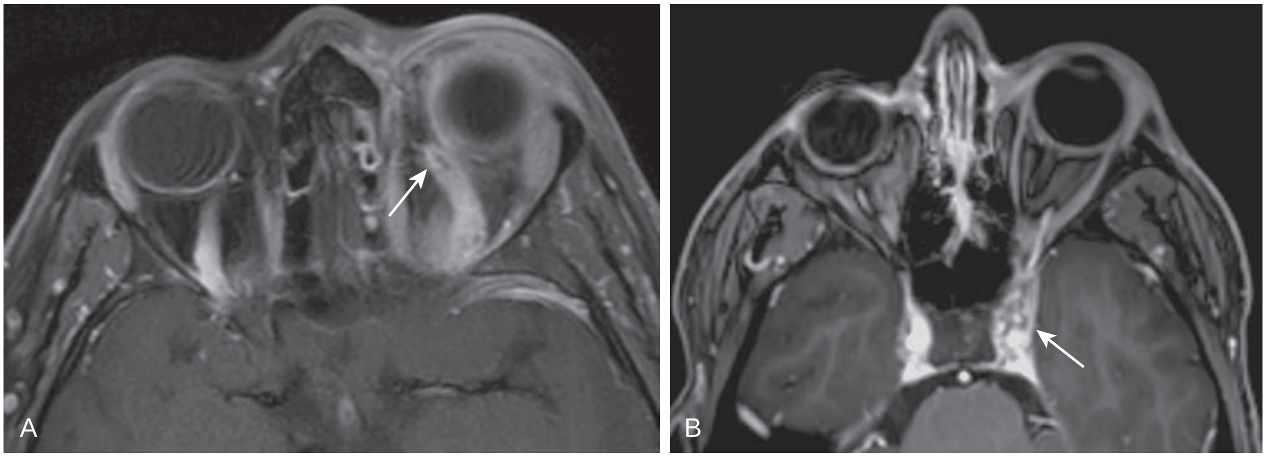

**Figure 6.2. Orbital cellulitis with superior ophthalmic vein and cavernous sinus thrombosis.** (A) Axial T1-weighted postcontrast fat-saturated MR image of the orbit demonstrates a focal filling defect in the superior ophthalmic vein consistent with thrombus in the setting of orbital cellulitis *(arrow)*. (B) Axial T1-weighted post contrast MR image of the brain demonstrates filling defect in the ipsilateral cavernous sinus consistent with thrombus *(arrow)*.

sclera with thickening and enhancement (Fig. 6.4). Perineuritis, which involves the optic nerve sheath, demonstrates “tramline” inflammatory changes and enhancement surrounding the optic nerve (see Fig. 6.4). Inflammation can extend through the orbital fissures and optic canal into the cavernous sinus and middle cranial fossa. The differential diagnosis includes infection, lymphoma, Wegener granulomatosis, sarcoidosis, and Graves orbitopathy. Diffusion-weighted imaging may be helpful in the diagnosis with the intensity of lymphoid lesions > OP > cellulitis on b-value = 1,000 images.[29]

***Treatment.*** Administration of oral corticosteroids often results in a rapid response (within 1–2 days); radiation is used in refractory cases.[25,30] Recurrence after withdrawal of steroids occurs frequently in adults (~50%) but has been reported in only one child.[24,31] Biopsy is reserved for atypical symptoms or poor response. Recently, cases of OP have been identified as part of IgG4-related disease, a systemic inflammatory disease demonstrating excellent response to rituximab and corticosteroids.[32,33]

## GRAVES ORBITOPATHY (THYROID ORBITOPATHY)

***Etiologies, Pathophysiology, and Clinical Presentation.*** Graves orbitopathy is an orbital inflammatory process seen in persons with Graves disease, which is an autoimmune thyroid disease from thyroid-stimulating hormone receptor autoantibodies. Pediatric Graves disease is uncommon, yet children who have the disease experience Graves orbitopathy at similar rates as do adults, in one-third to two-thirds of cases.[34–36] Graves orbitopathy is milder in children than in adults, with mild proptosis and mild eyelid retraction or lag. In children, no cases of compressive optic neuropathy have been reported, and strabismus is rare.

***Imaging and Treatment.*** Imaging demonstrates fusiform enlargement of extraocular muscles (involving muscle bellies and sparing tendons), which is bilateral in 90% of cases and frequently involves the inferior and medial recti (Fig. 6.5). Active disease can be differentiated from fibrotic disease by evaluating the T2 signal intensity and dynamic contrast enhancement of the muscles (T2

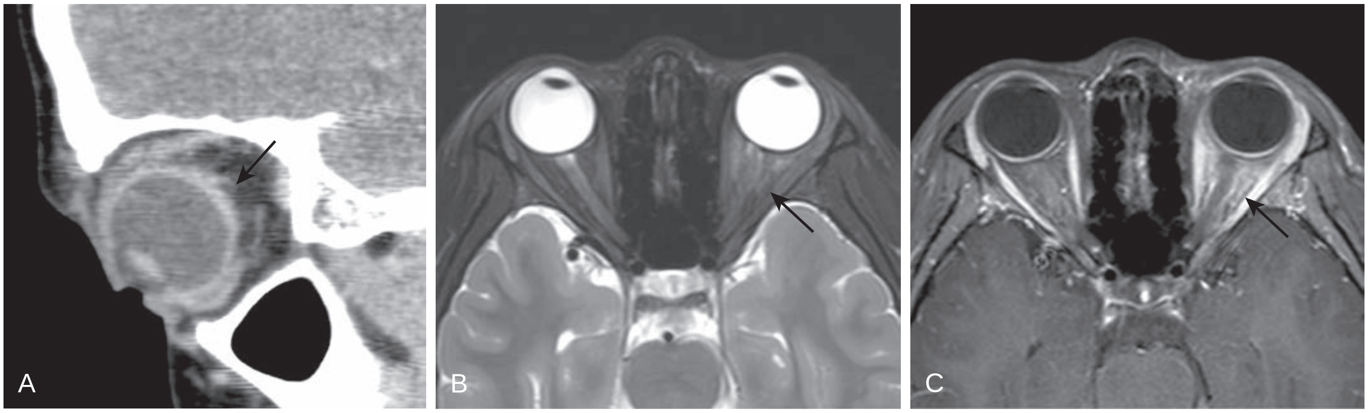

**Figure 6.4. Orbital pseudotumor.** (A) Sagittal contrast-enhanced CT image of scleral involvement by a pseudotumor causing posterior scleritis with subtle thickening of the posterior sclera *(arrow)*. (B) Axial T2-weighted fat-saturated MR image in a different patient with a pseudotumor demonstrating ill-defined T2 hyperintensity of the intraconal fat *(arrow)*. (C) Axial T1-weighted fat-saturated postcontrast MR image demonstrating corresponding "tramline" enhancement of the optic nerve sheath and ill-defined enhancement of the intraconal fat *(arrow)*.

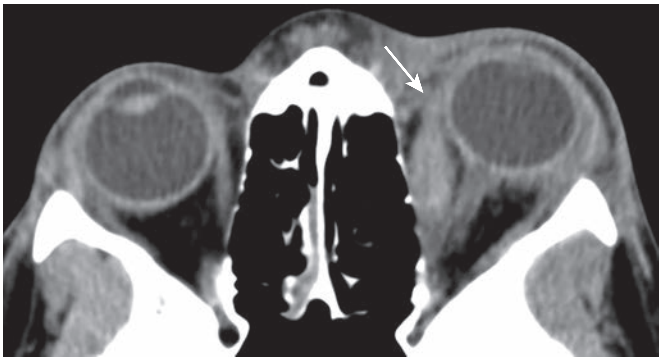

**Figure 6.5. Graves orbitopathy.** Contrast-enhanced CT image demonstrates fusiform enlargement of the medial rectus muscle belly with sparing of the tendons *(arrow)*.

hyperintensity, shorter time to peak, and greater enhancement and washout ratios are found in active disease), an important distinction because medical therapy is not effective in fibrotic disease.[37–39] Most pediatric cases can be controlled with antithyroid medication alone; steroids, radiation therapy, or surgery are not required, as is often the case with adults.[34–36]

## SARCOIDOSIS

Sarcoidosis is a multisystem disease of unclear etiology characterized by noncaseating granulomas. Sarcoidosis is rare in children; however, a unique form appears in children younger than 5 years and presents with rash, uveitis, and arthritis.[40] In older children and adults, ocular involvement is seen in ~25% of cases, most commonly with uveitis.[40–43] Additional orbital structures involved can include the lacrimal gland and sac, eyelid, orbital soft tissues, optic nerve and sheath, and extraocular muscles, with enlargement and enhancement of these structures.[44,45] Involvement can be well circumscribed (in 85% of cases) or diffuse (in 15% of cases). The mainstay of treatment is oral steroids, which generally results in a good response; methotrexate or surgery is used for refractory cases. In patients with isolated orbital involvement (63%), systemic disease develops in 8% within 5 years.[46]

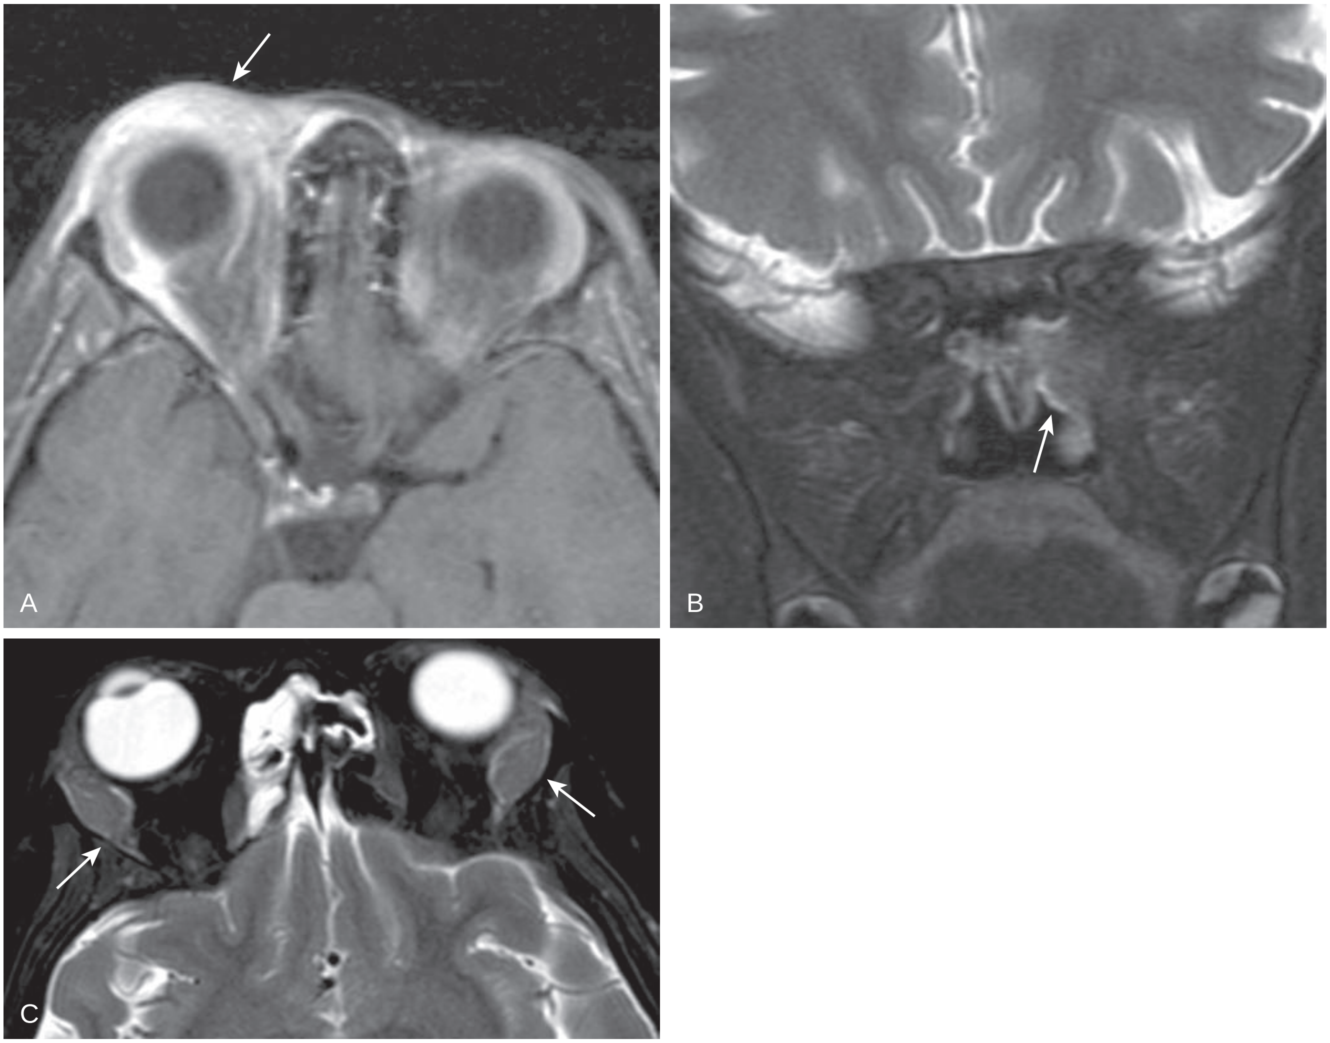
## WEGENER GRANULOMATOSIS

Wegener granulomatosis is a necrotizing granulomatous vasculitis of small- and medium-sized vessels associated with antineutrophil cytoplasmic antibodies. Pediatric Wegener granulomatosis is rare; it presents in adolescence with a female predominance.[47,48] Orbital involvement occurs in approximately 50% of adults (and is the presenting feature in 15%), but it is less common in children.[49,50] Orbital disease may be primary or extend from the sinuses with osseous erosion. The globe (conjunctivitis and scleritis), lacrimal gland, retrobulbar space, optic nerve, and extraocular muscles all can be involved. Imaging demonstrates granulomatous masses with variable enhancement and characteristic T2-weighted hypointensity on MRI, presumably related to fibrocollagenous tissue (e-Fig. 6.6).[51,52] Symmetric lacrimal gland enlargement can also be seen. Treatment in children can vary but typically consists of administration of steroids and cyclophosphamide.

## OPTIC NEURITIS

***Etiologies, Pathophysiology, and Clinical Presentation.*** Optic neuritis (ON) involves inflammation or demyelination of the optic nerve and often presents with unilateral eye pain and visual loss. ON may be idiopathic or related to multiple sclerosis (MS), neuromyelitis optica, or acute disseminated encephalomyelitis. ON behaves differently in children than in adults, likely reflecting different etiologies, with parainfectious ON being common in children (in one-third to two-thirds of cases).[53–57] Compared with adults, ON in children is more often bilateral (in 37% to 66% of cases), less often painful (in 37% of cases), and more often demonstrates disk swelling (in 46%–85% of cases) and profound vision loss. In children, it tends to have better visual recovery and is less often associated with MS.

***Imaging.*** MRI demonstrates contrast enhancement (>90%), T2-weighted hyperintensity, and enlargement of the optic nerves acutely, with mild volume loss developing chronically.[58,59] Intraorbital involvement is most common (Fig. 6.7). Intracanalicular and long segment involvement and persistent signal change over time correlate to worse visual outcomes. Diffusion tensor imaging of optic nerves is difficult to perform clinically yet demonstrates decreased axial diffusivity acutely and increasing radial diffusivity and apparent diffusion coefficient values during recovery, correlating to changes in visual acuity and retinal nerve fiber layer thinning.[60–62] Decreased fractional anisotropy values also can be seen in the optic tracts and radiations, possibly as a result of Wallerian and transsynaptic degeneration.[63–65] Magnetization transfer ratios, which are thought to decrease with demyelination, are more sensitive than T2 spin echo imaging. They progressively decrease in the optic nerve, with a nadir at 240 days, and then mildly increase



**e-Figure 6.6. Wegener granulomatosis.** (A) Axial T1-weighted fat-saturated postcontrast MR image of the orbit demonstrating inflammatory changes and enhancement adjacent to the lacrimal gland in the preseptal orbit, similar in appearance to periorbital cellulitis *(arrow)*. (B) Coronal T2-weighted fat-saturated MR image demonstrates a mass centered on the sphenopalatine foramen with osseous erosion and extension to the orbital apex with characteristic T2 hypointensity, making it difficult to visualize on MR imaging *(arrow)*. (C) Axial STIR MR image of the orbits in another patient demonstrates diffuse, symmetric enlargement of the lacrimal glands *(arrows)*.

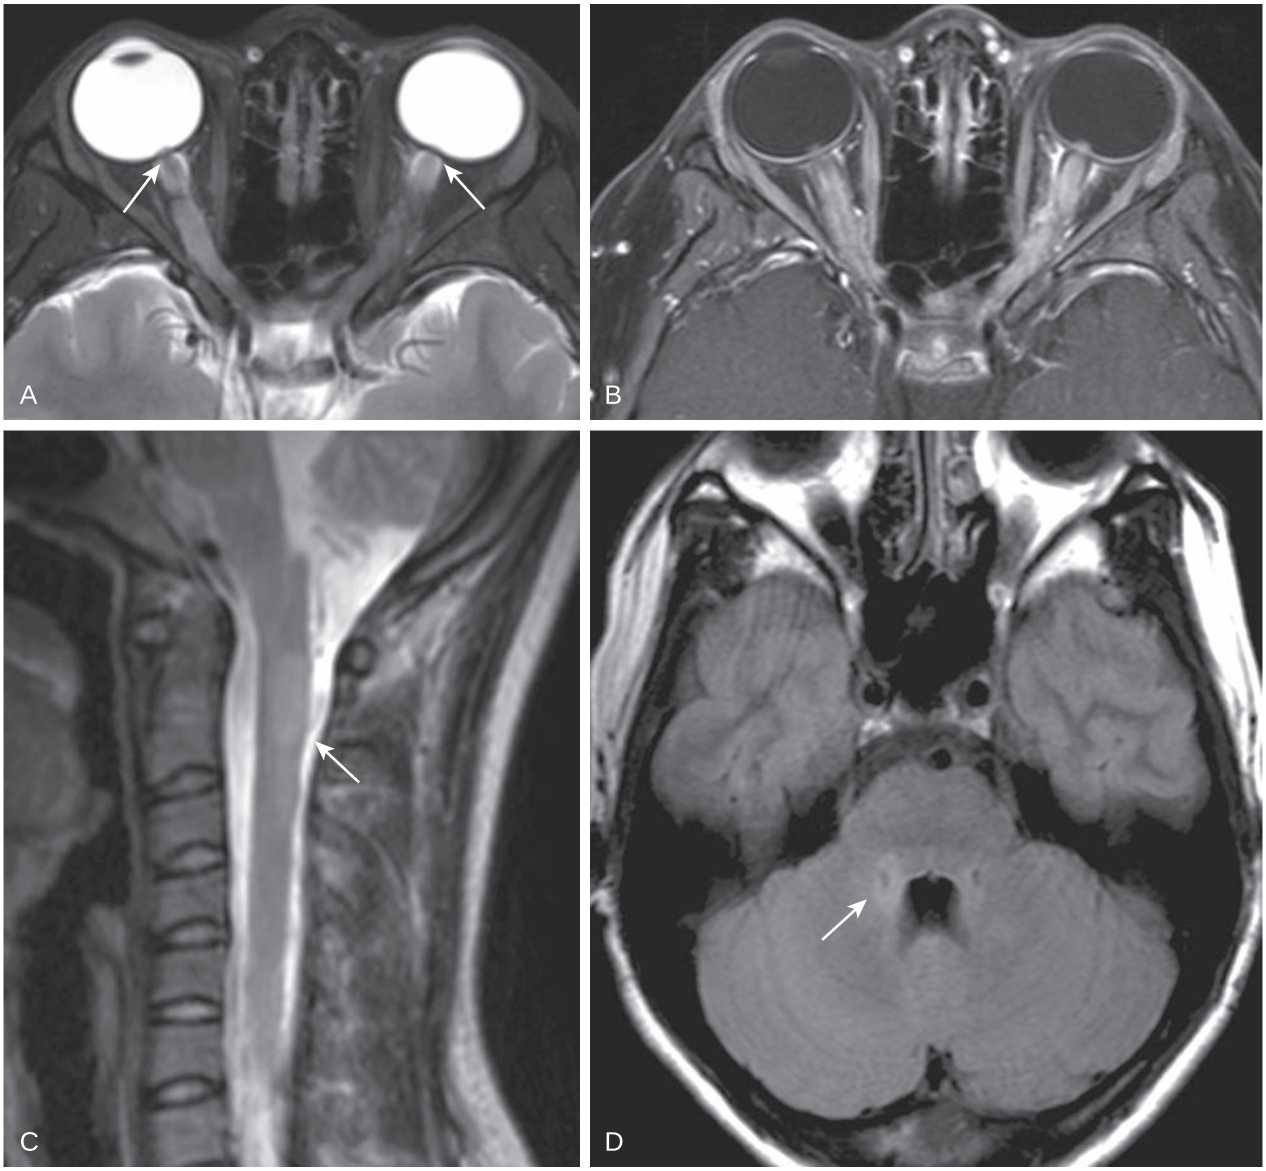


**Figure 6.7. Optic neuritis.** (A) Axial T2-weighted and (B) T1-weighted fat-saturated postcontrast MR images of the orbits demonstrating abnormal T2 hyperintensity and enhancement of the bilateral optic nerves with papilledema *(arrows)*. (C) Sagittal T2-weighted MR image of the cervical spine demonstrates a characteristic central long segment cord lesion in a patient with neuromyelitis optica (NMO) *(arrow)*. (D) Axial T2-weighted fluid attenuated inversion recovery MR image in the same patient with NMO demonstrating subtle hyperintensity adjacent to the fourth ventricle in regions of high aquaporin 4 concentration *(arrow)*.

(possibly from remyelination), also correlating to changes in visual acuity.[66,67]

***Treatment.*** ON in children is usually treated with IV methylprednisolone followed by an oral prednisolone taper.[68] Although no large randomized controlled trials have been performed in children, in adults this therapy accelerates visual recovery and decreases the risk of MS for 2 years.[69]

## Optic Neuritis and Multiple Sclerosis

Most ON research has been conducted with adult subjects, and it has been found that MS develops in 50% of adults with ON within 15 years.[69] In children, the largest series with the longest follow-up demonstrated a 19% conversion to MS (13% in 10 years).[56] As with adults, almost all children in whom MS developed had an abnormal MRI scan at baseline, and MS developed in almost no children who had a normal MRI scan.[53,54] Furthermore, optic disk swelling is associated with a decreased risk of MS in adults and is a common feature of pediatric ON, likely reflecting the often parainfectious nature of ON in children.[53–57]

## Optic Neuritis and Neuromyelitis Optica (Devic Disease)

***Etiologies, Pathophysiology, and Clinical Presentation.*** Neuromyelitis optica (NMO) is an inflammatory demyelinating disease of the optic nerves and spinal cord related to NMO–immunoglobulin G (IgG), a serum autoantibody targeting aquaporin 4, a water channel on astrocytes at the blood-brain barrier.[70,71] The distinction of NMO from MS is important because NMO has a worse prognosis and requires different treatment. Diagnostic criteria for children are similar to those for adults: clinical diagnosis of ON and transverse myelitis with either a cord lesion on MRI or NMO-IgG seropositivity.[72,73] The prognosis is poor: more than 50% of patients have vision loss or lose the ability to ambulate within 5 years. NMO-IgG seropositivity may indicate a worse prognosis with a relapsing course.[74–76] Parainfectious NMO is common in children and typically is NMO-IgG negative and monophasic.[77,78] Accordingly, pediatric NMO has a better prognosis and a longer time before the onset of disability.[79,80]

***Imaging.*** Characteristic cord lesions are centrally located and extend three or more segments in length (Fig. 6.7C). Up to 60% of patients also demonstrate brain lesions, which are part of the new diagnostic criteria.[81] Findings include nonspecific signal changes, MS-like lesions (10%), and T2-weighted hyperintensity in areas of high aquaporin 4 concentration adjacent to the third and fourth ventricles (Fig. 6.7D). Signal changes in the distribution of aquaporin 4 may be specific for NMO and are seen more frequently in children.[81,82]

***Treatment.*** Treatment of persons with NMO consists of immunosuppression (IV methylprednisolone ± plasmapheresis acutely, with oral prednisone and azathioprine for maintenance), compared with immunomodulation for persons with MS.[70,79] NMO-IgG positivity in persons with isolated ON or transverse myelitis may represent a limited form of NMO, requiring more aggressive treatment.[76] Similarly, NMO-IgG negativity in children may predict a parainfectious etiology with a monophasic course not requiring immunosuppressive therapy.[74,75]

### Optic Neuritis and Acute Disseminated Encephalomyelitis

Acute disseminated encephalomyelitis (ADEM) is an autoimmune inflammatory and typically monophasic demyelinating disease of the central nervous system that occurs days to weeks after a viral illness or vaccination. Visual loss is seen in up to one-fourth of patients with ADEM, and ON in persons with ADEM tends to be bilateral with swollen optic discs.[83–85] Although no clear guidelines exist, treatment usually consists of IV steroids with favorable outcomes.[86] The high frequency of parainfectious ON in children (in one-third to two-thirds of cases) likely contributes to the different presentation and more favorable prognosis of ON in children compared with adults.

## PAPILLEDEMA

Papilledema is another cause of optic disc swelling in children. It is the result of elevated intracranial pressure due to intracranial mass/inflammation, hydrocephalus, venous sinus thrombosis, or pseudotumor cerebri. Visual loss may result.[87] MRI demonstrates optic disc elevation, dilated perioptic subarachnoid spaces, and optic nerve tortuosity (see Fig. 6.7A and B).[88,89] Enhancement and restricted diffusion of the optic disc have been described, perhaps as a result of venous congestion and ischemia.[90,91]

## SICKLE CELL DISEASE

***Etiologies, Pathophysiology, and Clinical Presentation.*** Sickle cell disease (SCD) is an inherited autosomal-recessive disease of the sickle beta globin gene that results in chronic hemolytic anemia and recurrent vaso-occlusive crises and infection. A vaso-occlusive crisis can affect any bone with active bone marrow. Orbital wall involvement is seen almost exclusively in children because of a greater volume of marrow space in this location during childhood. Patients present with acute periorbital pain, swelling, proptosis, and restricted extraocular movements. Subperiosteal hemorrhage can be a complication in 36% of cases. Resultant orbital compression syndrome can cause optic nerve compression and vision loss.[92–95]

***Imaging.*** MRI demonstrates bone marrow edema and hemorrhage with or without subperiosteal hemorrhage (Fig. 6.8A). It is important to differentiate bone marrow infarction from osteomyelitis given that both can occur in persons with SCD. On MRI, infarction demonstrates thin peripheral contrast enhancement, whereas infection demonstrates thick peripheral, geographic, or irregular contrast enhancement with or without cortical defects.[96] Areas of high signal intensity on T1-weighted fat-saturated

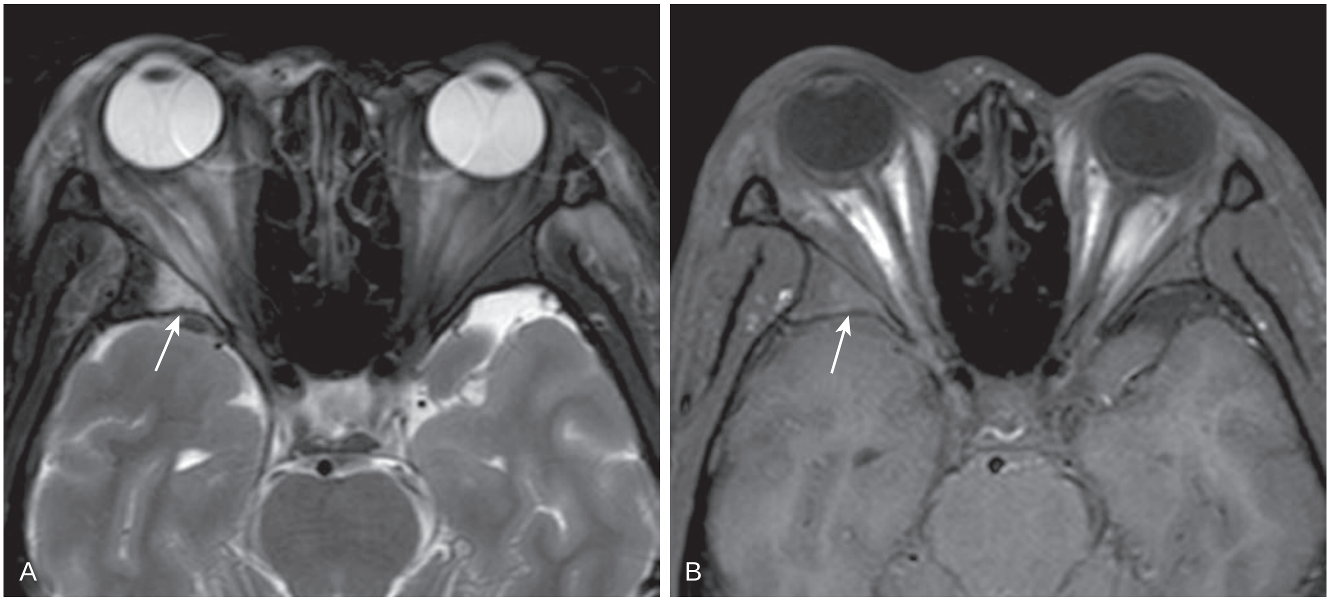

**Figure 6.8. Sickle cell disease.** (A) Axial T2-weighted fat-saturated MR image of the orbits demonstrating bone marrow infarction in a patient with sickle cell disease, with T2 hyperintensity of the bone marrow of the lateral wall of the right orbit and adjacent inflammatory changes of the extraconal fat *(arrow)*. (B) Axial T1-weighted fat-saturated noncontrast MR image of the orbit in the same patient demonstrating subtle T1 hyperintensity of the bone marrow from sequestration of red blood cells *(arrow)*.

noncontrast MRI due to sequestration of red blood cells also has been found to be helpful in detecting areas of infarction and distinguishing them from infection (Fig. 6.8B).[97]

***Treatment.*** Treatment consists of conservative management for SCD crises. In cases of optic nerve compression and vision change, IV steroids and/or surgical drainage of hematomas may be required.

## LEBER HEREDITARY OPTIC NEUROPATHY

***Etiologies, Pathophysiology, and Clinical Presentation.*** Leber hereditary optic neuropathy (LHON) is the most common genetic mitochondrial disease, affecting 1 in 25,000 persons.[98] Deficient adenosine triphosphate production leads to degeneration of retinal ganglion cells. Three mitochondrial deoxyribonucleic acid mutations (G3460A, G11778A, and T14484C) account for more than 90% of cases with incomplete penetrance: 50% in males and 10% in females. Accordingly, LHON is most common in young males, with a median age of 24 years. Painless bilateral clouding of vision, centrocecal scotoma, and impairment of color vision progresses to vision loss and optic nerve atrophy in 6 months. Most patients show no functional improvement, remaining legally blind.

***Imaging.*** Most patients demonstrate no imaging findings, yet acutely, T2 hyperintensity, enlargement, and enhancement of the optic nerves, chiasm, and tracts can be seen. A small portion of patients, particularly females, demonstrate MS-like lesions in the brain preceding or more commonly after optic nerve involvement after an average of 4.3 years.[99,100]

***Treatment.*** No treatment is available that significantly improves visual outcome, but recent trials have focused on Idebenone.[101,102] Patients with LHON and MS-like lesions may need immunosuppressive therapy.

## AUTOSOMAL-DOMINANT OPTIC ATROPHY

Autosomal-dominant optic atrophy (ADOA) is the most common hereditary optic neuropathy related to mutations in the optic atrophy 1 *(OPA1)* gene (encoding a mitochondrial guanosine triphosphatase).[103] Selective retinal ganglion cell loss results in isolated, progressive, and permanent vision loss, typically in the first 2 decades of life. Extraocular neurologic involvement is seen in up to one-sixth of patients, with sensorineural hearing loss being the most common manifestation, likely as a result of *OPA1* expression in the inner ear.[104] Few studies describe the imaging appearance of ADOA, although a decrease in the size of the optic nerves throughout their length can be seen.[105]

## KRABBE DISEASE (GLOBOID CELL LEUKODYSTROPHY)

Krabbe disease is an autosomal-recessive neurodegenerative disorder with a deficiency in galactosylceramide β-galactosidase, a lysosomal enzyme responsible for myelin breakdown and turnover. This deficiency leads to accumulation of neurotoxic psychosine and galactosylceramide, which form globoid cells. Early-, late-, and adult-onset forms are described. Presentation is most common at 3 to 6 months of age, with death by 2 to 3 years of age. Optic nerve enlargement is an uncommon manifestation, perhaps as a result of globoid cell accumulation in optic nerves, as described at autopsy (e-Fig. 6.9).[106–109] The major differential considerations in children with enlarged optic nerves and signal changes in both the white matter and deep grey nuclei are Krabbe disease and neurofibromatosis type 1 with optic pathway gliomas.

### KEY POINTS

- Infection involving the postseptal orbit carries the risks of abscess formation, vision loss, venous thrombosis, intracranial extension, and death, requiring admission for monitoring and IV antibiotics.
- Many disease processes in the orbit can look similar on imaging, with presentation as an ill-defined inflammatory mass: infection, OP, Wegener granulomatosis, sarcoidosis, and lymphoma.
- Causes of optic neuritis in children include an idiopathic cause, MS, NMO, and ADEM.
- Optic neuritis behaves differently in children, which likely is related to its frequent parainfectious nature: it is painless, bilateral, presents with disk edema and profound vision loss, generally results in a good recovery, and infrequently progresses to MS.
- Although uncommon, metabolic disease also should be considered in a child with vision loss and changes to the optic nerves on imaging.

# 7 Orbital Neoplasia

Tamara Feygin and Avrum N. Pollock

A wide variety of primary and secondary neoplasms may affect the orbit. Most orbital masses are benign and slow growing, but approximately 20% are malignant. Making the correct diagnosis may be difficult for several reasons. In children, it may be challenging to obtain an accurate history and physical examination. The presenting symptoms (and imaging findings) of different pathologic entities may overlap considerably. Nonneoplastic masses may present with visual loss and destructive changes of the orbit, raising concerns for malignancy. At the same time, some malignant tumors of the orbit may closely resemble inflammatory cellulitis, both clinically and on imaging. Some orbital lesions have a high association with systemic and genetic disorders, and, in these cases, represent just the "tip of the iceberg." Diagnosis of an orbital lesion behooves the interpreter to diligently search for concurrent lesions elsewhere in the body.

A precise and timely diagnosis of an orbital mass can be crucial for successful treatment and prevention of blindness. Imaging plays an integral role, and, at times, more than one imaging modality may be required to allow delineation of the lesion's morphology and extent. Proper utilization of imaging modalities, in particular ultrasonography (US), computed tomography (CT), magnetic resonance imaging (MRI), positron emission tomography (PET), and, in selected cases, conventional angiography, should be thoughtfully considered. Newer advanced imaging technologies contribute to the precise diagnosis of orbital pathology. The radiologist should recommend the best imaging modality to be used in specific clinical scenarios.

US is primarily a tool used by ophthalmologists in the assessment of diseases of the globe and extraocular muscles (EOMs). This modality is especially valuable for the evaluation of young children with leukocoria but may be suboptimal in assessing the full extent of extraocular and intracranial spread of a primary ocular mass.

CT is a very effective tool in the diagnosis of pediatric orbital disease. It is widely available and often may serve as the initial imaging modality for evaluation of acute proptosis, orbital cellulitis, and trauma. CT is excellent at depicting calcifications and evaluating potential bony involvement. Current CT equipment allows for rapid acquisition of high-resolution images in the axial plane, with near real-time additional computed reformation images in the coronal and/or sagittal planes, thus avoiding the need for direct acquisition of images in orthogonal planes. Three-dimensional (3D) reformations are important for surgical planning and better depiction of orbital volumes (e-Fig. 7.1A). The data acquisition is rapid enough to obviate the need for sedation in many cases. Pediatric CT use has declined in recent years due to the continued trepidation regarding potential deleterious effects of radiation.

Many orbital lesions are optimally imaged utilizing MRI, especially since the advent of surface coils and fat suppression (FS) techniques. Protocols for orbital imaging include high-resolution, small field of view (FOV) thin-slice T1-weighted (T1W), T2-weighted (T2W), and postcontrast-enhanced (CE) sequences in the orthogonal planes.

Utilization of FS is essential when imaging the orbit, as it allows better tissue discrimination and distinction from intraorbital fat and better assessment of the bone marrow within the bony orbit. Diffusion-weighted imaging (DWI) plays an important role in further characterizing the tissues within and around tumors. Diffusion sequences based on nonecho planar principles and on parallel imaging produce images of better quality with less geometric distortion. Apparent diffusion coefficient (ADC) mapping may help in the differentiation of benign and malignant lesions and may play a role in the grading of malignancies as poorly differentiated versus well differentiated. DWI/ADC can increase the conspicuity of early bone marrow infiltration (e-Fig. 7.1B). Increased ADC values within a diffusion-restricting mass, after the initiation of therapy, usually indicates a favorable response to therapy. Arterial spin labeling (ASL) is a noninvasive method utilizing magnetized protons/water molecules in arterial blood as a tracer (e-Fig. 7.1C). It allows measurement of tissue perfusion and may be helpful in the delineation of high-flow vascular lesions, benign and malignant, and in the potential assessment of treatment response. Both DWI and ASL imaging may help to pinpoint the most aggressive component of an orbital lesion (with restricted diffusion and increased perfusion) and help to target biopsy sites to allow successful tissue sampling. Constructive interference steady-state (CISS) is a heavily T2W volumetric sequence that allows isotropic image reformations in any plane, and exquisite depiction of minute lesions (e-Fig. 7.1D).

Meticulous attention should be paid for the presence of bone erosion and possible intracranial invasion. Tumor extension through the orbital foramina and fissures is better delineated on MRI, whereas erosive bony changes are better depicted on CT. CT and MRI are complimentary imaging techniques in the evaluation of orbital tumors, and, in some cases, both may be indicated for proper and complete evaluation of complex orbital masses. Most protocols for imaging of orbital tumors include brain imaging in the evaluation of potential intracranial extension or in the search for additional lesions. When planned in advance, CT and MRI may also allow for intraoperative navigation, thereby assisting the surgeon with lesion localization in the operating theater. PET imaging and recently introduced hybrid PET/CT systems may be successfully utilized in assessing malignant orbital lesions. Most malignant orbital masses demonstrate increased uptake of $^{18}$F-fluorodeoxyglucose (FDG) (e-Fig. 7.1E). PET/CT is most often helpful in monitoring therapeutic response, particularly if a residual mass remains on MRI after completion of therapy. Residual or recurrent active disease will continue to exhibit increased uptake of FDG, while masses with inactive, scarred tumor will show no uptake on PET. PET/CT can also identify other areas of involvement remote from the orbit, which can be seen with metastases and lymphoma. Metaiodobenzylguanidine (MIBG) scintigraphy is mainly used for the detection of distant neuroblastoma (NB) metastases (e-Fig. 7.1F). Recently introduced optical coherence tomography (OCT), a noninvasive method based on the utilization of near-infrared light, is remarkable for very good tissue penetration and excellent resolution. OCT has recently been applied in the imaging of optic pathway gliomata and retinal lesions.

A combination of imaging findings, along with clinical signs and symptoms, may narrow the differential diagnosis, although the definitive diagnosis is almost always based on histopathologic findings.

The following discussion of orbital pathology imaging is divided into four categories: (1) ocular lesions, (2) optic nerve sheath lesions, (3) primary orbital lesions, and (4) lesions that secondarily involve the orbit.

## Abstract:

This chapter is dedicated to orbital imaging in children. The common and uncommon imaging features of a variety of benign and malignant orbital lesions are described.

Imaging plays an important role in evaluation of orbital disease. To make the correct diagnosis of orbital lesions in children may be challenging. The presenting symptoms (and imaging findings) of different pathologic entities in the orbits may overlap considerably. Non-neoplastic orbital masses may present in a dramatic fashion with visual loss and destructive changes of the orbit, raising concerns for malignancy. At the same time, some malignant tumors of the orbit may closely resemble inflammatory cellulitis both clinically and on imaging. Some of the orbital lesions have a high association with systemic and genetic disorders and, in these cases, represent just the "tip of the iceberg." Diagnosis of the orbital lesion may prompt diligent search of concurrent lesions elsewhere in the body. New imaging modalities and new applications of existing technologies have been developed and successfully implemented in clinical practice. The radiologist should be familiar with modern orbital imaging modalities and should be able to recommend appropriate testing for the ordering clinician.

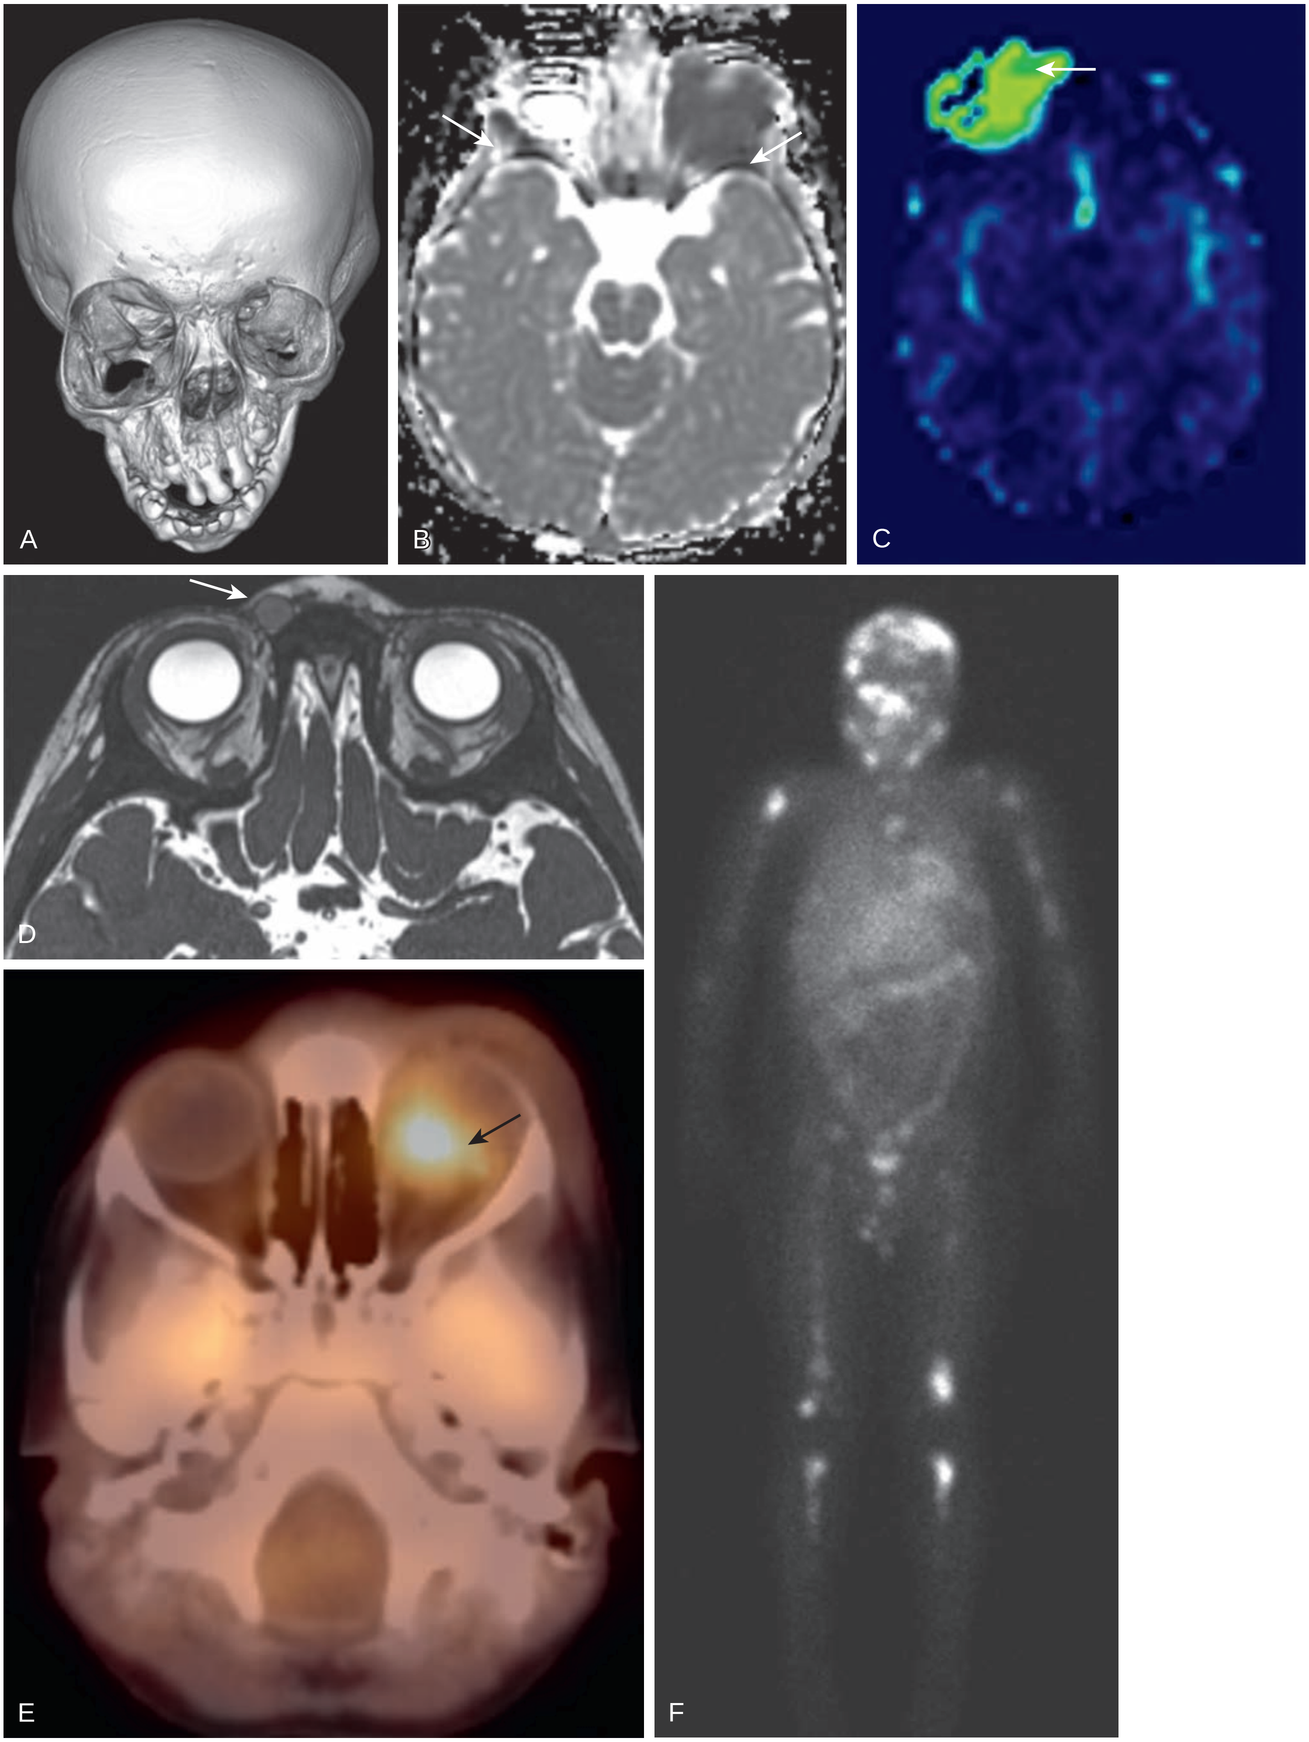
orbital imaging
retinoblastoma
RMS
teratoma
benign orbital lesions
primary orbital malignant tumors
orbital metastases



**e-Figure 7.1. Imaging techniques.** (A) Three-dimensional reconstructed orbital noncontrast CT in a patient with NF1 with sphenoid wing dysplasia and marked enlargement of the right bony orbit. (B) Apparent diffusion coefficient (ADC) mapping in patient with leukemia demonstrates restricted diffusivity within the left orbital chloroma and within bone marrow *(arrows),* indicative of leukemic infiltration. (C) Arterial spin labeling (ASL) image demonstrates a highly vascular lesion *(arrow)* of the right orbit (infantile hemangioma). (D) Axial constructive interference steady-state (CISS) image demonstrates a small epidermoid of the right orbit without osseous involvement *(arrow)*. (E) PET/CT images in a patient with a left orbital mass demonstrates increased uptake of $^{18}$F-fluorodeoxyglucose (FDG) *(arrow)* within the lesion (rhabdomyosarcoma). (F) I-123 Metaiodobenzylguanidine (MIBG) scan in a patient with metastatic NB demonstrates multiple foci of increased tracer uptake in the appendicular skeleton and the skull/face, including within the orbits.

## OCULAR LESIONS

### Retinoblastoma

Retinoblastoma (RB) is the most common intraocular pediatric tumor, arising from retinal cone precursor cells. This tumor typically affects children younger than 4 years of age. Even though RB is considered a congenital type of malignant tumor, it is rarely recognized in neonates. Attempts to detect small fetal ocular lesions in utero in high-risk fetuses have, to date, been unsuccessful. Loss or mutation of RB genes (*RB1* gene located on chromosome 13 band q14) causes absence of RB control protein and subsequent uncontrolled cell division and tumor growth. Two forms of RB—germline (familial or sporadic) and somatic sporadic—differ in their clinical presentations and prognoses. Germline RB may be autosomal dominant (familial), but is more likely to result from a new sporadic mutation. Familial RB usually manifests as bilateral multifocal disease, but in 10% to 15% of patients with unilateral involvement, a germline mutation can be found. Familial RB clinically presents at an earlier age (mean age, 6 months). Patients with heritable *RB1* mutations have increased risk (progressive throughout their lifetime) of the development of other malignancies. This risk is tripled in patients who have undergone radiation therapy. Secondary tumors include osteogenic and soft tissue sarcomas, leukemia, and malignant melanoma. Secondary non-ocular tumors are the leading cause of death in these patients, rather than the primary RB itself. Patients with heritable RB are at a 50% risk for the transmission of the disease to their offspring.

Sporadic RB is usually solitary, unilateral, and associated with postzygotic somatic mutation of the *RB1* gene. This type of RB is usually present in older children (the average age at presentation varies from 13–18 months). Genetic testing is indicated in all patients with RB. Patients with sporadic noninvasive intraocular tumors have an excellent prognosis, with a survival rate greater than 90% in countries with resources to provide modern treatment.

Recent advances in RB treatment have resulted in a new approach to tumor classification. The International Retinoblastoma Classification Grouping is based on expected results of modern chemotherapy regimens and predicted salvage of the globe. There are several variants of this classification, which are based on tumor size, location, and associated seeding (Box 7.1). The tumors range from group A (RB less than 3 mm) to group E (massive destructive RB) (Fig. 7.2A). The pathologic TNM system for RB describes important prognostic information about tumor spread through the sclera into the orbit, invasion of the optic nerve, and presence of distant metastases.

RB may present with a variety of symptoms, the most frequent clinical signs being that of leukocoria (Fig. 7.2B) and strabismus. Leukocoria (or white pupillary reflex) is the most common presenting sign of RB and reflects replacement of vitreous by tumor tissue. Retinal hemorrhage may obscure the visibility of the underlying mass on clinical exam; therefore every unexplained retinal hemorrhage in a young child requires mandatory imaging assessment. Strabismus is usually related to a tumor located within the macula. In contrast to leukocoria, tumors presenting with strabismus as their initial sign are associated with a higher survival rate and a higher chance of salvage of the globe.

Clinical presentations may differ depending on patterns of tumor growth. Endophytic tumors, which arise from internal retinal layers, grow anteriorly into the vitreous, with resultant tendency to vitreous seeding. Exophytic tumors, which arise from external retinal layers grow into the subretinal space and tend to have retinal detachment, earlier choroidal involvement, and increased risk of metastatic spread. Most tumors develop mixed patterns. A rare diffuse form of RB occurs in 2% of cases and manifests by diffuse infiltrative growth within the retina, without noticeable nodular mass, and without intralesional calcifications. This diffuse infiltrative type of RB presents at a later age, with the clinical symptoms at times mimicking an inflammatory process such as pseudoinflammatory glaucoma.

Imaging may reliably distinguish RB from a host of other conditions that also may present with leukocoria (persistent hyperplastic primary vitreous [PHPV], retinopathy of prematurity [ROP], congenital cataract, Coats disease, and acquired toxocariasis). In many RB centers, ocular US has replaced orbital CT for initial disease assessment. Three-dimensional high-frequency US is sufficient for assessment of tumor and calcifications but is less suitable for the evaluation of extraocular spread. RB is readily visible on US as an echogenic irregular retinal mass with focal acoustic shadows. CT is an excellent tool for depicting ocular

**BOX 7.1** International Classification of Retinoblastoma

- Group A—Retinoblastoma < 3 mm
- Group B—Retinoblastoma > 3 mm, macular location, or minor subretinal fluid
- Group C—Retinoblastoma with localized seeds
- Group D—Retinoblastoma with diffuse seeds
- Group E—Massive retinoblastoma necessitating enucleation

Notes: This classification is based on tumor size, location, and associated seeding. This new classification system is designed to simplify grouping and assist in predicting treatment outcomes.

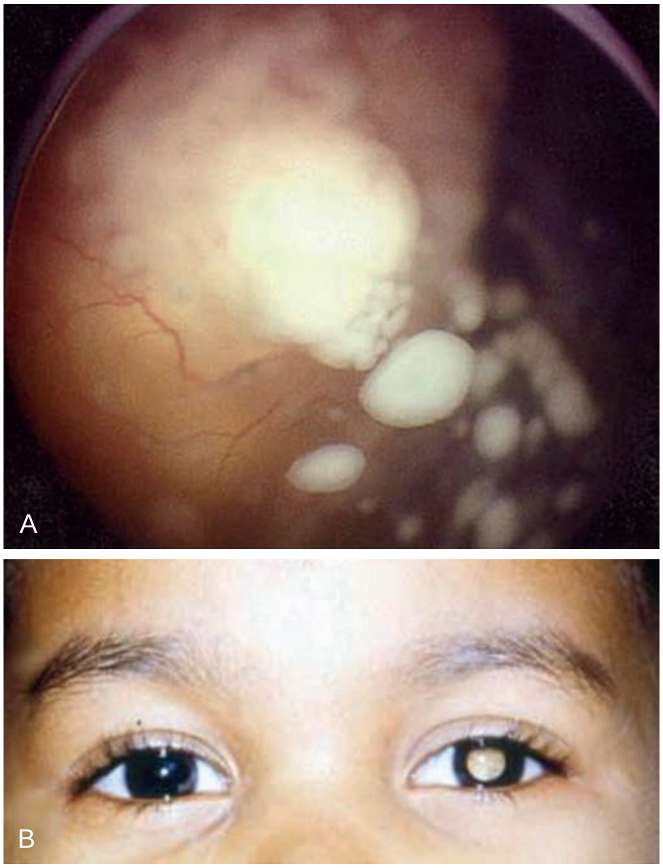


**Figure 7.2. Retinoblastoma (RB).** (A) Ophthalmoscopic examination under anesthesia photo demonstrates multifocal RB (white plaques), indicating group D disease. (B) Clinical photo demonstrates left-sided leukocoria in a patient with RB.

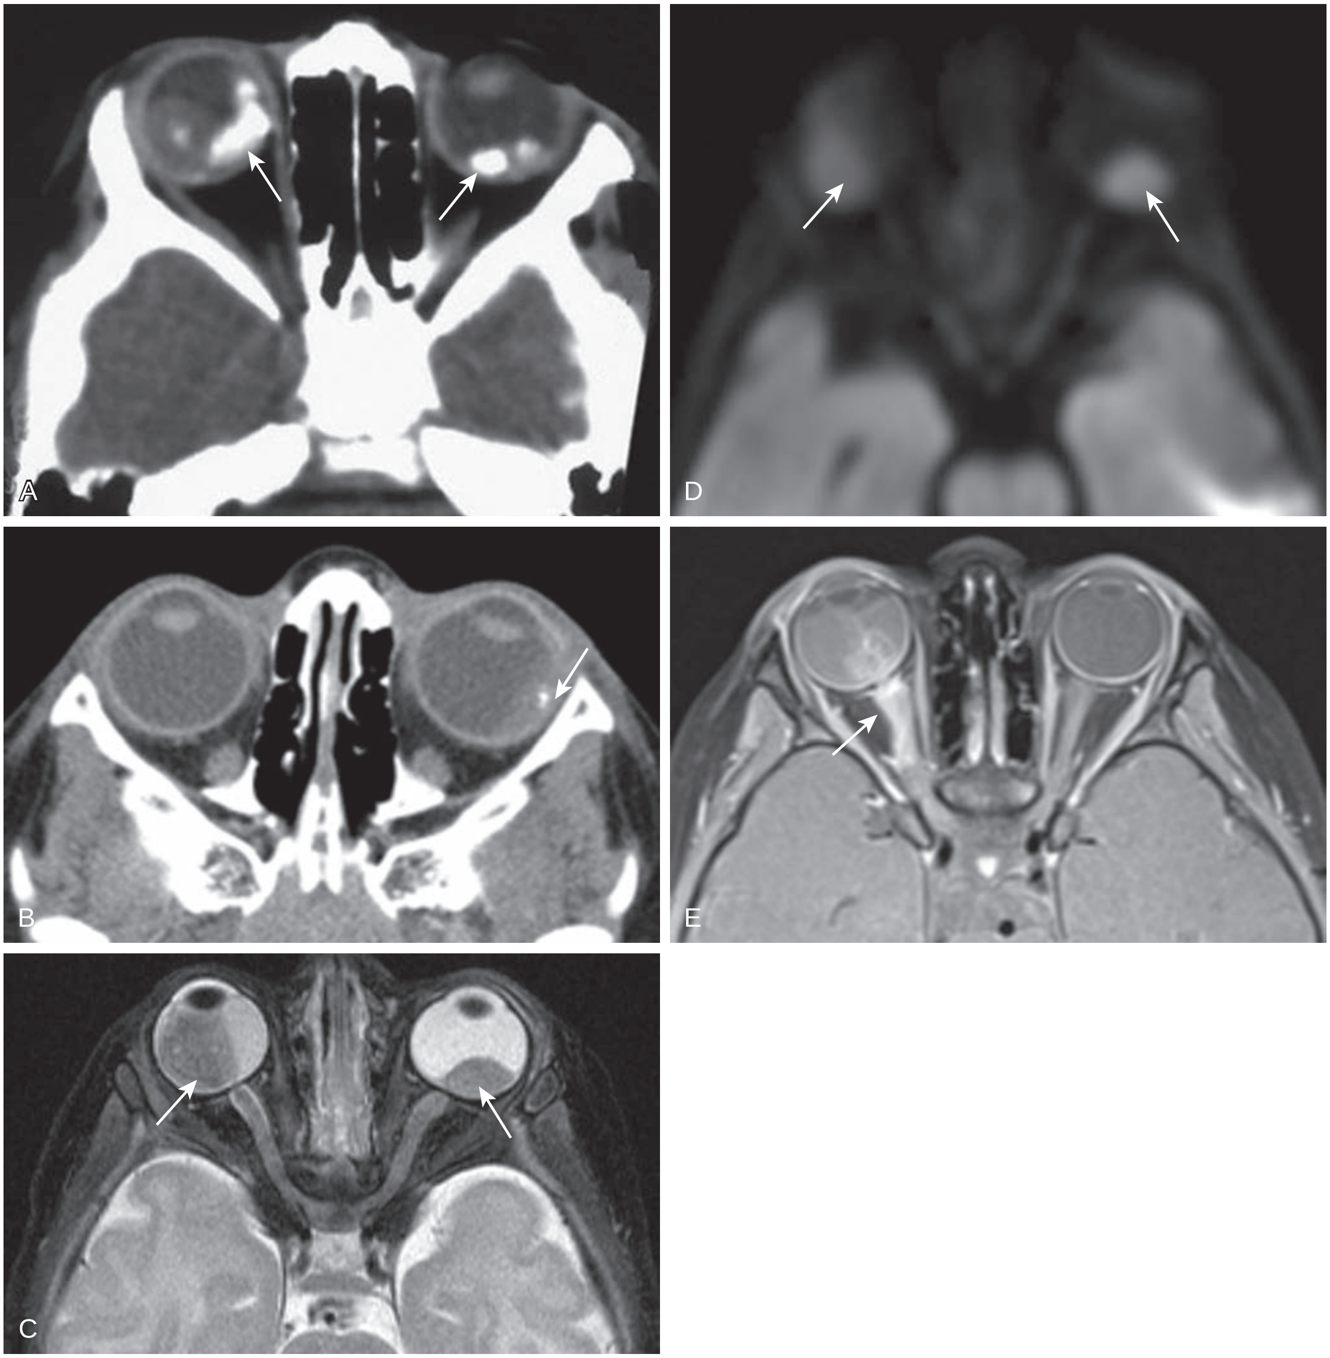

**Figure 7.3. Retinoblastoma in four different patients.** (A) Noncontrast CT image through the orbits demonstrates bilateral, markedly calcified bilateral ocular masses *(arrows)*. (B) Noncontrast CT image in another patient demonstrates a unilateral, left-sided, small calcified mass *(arrow)*. (C) Axial fat-saturated T2-weighted and (D) axial diffusion-weighted imaging (DWI) MR image demonstrate bilateral, lobulated, T2-hypointense, retinal-based masses that exhibit diffusion restriction *(arrows)*. (E) Axial contrast-enhanced fat-saturated T1-weighted MR image demonstrates advanced RB of the right globe involving intraorbital optic nerve *(arrow)*.

calcifications (Figs. 7.3A and B), but its use in RB evaluation has decreased due to concerns of associated radiation risks. MRI has become a relatively quick and convenient modality in the evaluation of RB. A variety of tailored MRI sequences are beneficial in illustrating RB morphology and extension. The malignant, markedly cellular nature of this neoplasm (composed of immature retinoblasts) is confirmed on T2W and DWI sequences (Figs. 7.3C and D), whereas intraocular hemorrhages and calcifications are best depicted on gradient echo (GE) sequences. Essential detection of the aggressive features of advanced disease, such as invasion of the postlaminar optic nerve or anterior chamber, can be best demonstrated on contrast-enhanced sequences, although are best demonstrated histologically on the enucleated specimen. It is essential to thoroughly search for even subtle choroidal thickening, and abnormal uveal or optic nerve enhancement (Fig. 7.3E). At times, retinal detachment and hemorrhage may be indistinct from tumor margin; therefore even the most modern imaging techniques may underestimate the degree of tumor extension.

Advanced disease may present with intraorbital, intracranial tumor extension and/or with distant metastases. Distant osseous metastases from RB can be found in the skull, spine, and long bones, with focal and diffuse involvement of the bones' marrow (e-Figs. 7.4A and B). Leptomeningeal and parenchymal metastases may occur (e-Fig. 7.4C). Whole-body MRI or conventional whole-body bone scan can be performed in the metastatic workup. Orbital or intracranial secondary tumors may often be differentiated from primary advanced metastatic RB lesions by their different imaging features (e-Fig. 7.4D). MRI is a valuable tool for disease monitoring and in the evaluation of treatment response but does not replace an examination under anesthesia by an experienced ophthalmologic oncologist. Vitreous seeding is the leading cause of treatment failure requiring enucleation and is almost below the threshold level of detection of present MRI modern day scanning techniques.

Trilateral (single midline) and quadrilateral (occurrence with a second midline tumor) RB refer to the uncommon association (3%–8%) of bilateral RB (rarely with unilateral RB) with intracranial histologically similar primary intracranial neuroectodermal tumor, most often in the pineal region. Suprasellar location of trilateral tumor has been reported with increased frequency in young patients with the unilateral familial form of RB. These lesions usually present within a year of the initial discovery of the ocular lesions, although, in a minority of cases, may be seen at the time of RB diagnosis (e-Fig. 7.4E). Diligent search for potential associated intracranial tumor should be performed during the first 4 years from the time of diagnosis. The diagnosis of trilateral RB had been associated with a dismal prognosis. However, early detection of intracranial lesions, and aggressive strategies including stem cell transplant, may improve cure rates.

Over the past several decades, standard treatment for RB has evolved from prior methods of surgical enucleation or external radiation. Most RB referral centers are now using alternative therapies that are aimed at eye salvage and avoiding the risks inherent with radiotherapy. These methods include systemic chemotherapy, and intraarterial and intravitreous chemotherapy, along with focal treatments (eye-sparing radiotherapy [local plaque radiation], laser photocoagulation, and cryotherapy) as the primary treatment modality, especially when tumors are small.

## Medulloepithelioma

Medulloepithelioma is another pediatric intraocular tumor that may present with leukocoria. This tumor is histologically distinct from RB and represents a rare embryonal type of neoplasm arising from the nonpigmented epithelial lining of the ciliary body. Some authors consider poorly differentiated medulloepitheliomas to be under the category of primitive neuroectodermal tumor (PNET). Patients are usually diagnosed in the first decade of life (at a mean age of 6 years of age). Clinical signs and imaging features of medulloepithelioma may closely resemble those of an RB. The lesion presents as a nodular enhancing intraocular mass arising from the ciliary body and may reveal internal calcifications (Fig. 7.5) and may restrict on DWI. Retinal detachment is common. Tumors may be benign or malignant, but metastatic disease is uncommon. Medulloepitheliomas have been divided into two types, teratoid and nonteratoid (diktyoma), based on their histology. More complex teratoid medulloepitheliomas are composed of heteroplastic elements, including cartilage, which may have associated calcifications, whereas the nonteratoid diktyoma presents as a well-defined, noncalcified mass, with associated diffuse contrast enhancement.

## Hereditary Ocular Hamartomatosis

Many neurocutaneous disorders (phakomatoses) have typical ocular masses that may or may not be visible with imaging techniques. These lesions represent hereditary hamartomas, which are composed of tissues with limited capacity for proliferation. Examples may be seen in the setting of tuberous sclerosis (TS), neurofibromatosis (NF), as well as Sturge–Weber (SW) and von Hippel–Lindau (VHL) diseases.

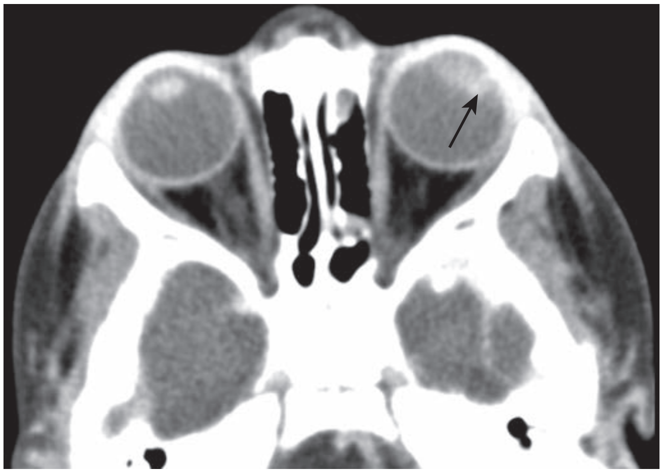

**Figure 7.5. Medulloepithelioma.** Axial contrast-enhanced CT of the orbit in a patient with a known medulloepithelioma demonstrates an amorphous lesion in the anterior chamber of the left globe, with associated punctate calcification, in the region of the ciliary body *(arrow)*.

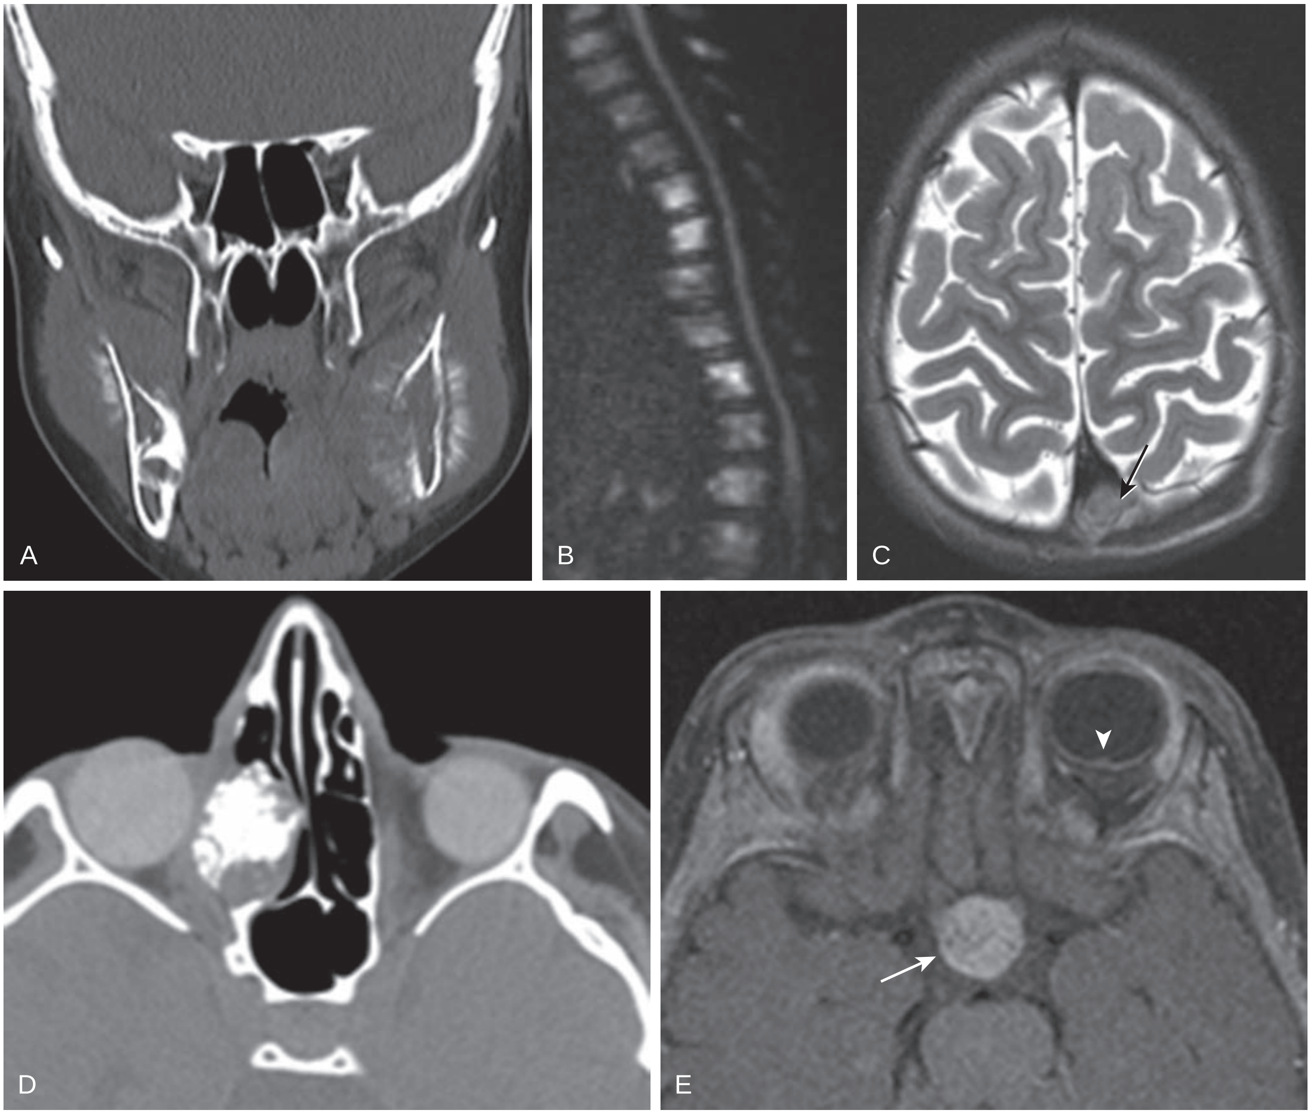
Ocular manifestations of TS include astrocytic hamartoma of the retina and optic disc. These lesions have a typical appearance on ophthalmologic examination; however, they may calcify as patients age and may resemble drusen when located on the optic disc. On high-resolution T2W imaging, hamartomas of TS are detectable as small hypointense nodules within the globe (e-Fig. 7.6A).

Ocular stigmata of NF may present as macrophthalmosis and neuronal hamartomas of the iris, called Lisch nodules, which only occur with NF type 1 (e-Fig. 7.6B). Lisch nodules can only rarely be visualized with imaging.

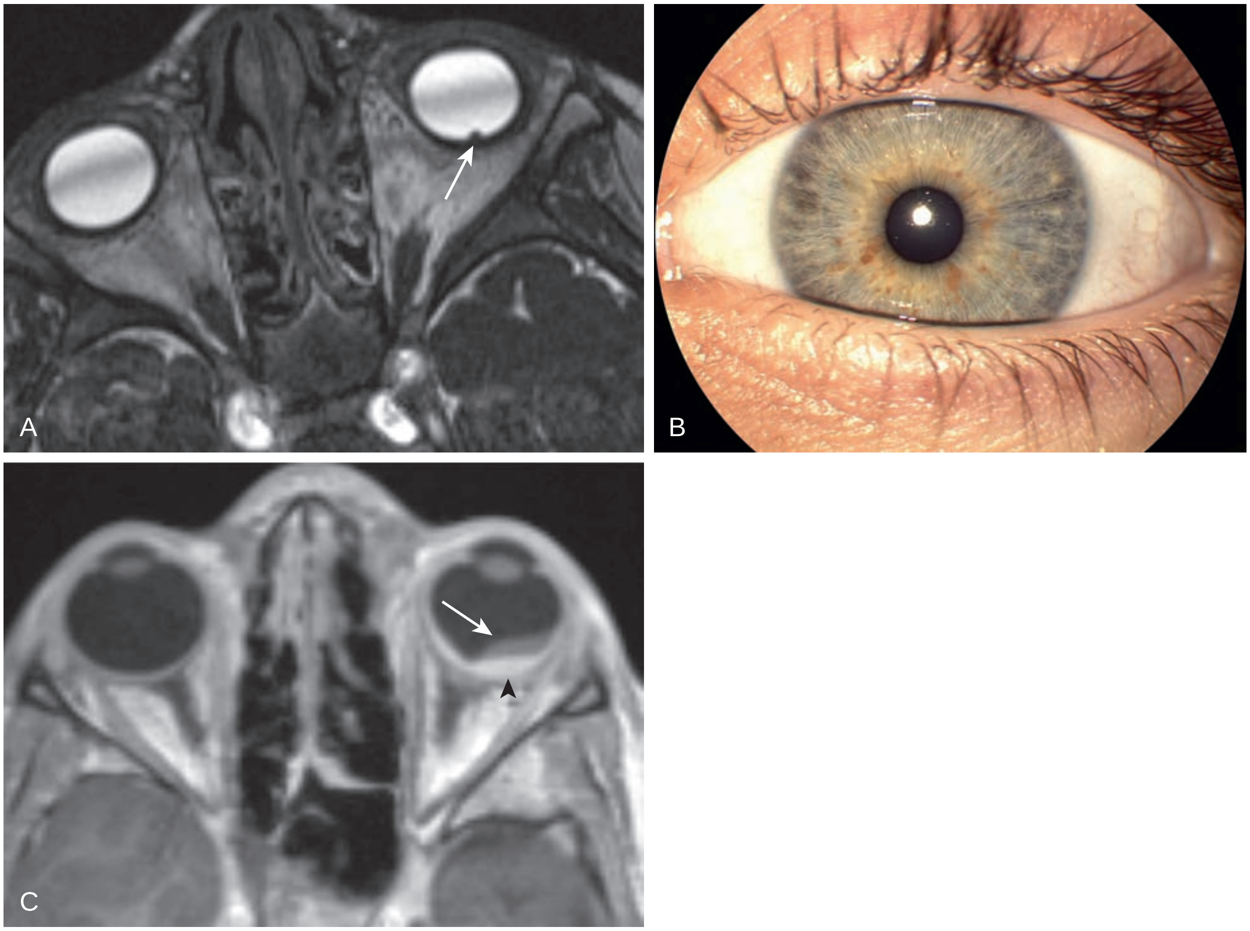
Patients with SW syndrome and VHL disease may have ocular vascular hamartomas (e-Fig. 7.6C). Choroidal vascular malformations (formerly known as hemangioma), typical for SW syndrome, may be diffuse or localized, and can simulate melanoma on fundoscopic exam. These lesions may be differentiated from one another on MRI examination. Choroidal vascular hamartoma demonstrates T1W and T2W hyperintensity, which is opposite to the T2W signal characteristics expected with melanoma (hyperintense T1W signal and a hypointense T2W signal). Ocular manifestations of VHL consist of retinal angiomatosis, which may cause severe complications including retinal detachment and ocular destruction, and usually present later in childhood or in early adulthood (second and third decades of life).

## Drusen

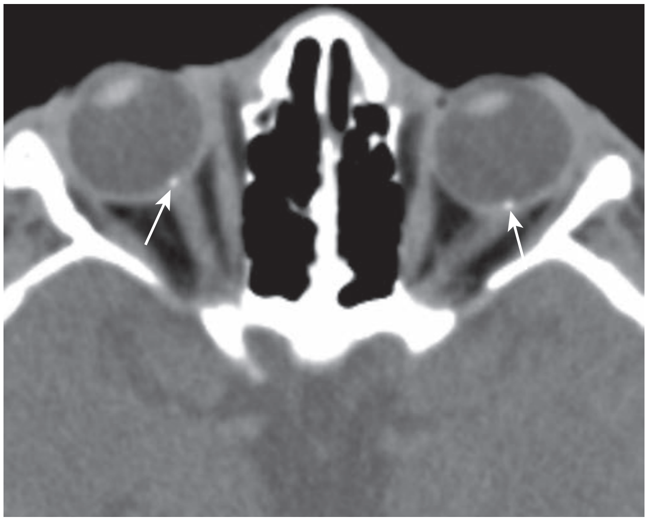
Disc drusen are nonhamartomatous subretinal lesions without astrocytic hyperplasia. They consist of intrapapillary, partially calcified hyaline bodies that form concretions of unknown nature. Drusen are likely the most common etiology for congenital bilateral elevation of the optic nerve discs. Drusen may be detected on fundoscopic evaluation or may be seen as an incidental finding on imaging. In both scenarios, it is important to establish the benign nature of disc elevation so as not to confuse drusen with true papilledema. Drusen may be diagnosed by US, which demonstrates foci of increased echogenicity, or these lesions can be seen on CT as punctuate calcifications within the optic nerve heads (e-Fig. 7.7). MRI demonstrates isolated mild protrusion of the optic discs into the vitreous without perioptic CSF space enlargement or other imaging features of papilledema. Clinically,



**e-Figure 7.4. Metastatic retinoblastoma (RB) in five different patients.** (A) Coronal noncontrast CT of the face demonstrates bilateral speculated/starburst type of periosteal new bone formation. (B) Sagittal diffusion-weighted imaging (DWI) MR image of the spine demonstrates multifocal vertebral restricted diffusion within the bone marrow. (C) Axial fat-saturated T2-weighted MR image through the vertex demonstrates a mass within the left parietal bone marrow, abutting the posterior aspect of the superior sagittal sinus/dura *(arrow)*. (D) Axial noncontrast CT image through the midorbital level in a patient with bilateral ocular prostheses postbilateral enucleation demonstrates a markedly dense (bony-type matrix) mass in the posterior right ethmoid air cells in keeping with a radiation-induced osteosarcoma. (E) Axial contrast-enhanced fat-saturated T1-weighted MR image at the level of the optic chiasm demonstrates rounded avidly enhancing suprasellar mass *(arrow)* in keeping with a trilateral retinoblastoma (RB). Note the tiny lesion at the 6 o'clock position of the left globe *(arrowhead)* in keeping with RB.



**e-Figure 7.6. Hereditary ocular hamartomatosis in three separate patients.** (A) High-resolution T2-weighted (constructive interference steady-state, CISS) MR image of a patient with tuberous sclerosis (TS) demonstrates a T2 hypointense nodule *(arrow)* at the 5 to 6 o'clock position of the left globe, in keeping with an astrocytic hamartoma of the retina. (B) Clinical photo of the iris of a patient with NF1 demonstrates yellowish-brown areas of discoloration at the 5 and 7 o'clock positions, in keeping with Lisch nodules (neuronal hamartomas of the iris). (C) Axial contrast-enhanced T1-weighted MR image at the mid-orbital level in a patient with von Hippel–Landau (VHL) demonstrates a biconvex enhancing mass extending from the 5 to 7 o'clock positions of the left globe in keeping with a retinal angioma *(black arrowhead)*. There is an associated retinal detachment *(white arrow)*.



**e-Figure 7.7. Drusen.** Axial noncontrast CT image of the orbit in a patient with pseudopapilledema demonstrates bilateral mineralization of optic nerve discs *(arrows)*.

drusen are usually asymptomatic and only rarely may be associated with slowly progressive visual loss.

## OPTIC NERVE-SHEATH COMPLEX TUMORS

Optic nerve-sheath complex lesions include neoplasms of the optic nerves (gliomata), optic nerve sheaths (meningiomas), or rare cases of intraconal peripheral primitive neuroectodermal tumors (pPNETs).

### Optic Nerve Glioma

Optic nerve glioma (ONG) is the most common primary neoplasm of the optic nerve in children. ONG may be seen in the setting of NF1 (Fig. 7.8A) or may present as an isolated tumor (nonsyndromic) (Fig. 7.8B). ONGs, which are associated with NF1 (also see Chapter 35), are most often bilateral lesions that may involve the optic nerve and surrounding subarachnoid space, and are remarkable for their low-grade nature and favorable prognosis. Nonsyndromic ONGs are usually unilateral and histologically are either pilocytic or fibrillary astrocytomas. The mortality rate for these tumors is approximately 5% when the tumor involves only the optic nerve, but hypothalamic involvement portends a more ominous prognosis. Despite their benign histology, some series report mortality rates approaching 50%.

### Orbital Meningioma

Orbital meningioma is not a common pediatric lesion, but can be seen in patients in the first decade of life. It differs in many ways from adult meningioma. Meningioma of the orbit may be seen more frequently in children than in adults, and tend to grow more rapidly and to a larger size, undergo malignant changes, and have a greater rate of recurrence. Orbital meningioma may be a primary tumor of the perioptic space (pediatric primary optic nerve sheath meningioma [PPONSM]) (e-Figs. 7.9A and B). PPONSM is the most common form seen in children, possibly due to early presentation with visual symptoms, but may be poorly discernable on imaging in its early stages and may present only with slowly progressive optic nerve atrophy (e-Fig. 7.9C). Perioptic meningioma in children is associated with NF2 with greater incidence than in adults. Detection of PPONSM in a child requires a thorough search for NF or rare meningiomatosis. Meningioma may occur in an extraconal location arising from the orbital wall periosteum. Meningioma may also extend into the orbit from a primary intracranial meningioma (e-Fig. 7.9D) arising from the cavernous sinus, falciform ligament, anterior clinoid process, sphenoid wing, etc. On CT, meningioma may appear as a hyperattenuating/isoattenuating mass containing internal stippled calcifications. It is often associated with bony changes, including hyperostosis, enlargement of the optic canal, and occasionally pneumosinus dilatans (e-Fig. 7.9E).

The tram-track sign, which reflects a thickened optic nerve sheath, is a common imaging feature of perioptic meningioma. MRI is the most accurate imaging modality to diagnose and follow patients with meningioma. Most meningiomas demonstrate isointense/hypointense signal on T1W imaging, variable signal on T2W imaging, as well as avid enhancement on contrast-enhanced sequences, as well as restricted diffusion on DWI due to their increased/dense cellularity (e-Fig. 7.9F). Younger patients may have a higher incidence of intracranial extension.

### Peripheral Primitive Neuroectodermal Tumor

Peripheral primitive neuroectodermal tumor (pPNET) is malignant tumor of neuroepithelial origin that arises outside of the central nervous system. An orbital location is extremely rare, but most reported cases do occur in children. It appears that pPNET is the least aggressive subtype of tumor among other similar small cell tumors, with a favorable prognosis seen after complete tumor resection.

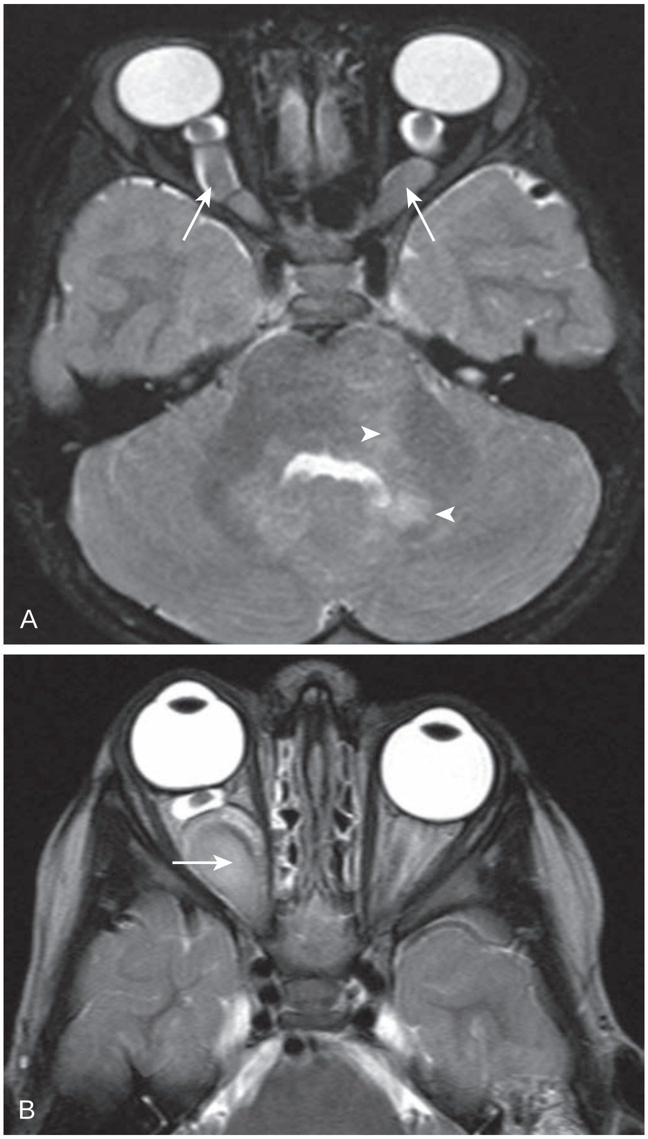


**Figure 7.8. Optic nerve glioma (ONG).** (A) ONG in a patient with neurofibromatosis NF1. Axial fat-saturated T2-weighted MR image of the orbits demonstrates bilaterally symmetrically enlarged and tortuous intracanalicular portions of the optic nerves associated *(arrows)*. Areas of signal abnormality within the cerebellar white matter indicate spongiform changes of NF1 *(arrowheads)*. (B) Isolated right ONG. Axial T2-weighted MR image of the orbits demonstrates an ONG with similar expansion and tortuosity of the optic nerve to the case in A *(arrow)* but with unilateral involvement of the right optic nerve and without additional imaging findings of NF1.

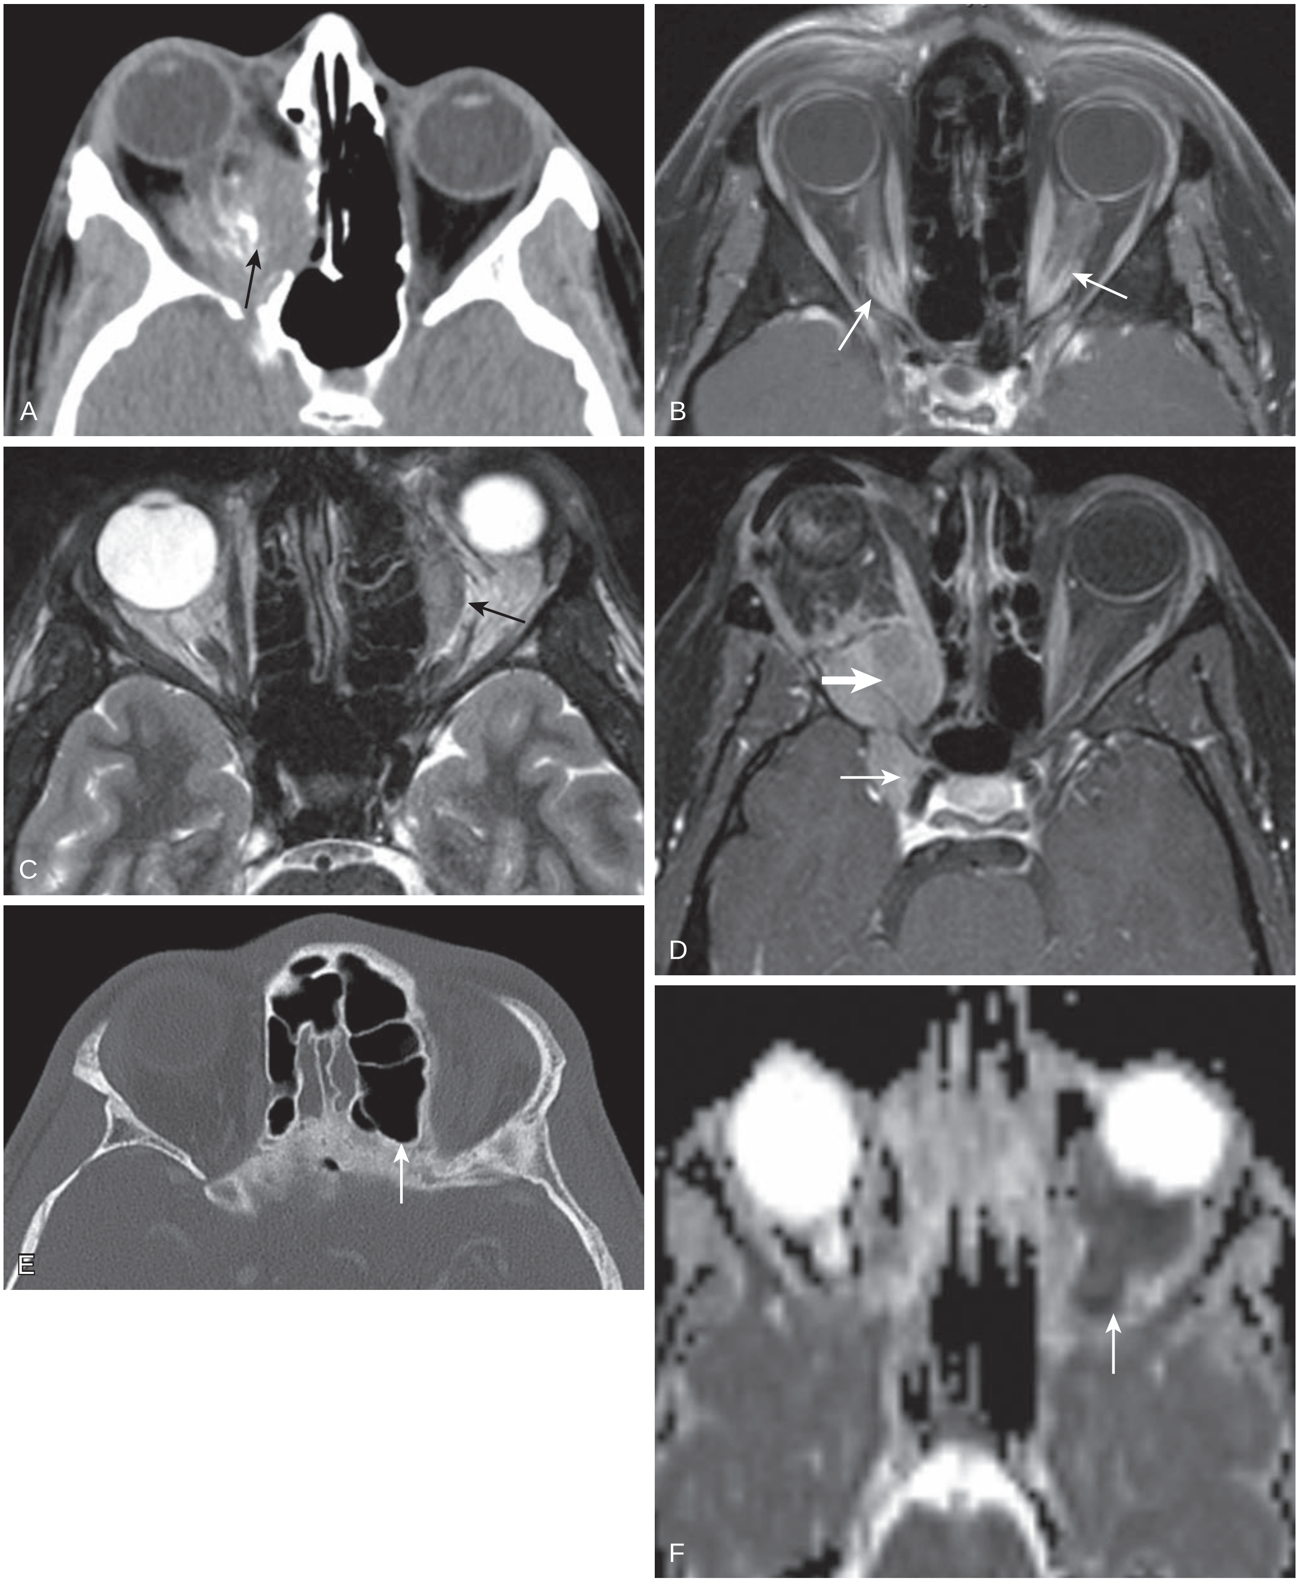
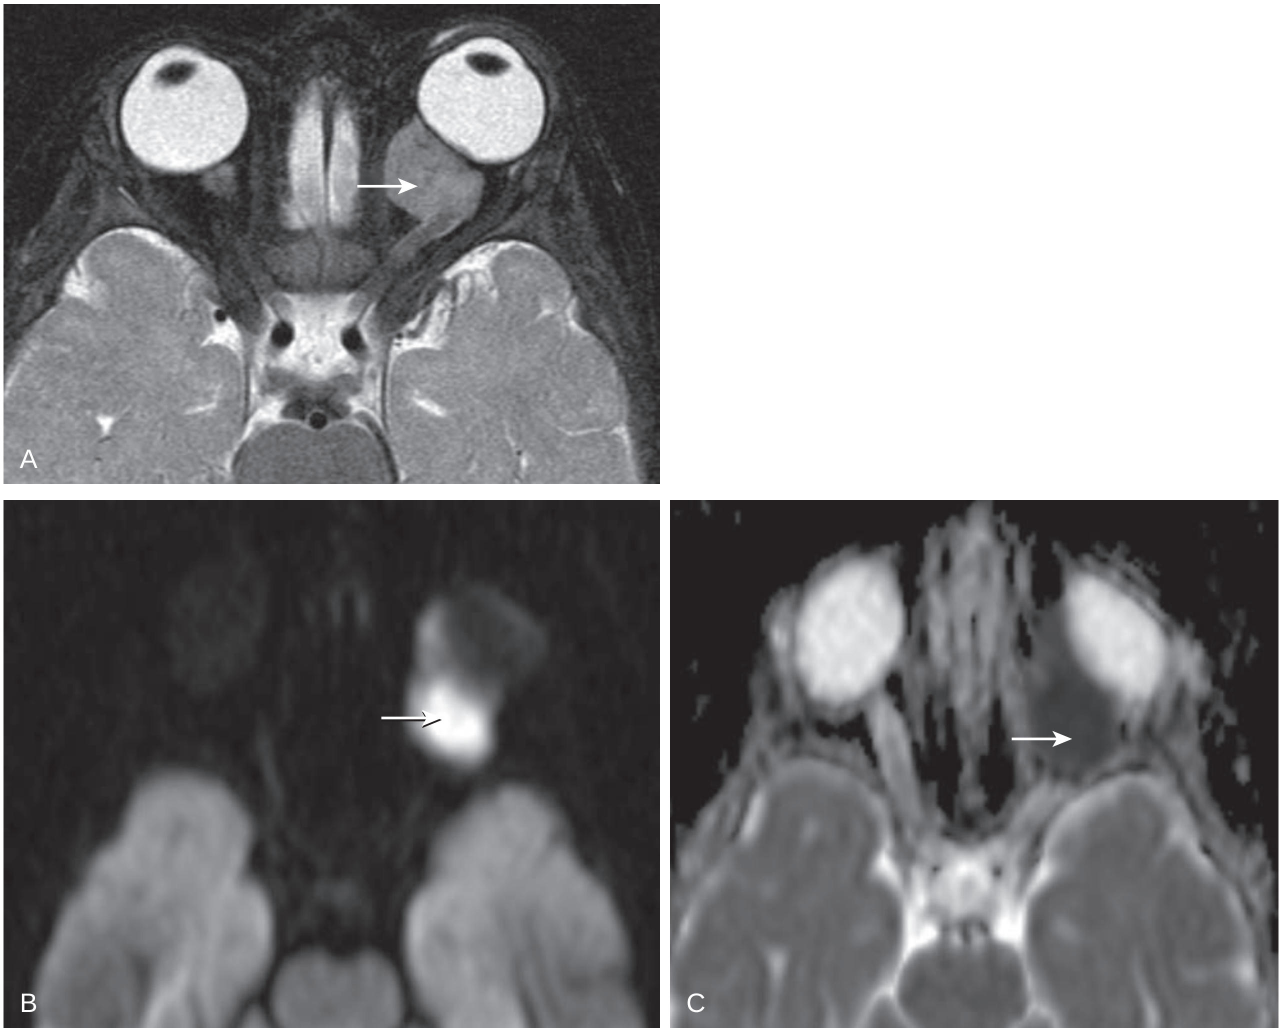
Histopathologically, pPNETs demonstrate small blue round cells, and many authors consider pPNET and extra-osseous Ewing sarcoma at opposite ends of the same spectrum due to their similar histopathologic features and chromosomal rearrangements with translocation (q24; q12). This rare tumor of the orbit presents as an enhancing, T2W hypointense intraconal lesion with restricted diffusion (e-Fig. 7.10). Treatment usually includes globe enucleation, high-dose chemotherapy, and stem cell transplantation. Orbital Ewing sarcoma can also represent metastatic disease from a primary Ewing sarcoma elsewhere in the body.



**e-Figure 7.9. Orbital meningioma/pediatric primary optic nerve sheath meningioma (PPONSM) in six different patients.** (A) Axial contrast-enhanced CT image through the orbits demonstrates dural enhancement along the distal intraorbital and intracanalicular segments of the right optic nerve *(arrow)*. (B) Axial contrast-enhanced fat-saturated T1-weighted MR image through the orbits demonstrates dural enhancement along the distal intraorbital and intracanalicular segments of the bilateral optic nerves *(arrows)*. (C) Axial fat-saturated T2-weighted MR image through the orbits demonstrates optic nerve atrophy on the left *(arrow)*. (D) Axial contrast-enhanced fat-saturated T1-weighted MR image through the orbits demonstrates right-sided orbital extension *(thick arrow)* from a primary intracranial meningioma *(thin arrow)* emanating from the region of the ipsilateral cavernous sinus. (E) Axial contrast-enhanced CT image through the orbits demonstrates focal left ethmoid sinus expansion *(arrow),* known as pneumosinus dilatans. (F) Axial apparent diffusion coefficient (ADC) MR image through the orbits demonstrates left-sided diffusion restriction on ADC image *(arrow)*.



**e-Figure 7.10. Orbital peripheral primitive neuroectodermal tumor (pPNET).** (A) Axial fat-saturated T2-weighted, (B) diffusion-weighted imaging (DWI), and (C) axial apparent diffusion coefficient (ADC) MR images show a left-sided, posteriorly located intraconal T2-hypointense lesion with associated marked restricted diffusion *(arrows)*. The restricted diffusion suggests a densely cellular tumor, a finding almost invariably seen with PNETs.

Primary optic nerve tumors are not the only cause of optic nerve enlargement. Other causes include nonneoplastic conditions such as inflammatory pseudotumor, optic neuritis, and sarcoid granulomata. Enlargement of the optic nerve-sheath complexes/dilated perioptic space may be related to increased intracranial pressure, posttraumatic perineural hematoma, or leukemic infiltration or may represent a normal variant.

## ORBITAL LESIONS

### Vascular Lesions

The Mulliken and Glowacki classification is widely accepted and divides a heterogeneous group of vascular lesions (including orbital vascular pathology) into two types: true neoplasms and nonneoplastic vascular malformations. Vascular malformations are congenital lesions but are often clinically occult at birth and tend to present later in life. However, infantile hemangiomas (IH) become clinically apparent shortly after birth, and some of the rarer orbital vascular tumors may even be diagnosed prenatally.

#### Orbital Hemangioma

Orbital hemangiomas affect 2.5% to 10% of infants and are almost solely benign IH. Orbital IH usually appears shortly after birth, although up to 40% may be visible at birth as only a faint cutaneous mark. IHs are known for their predictable clinical course: proliferation, stabilization, and involution. During the proliferative phase of growth, they will become raised, bulky, and compressible. The most variable stage of involution may occur over a period of years. Some persistent fibro-fatty mass without calcifications or abnormal cutaneous pigmentation may remain even after resolution, mainly leading to cosmetic concerns rather than functional stigmata. Only a small percentage of IH lead to complications, such as ulcerations and bleeding. However, due to their location, early age of presentation, and potential for very rapid growth, orbital IH may cause devastating visual impairment. This complication results from obscuration of light delivery to the eye, especially if the eyelids are involved. Impairment of visual input early in life prevents the formation of the neural pathways necessary for the development of proper vision later in life and can cause deprivation amblyopia ("lazy" eye) and blindness.

IH often appears hyperintense on T2W imaging, avidly takes up gadolinium, and may have multiple flow voids (Figs. 7.11A and B) and increased vascularity seen on perfusion imaging. Although usually nonsyndromic, some hemangiomas are known to occur in conjunction with other systemic abnormalities, such as the PHACES syndrome (**P**osterior fossa malformations, **H**emangiomas, **A**rterial abnormalities, **C**ardiac abnormalities, **E**ye abnormalities, and **S**ternal clefts) (Fig. 7.11C).

The imaging differential diagnosis for hemangioma includes rhabdomyosarcoma (RMS), vascular malformation, infantile fibromatosis, and infantile fibrosarcoma. The vascular features of IH, particularly the flow voids on MRI, help to distinguish IH from these other lesions. RMS may be very vascular and contain flow voids but typically occurs in an older age group and often will demonstrate restricted diffusion on DWI. Most IH are managed conservatively as they tend to resolve on their own. However, tumors that can or do compromise vision are aggressively treated. Therapeutic options include propranolol, systemic or intralesional corticosteroids, interferon, and laser therapy or surgery.

#### Veno-lymphatic Malformation

Veno-lymphatic malformation (VLM) encompasses a group of vascular lesions consisting of vascular channels of varying sizes and histologic types. Some lesions consist primarily of lymphatic vessels and are called lymphatic malformations, whereas others are composed mainly of venous channels and thus are called venous malformations (formerly known as cavernous hemangiomas). Most lesions contain both types of vessels, and their clinical presentation and imaging appearances depend on the prevalence of lymphatic or venous components within the individual lesion. Orbital VLMs are classified into three groups on the basis of anatomic location: superficial, deep, and combined lesions. The superficial lesions mostly contain lymphatic vessels, whereas in contrast, the deep lesions are predominantly or completely venous in nature, reflecting the distribution of vessels within the normal orbit. Superficial lesions may involve the eyelid and/or conjunctiva and tend to present at an early age. Deep lesions in the retrobulbar orbit, although present from birth, may manifest later in life and even in young adulthood. Unlike IH, VLMs grow with the patient and don't involute spontaneously. Clinically, these lesions usually present with progressive or acute painless proptosis, but they may present with restricted movement of the EOMs. Intermittent change in size may occur as a result of recurrent hemorrhage, secondary to fragile vessels within the intervening connective tissue. Imaging features may reflect the dual nature of these vascular malformations, with multicystic lymphatic components often containing blood-fluid levels, while enhancing solid venous components at times will contain phleboliths. Uncomplicated lymphatic components usually do not demonstrate contrast enhancement or at most may show some peripheral enhancement. On US, lymphatic malformations demonstrate cystic spaces filled with blood and fluid, which lack Doppler flow. The CT appearance may be inconclusive, not fully reflecting the internal complexity of the lesion (Fig. 7.12A) at times, with the lesion presenting as a nonspecific soft tissue mass with associated proptosis. MRI fully demonstrates the complex natures of VLMs (Figs. 7.12B and C).

Treatment of orbital vascular lesions remains challenging. In the past, conservative management was preferred if the patient's vision was not jeopardized. Surgical excision is often difficult and associated with numerous complications, in addition to a high rate of recurrence. Intralesional sclerotherapy is an effective method of debulking low-flow malformations, as well as an attractive alternative to surgical resection.

#### Orbital Varix

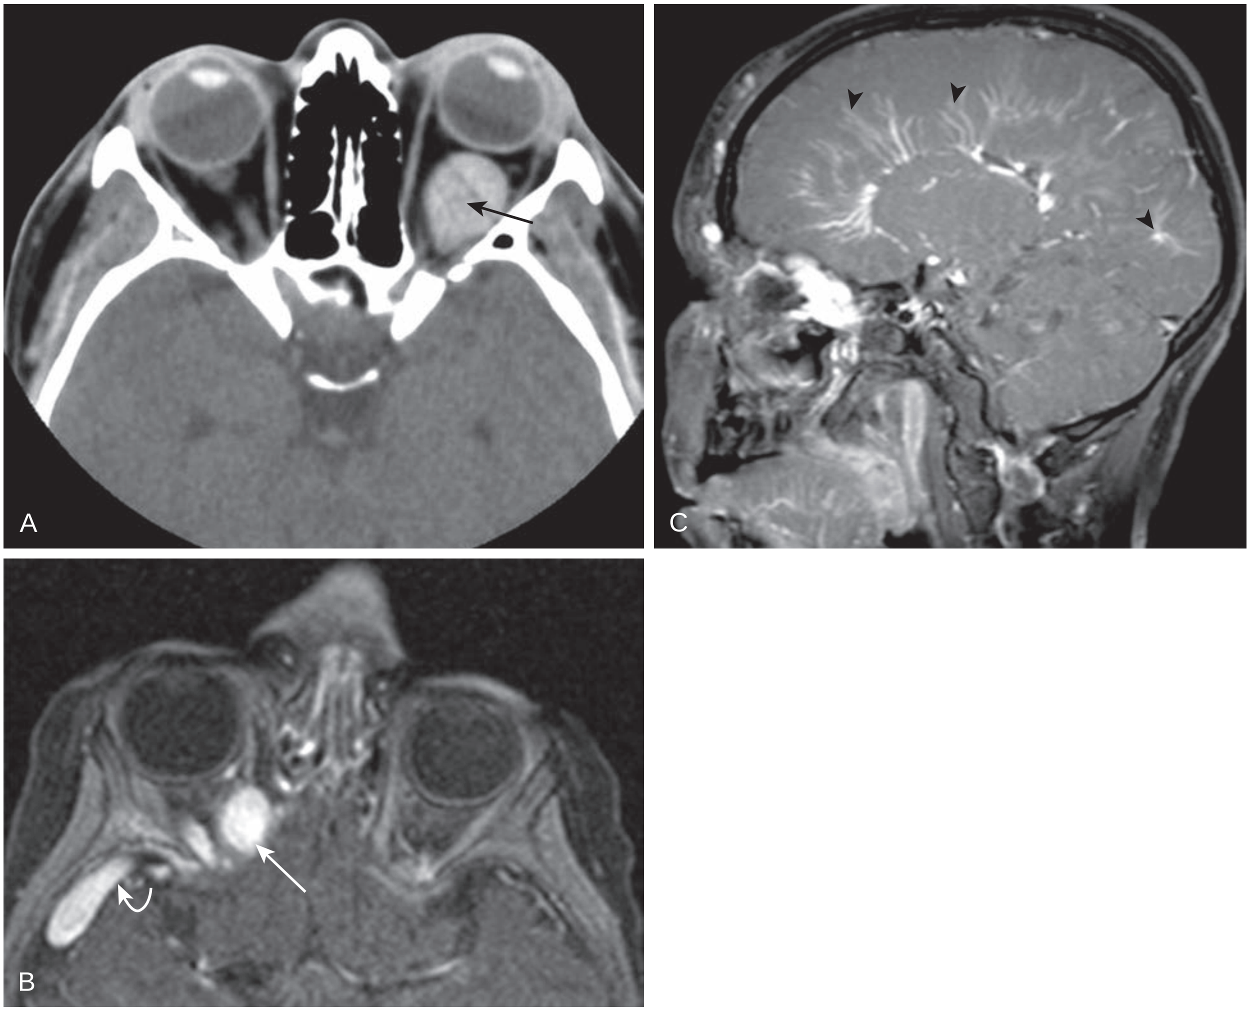
Primary congenital venous varices (uncommonly affecting children) represent distensible venous malformations in the retrobulbar compartment of the orbit or elsewhere in the orbit (e-Figs. 7.13A and B), which may enlarge with dependent posture. The varix may consist of marked enlargement of a single orbital vein or may present as a tangled multivascular mass. Clinically, these lesions may present with globe displacement that may augment and increase in conspicuity when the Valsalva maneuver is performed. At times, these lesions are collapsed and may be undetectable. There is a high association of orbital varices with intracranial developmental venous (e-Fig. 7.13C). Occasionally, these lesions may lead to spontaneous orbital hemorrhage. Secondary varices may occur in the setting of intracranial dural venous thrombosis or arteriovenous shunting.

## NONVASCULAR ORBITAL MASSES

Orbital masses constitute a mixed group of benign and malignant, primary and secondary tumors, inflammatory masses, and congenital cysts.

#### Orbital Schwannomas

Orbital schwannomas in children are very uncommon and mostly seen in association with NF2. Schwannomas of any nerve in and around the orbit may be observed. These are eccentrically located, T1 isointense-hypointense and T2 hyperintense masses, with avid



**e-Figure 7.13. Orbital varix.** (A) Axial contrast-enhanced CT of the orbits in a patient with a left-sided venous varix demonstrates tubular enhancement within the posterior half of left orbit *(arrow),* indicating a vascular lesion that is not specific for, but is suggestive of, a venous varix. (B) Axial contrast-enhanced fat-saturated T1-weighted MR image at midorbital level and (C) sagittal midline contrast-enhanced fat-saturated T1-weighted MR image of the brain in a patient with multiple venous abnormalities. Note the posteromedial left orbital venous varix *(straight arrow)* and associated anterolateral right middle cranial fossa varix (*curved arrow* in B). Note the multiple associated intracranial developmental venous anomalies (DVA) (*arrowheads* in C), a known association of orbital varices with DVAs.

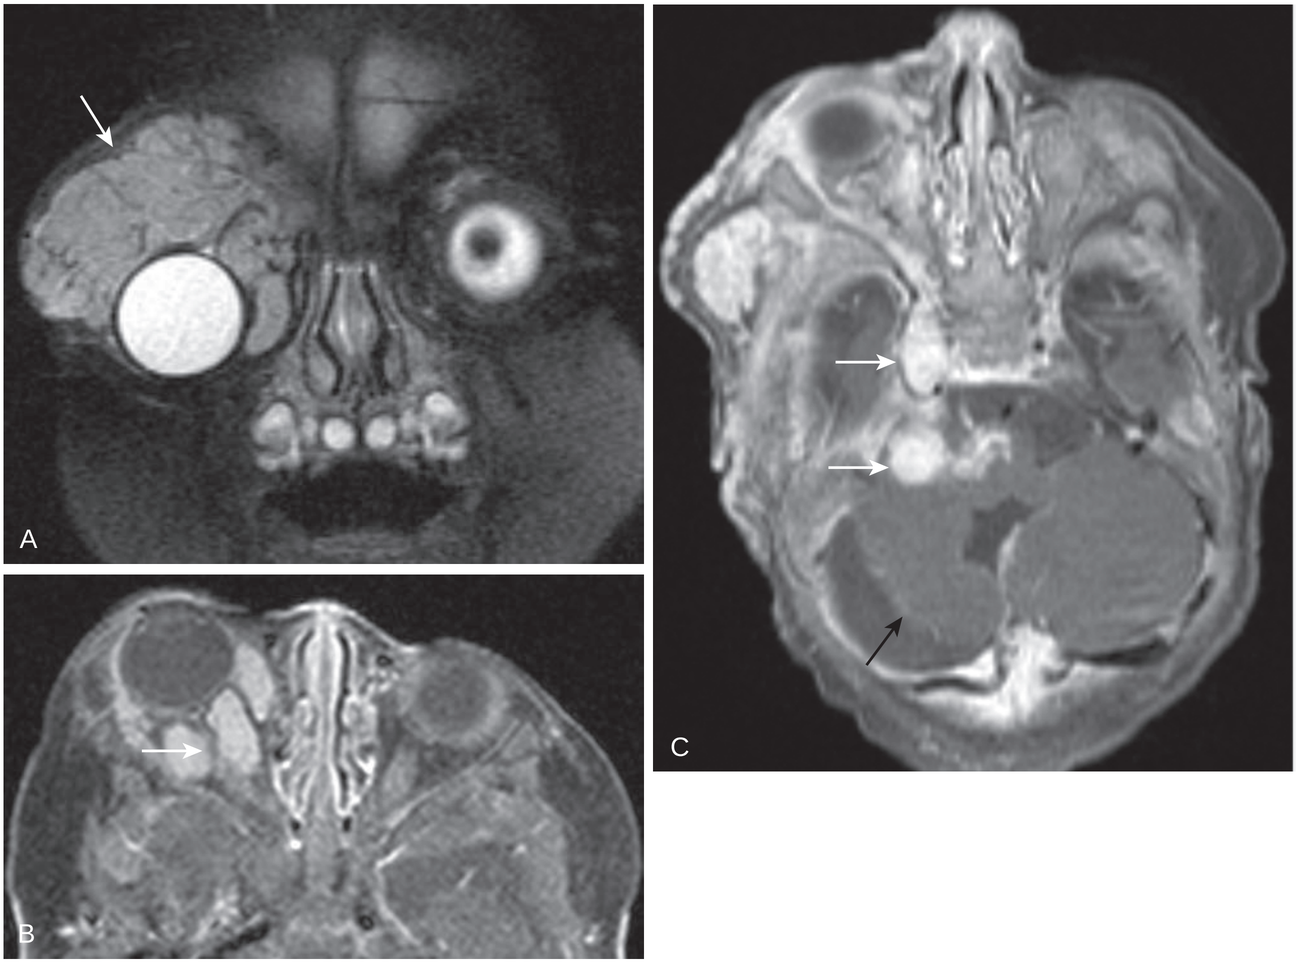


**Figure 7.11. Infantile hemangioma (IH).** (A) Coronal fat-saturated T2-weighted MR image demonstrates a lobulated mass surrounding the right globe in the supraorbital region *(arrow),* with associated flow voids. (B) Axial contrast-enhanced fat-saturated T1-weighted MR image demonstrates intraconal extension of this avidly enhancing lesion *(arrow)*. (C) Axial contrast-enhanced fat-saturated T1-weighted MR image in a patient with PHACES syndrome demonstrates multiple facial and orbital and intracranial IHs *(white arrows)*. In addition, the cerebellum is anomalous *(black arrow),* with diminution of the right cerebellar hemisphere, which is a common association of PHACES.

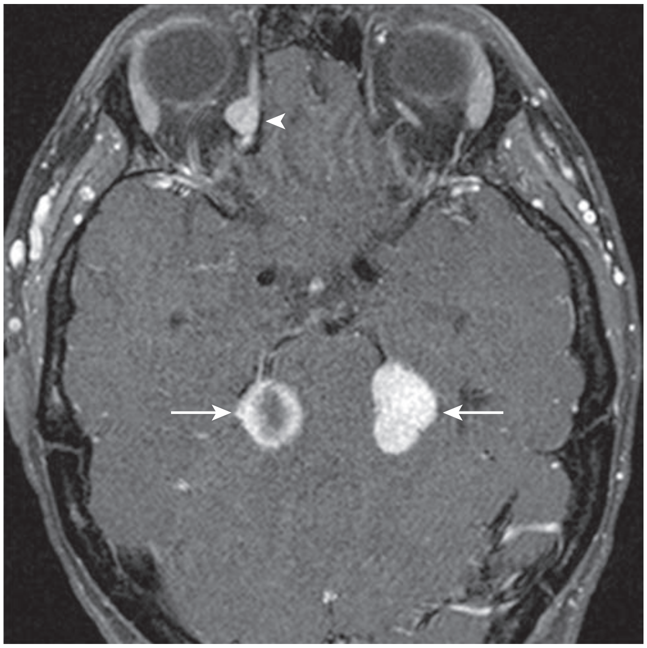
contrast enhancement (e-Fig. 7.14). These tumors are usually much smaller than plexiform neurofibromas. When schwannomas become large, they can undergo internal cystic degeneration.

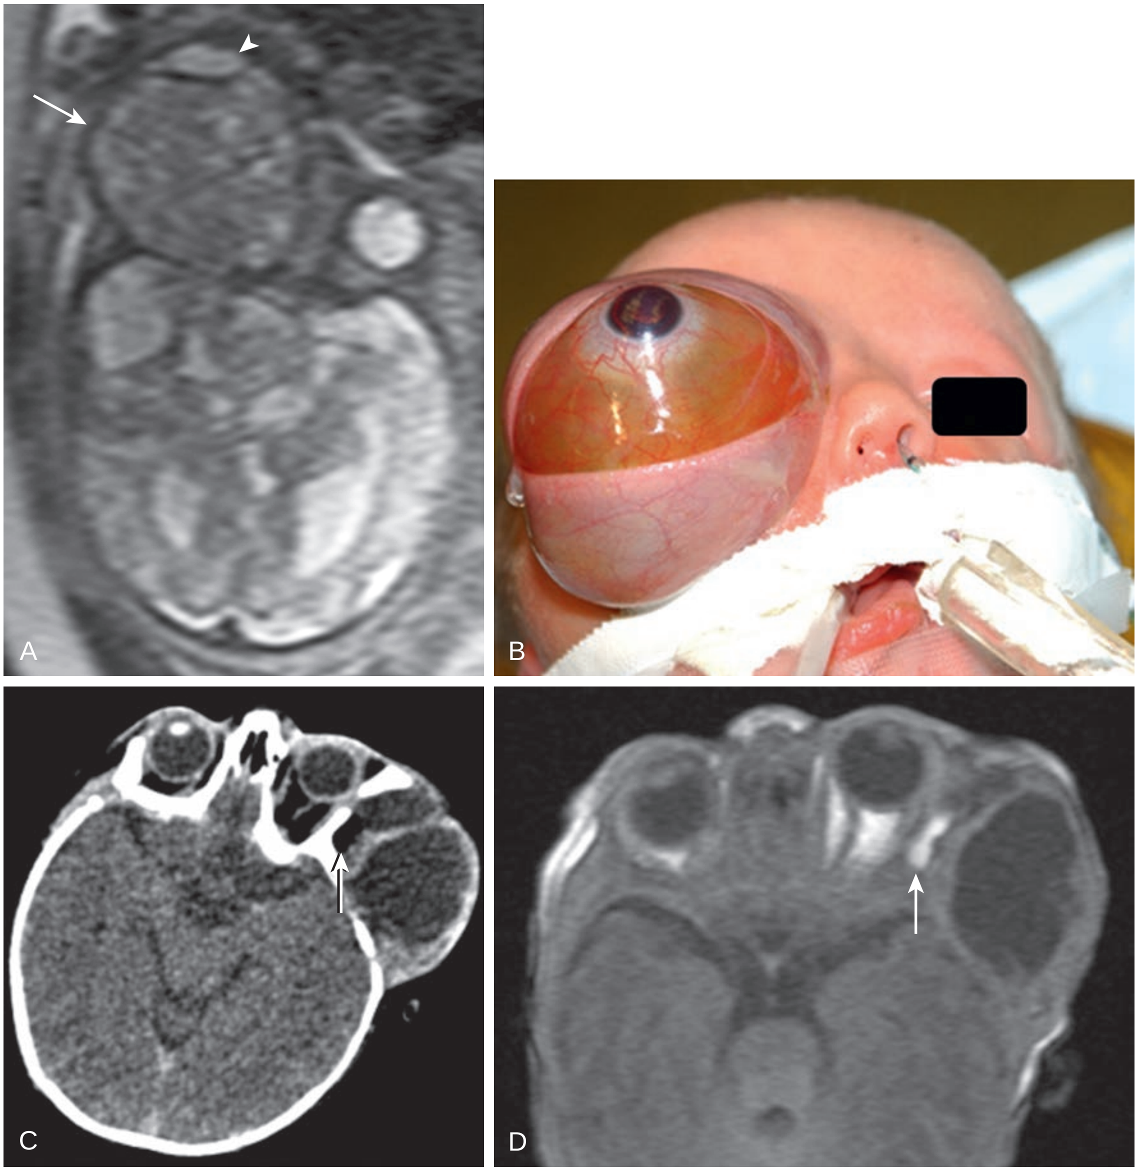
**Orbital Teratoma.** Orbital teratoma is a very rare congenital tumor often diagnosed prenatally with US and fetal MRI (e-Fig. 7.15A). These tumors usually contain multiple tissue types, including fat, calcium, and bone. Teratomas of the orbit are most often benign and well differentiated; however, they may lead to significant proptosis when located at the orbital apex (e-Fig. 7.15B). The imaging appearance of a teratoma is quite distinctive; it presents as a very large multicystic mass with enhancing solid component and calcification. Presence of intralesional fat is almost pathognomonic (e-Figs. 7.15C and D).

**Orbital Rhabdomyosarcoma.** RMS is the most common malignant soft tissue tumor in childhood, and the orbits and paranasal sinuses are the second most common site of occurrence. The embryonal type is the most common variety of orbital RMS; the alveolar and pleomorphic varieties occur rarely. The mean age at presentation is 6 years. RMS was previously thought to arise from skeletal muscle but now is generally believed to originate from pluripotential mesenchymal cells that have the capacity to differentiate into skeletal muscle. RMS is an aggressive, fast-growing tumor that most often manifests with rapidly progressive proptosis or globe displacement and should be considered in the differential diagnosis in any child with this clinical presentation. Other common signs and symptoms include conjunctival and palpebral swelling, which may erroneously suggest the clinical diagnosis of orbital cellulitis, and may lead to confusion with respect to patient presentation and imaging appearance.

Most tumors are extraconal in location, but intraconal components may also be present. The most typical location for the common embryonal is in the superonasal quadrant. The less prevalent alveolar form more often affects the inferior orbit. RMS grows rapidly and behaves aggressively, frequently invading the adjacent bones and soft tissues, although advanced disease is less often encountered today due to greater awareness of the diagnosis. Both CT and MRI play important roles in the preoperative evaluation, staging, and follow-up of orbital RMS tumors. On T2W imaging, these lesions may appear as hypointense, isointense, and even hyperintense with respect to EOMs (Figs. 7.16A and B). Due to the high degree of RMS cellularity, the lesions may be predominantly hyperattenuating on CT and exhibit restricted



**e-Figure 7.14. Orbital schwannoma.** Axial contrast-enhanced fat-saturated T1-weighted MR image of the orbits in a patient with NF2 and multiple schwannomas. Note the avidly enhancing ovoid mass in the medial left orbit near its roof *(arrowhead),* in keeping with a V1 branch schwannoma of left CN V. Note also the bilateral asymmetric (left greater than right) similar appearing lesions around the lateral margins of the brainstem/cerebral peduncles in keeping with additional intracranial schwannomas.



[redacted]

**e-Figure 7.15. Orbital teratoma in two different patients.** (A) Axial HASTE fetal MR image of the orbits demonstrates a very large, slightly T2-hypointense lesion in the region of the left orbit *(arrow),* with associated marked anterior/ventral displacement of the globe *(arrowhead),* in keeping with a teratoma. (B) Clinical photo of the same patient postdelivery demonstrates a markedly enlarged bulbous appearing right globe (buphthalmos). (C) Axial noncontrast CT and D, axial T1-weighted MR images of the orbits in another patient demonstrate a large soft tissue mass lateral to the left orbit with a visible fatty component *(arrow)* (low attenuating on CT and hyperintense on T1W imaging).

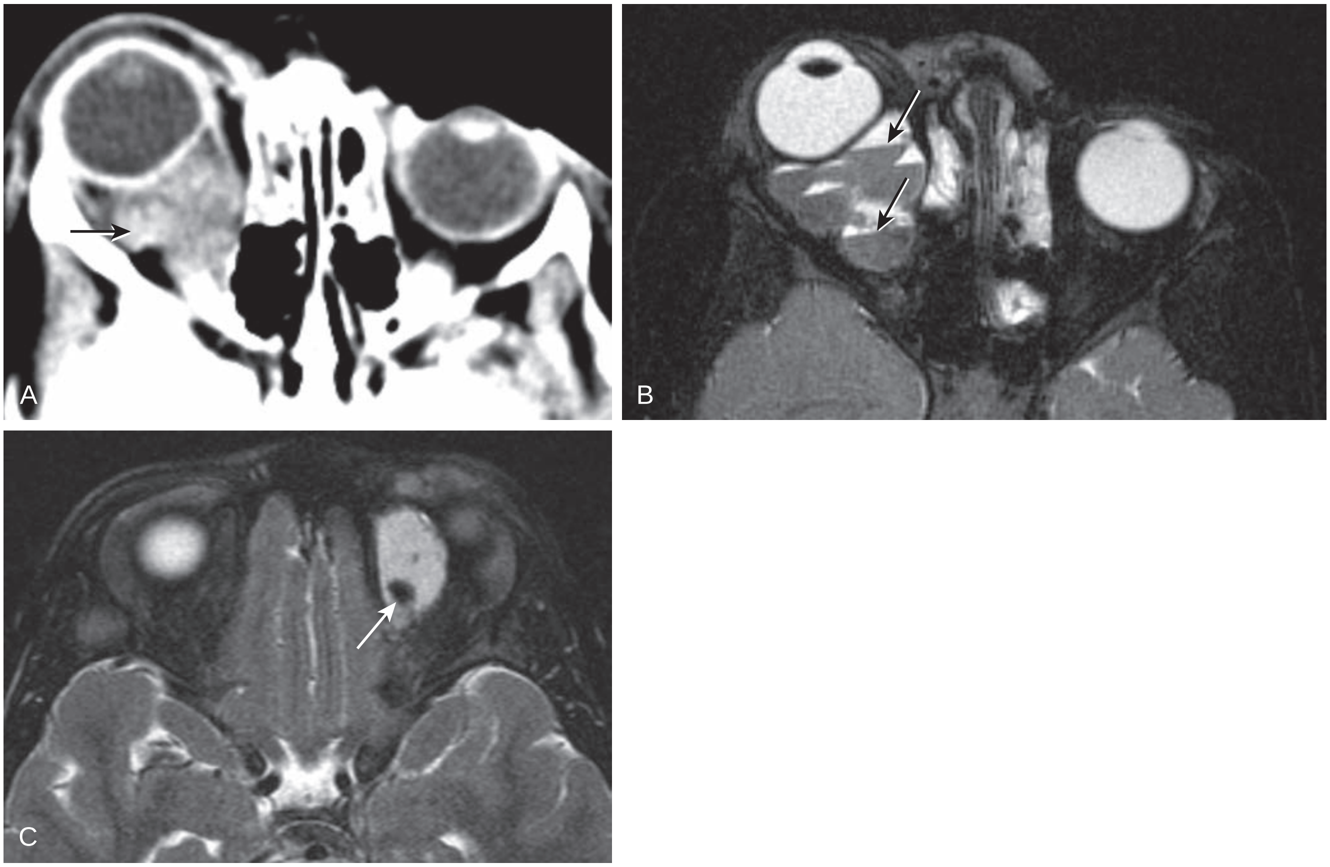


**Figure 7.12. Veno-lymphatic malformation (VLM) in two different patients.** (A) Axial contrast-enhanced CT image and (B) axial fat-saturated T2-weighted MR image of the orbits demonstrates a right-sided intraconal soft tissue mass posterior to the right globe (*arrow* in A), which is associated with anterior displacement of the right globe. Although the finding on CT is nonspecific, the multiple fluid-fluid levels on MRI (*arrows* in B) help to clarify the diagnosis. (C) Axial fat-saturated T2-weighted MR image of the orbits in another patient with a venous predominant VLM demonstrates an ovoid T2 hypointense lesion near the roof of the left orbit secondary to a phlebolith *(arrow)*.

diffusion on DWI. On T1W contrast-enhanced MR images, RMS will have moderate to marked enhancement, and, in some cases, a component of highly vascular internal tissue that may mimic the appearance of a hemangioma (Fig. 7.16C). Meticulous search is required for assessment of local invasion into the paranasal sinuses, as well as for intracranial spread via the orbital fissures, with potential spread into the cavernous sinuses, and, at times, into the middle cranial fossa (Fig. 7.16D). Favorable prognostic factors include lack of distant metastases, a primary site within the orbit, disease confined to the orbit, gross total surgical resection, a patient age younger than 10 years, an embryonal histologic type, and a tumor size of 5 cm or less. The most important prognostic factor is response to therapy, which is assessed with follow-up imaging. Advances in chemotherapy and radiotherapy have improved survival rates of patients with orbital RMS. This improved survival rate has allowed observation of the late effects of radiotherapy on both facial growth (e.g., bony hypoplasia/growth arrest of the orbit and facial asymmetry) and visual function (e.g., cataract, keratopathy, and retinopathy).

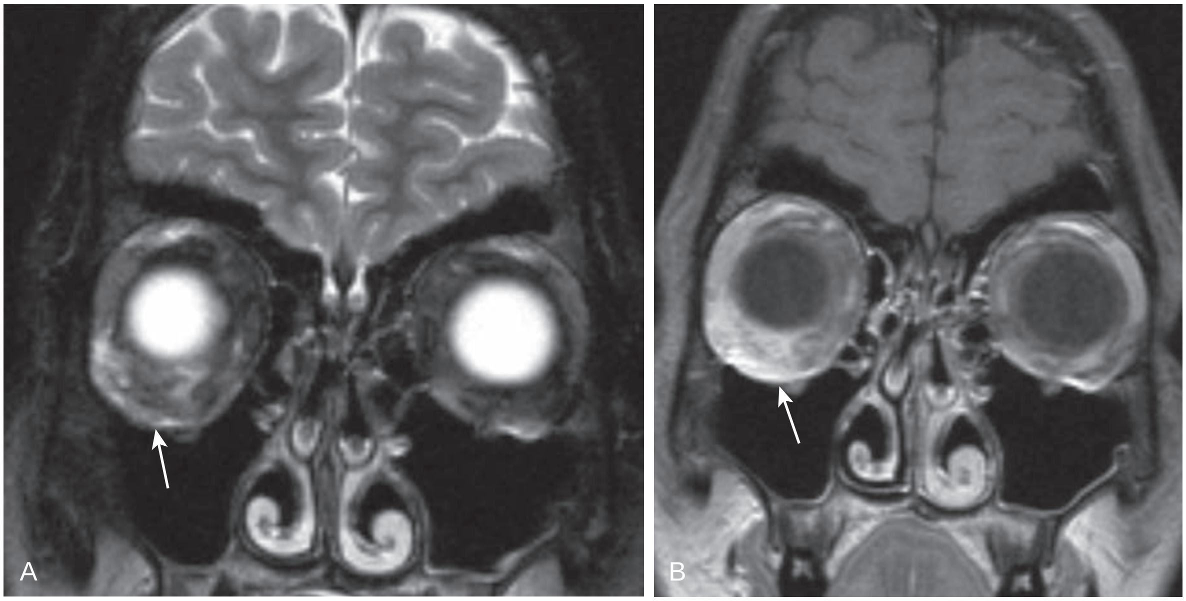
## Fibrous Tumors

Solitary fibrous tumor (SFT) is an uncommon spindle cell tumor of mesenchymal origin. This tumor mainly occurs in the visceral cavities; an orbital location is infrequent. Presently, SFT is considered to be in the same spectrum of neoplasms as hemangiopericytoma; it may be benign or more aggressive depending on the number of mitoses present pathologically. Orbital hemangiopericytoma and some cases previously regarded as fibrous histiocytoma, giant cell angiofibroma of the orbit, and SFT, have overlapping morphologic and immunohistochemical features and should be designated as SFT. Orbital SFT demonstrates great variability and may present as a slow-growing, well-circumscribed enhancing mass, or may resemble an inflammatory lesion (e-Fig. 7.17), and hence the imaging features are nonspecific. Painless proptosis is a common clinical sign. Aggressive bony or intracranial invasion is not typical for SFT. The diagnosis mainly relies on immunohistochemistry confirmation.

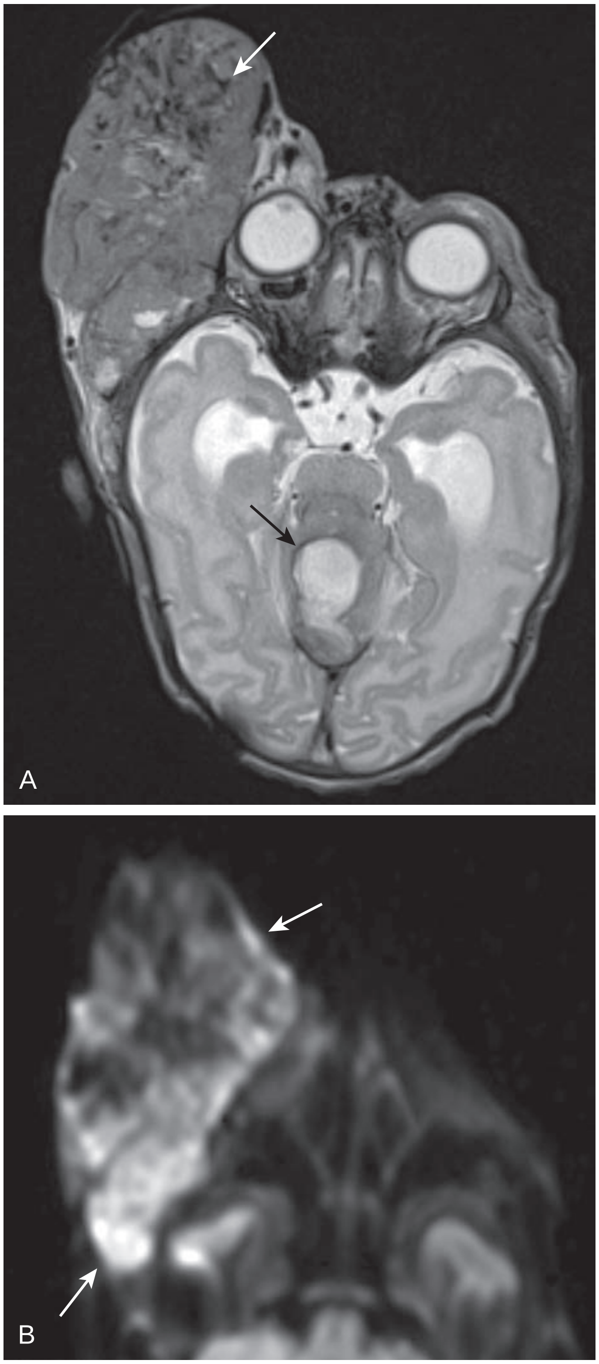
The spectrum of other orbital fibrous tumors in children may be exemplified by benign fibromatosis and fibrosarcoma. Differentiation of these lesions may be very difficult due to marked overlap of imaging features, and at times, even their histologic appearances. Some authors believe that the only reliable diagnostic criterion for malignancy in infants is the presence of metastasis.

## Rhabdoid Tumors

Rhabdoid tumors of the orbital region occur in young children with a mean age of 15 months at presentation. This lesion can be highly vascular (e-Fig. 7.18 A) and may mimic more benign lesions such as IH. These rare malignant tumors are highly aggressive and lethal, with death occurring within 12 months of presentation.



**e-Figure 7.17. Solitary fibrous tumor (SFT).** (A) Coronal fat-saturated T2-weighted and (B) coronal contrast-enhanced fat-saturated T1-weighted MR images demonstrate a fairly T2 dark (suggesting its fibrous nature) and contrast avid lesion in the lower orbital region on the right *(arrows)*.



**e-Figure 7.18. Congenital rhabdoid tumor.** (A) Axial fat-saturated T2-weighted and (B) axial diffusion-weighted imaging MR images demonstrate a right-sided lobulated, heterogeneous, extremely vascular mass along the right lateral orbit, with numerous intratumoral flow voids indicating marked vascularity (*white arrow* in A). Note the area of hemorrhage (*black arrow* in A) in the posterior fossa, secondary to Kasabach-Merritt syndrome, due to platelet sequestration by the large orbital vascular mass. In addition, the lesion demonstrates restricted diffusion (*arrows* in B).

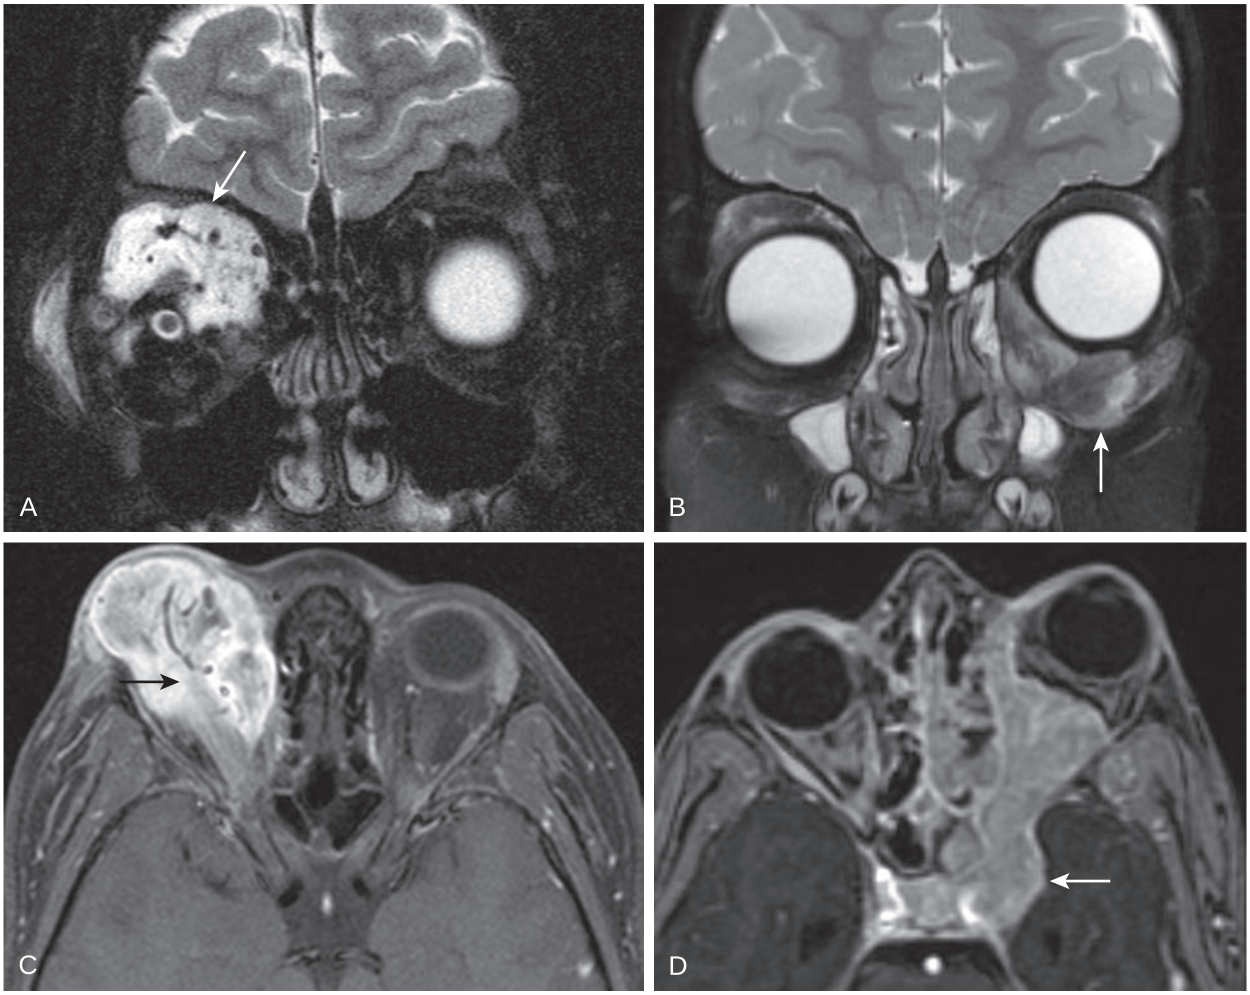


**Figure 7.16. Orbital rhabdomyosarcoma (RMS).** Coronal fat-saturated T2-weighted MR images (A and B) in two separate patients demonstrates the T2 hyperintense nature of these lesions *(arrows),* large, mainly extraconal lesion with flow voids seen in A, and more bland appearing along the lower left orbital region in B. (C) Axial contrast-enhanced fat-saturated T1-weighted MR image of the same patient as in A demonstrates an avidly enhancing tumor, with multiple flow voids *(arrow)* indicative of the highly vascular nature of this lesion. (D) Axial contrast-enhanced fat-saturated T1-weighted MR image in a different patient with left-sided orbital RMS demonstrates posterior intracranial extension of the tumor along the posterior orbital fissures/foramina into the ipsilateral middle cranial fossa, to involve the cavernous sinus *(arrow)*.

Their dense cellularity/cell packing produces restricted diffusion on DWI (e-Fig. 7.18 B).

## Inclusion Cysts (Epidermoid/Dermoid)

Dermoid and epidermoid cysts are congenital developmental ectodermal inclusion cysts, constituting up to 5% of all orbital masses. Inclusion cysts occur commonly around the orbit, especially around the region of sutures (frontozygomatic or frontolacrimal). Epidermoid cysts contain epithelial elements and cholesterol crystals and may be bounded by a thin capsule, whereas dermoid cysts may contain dermal appendages, including hair and sebaceous glands, and are surrounded by a fibrous capsule. Inclusion cysts usually present as a painless subcutaneous nodule, and they mainly cause cosmetic deformity, but later in life they may grow, partially rupture, and become inflamed and symptomatic. Osseous remodeling may occur but without associated periosteal reaction.

These lesions are well-demarcated, cystic-appearing, extraconal masses with differing degrees of fatty content. Uncomplicated superficial dermoid cysts are well depicted as low attenuating on orbital CT, without the need for intravenous contrast, as these lesions (if uninfected) should not enhance (Fig. 7.19A). MRI is superior for more detailed depiction of any possible intracranial connection and for the presence of a potential sinus tract. These lesions are hyperintense on T1W imaging due to their fatty content. Mild rim enhancement may occasionally be seen and is considered normal, whereas the appearance of a more irregular type of enhancement is suggestive of prior rupture with a secondary inflammatory reaction. Epidermoid cysts are hyperintense on T2W imaging (Fig. 7.19B) and fluid attenuated inversion recovery (FLAIR) sequences and exhibit restricted diffusion on DWI (Fig. 7.19C).

## Orbital Pseudotumor (Idiopathic Orbital Inflammation)

Orbital pseudotumor represents a noninfectious infiltration of the orbital structures by lymphocytes and plasma cells, usually without associated osseous involvement. The etiology remains

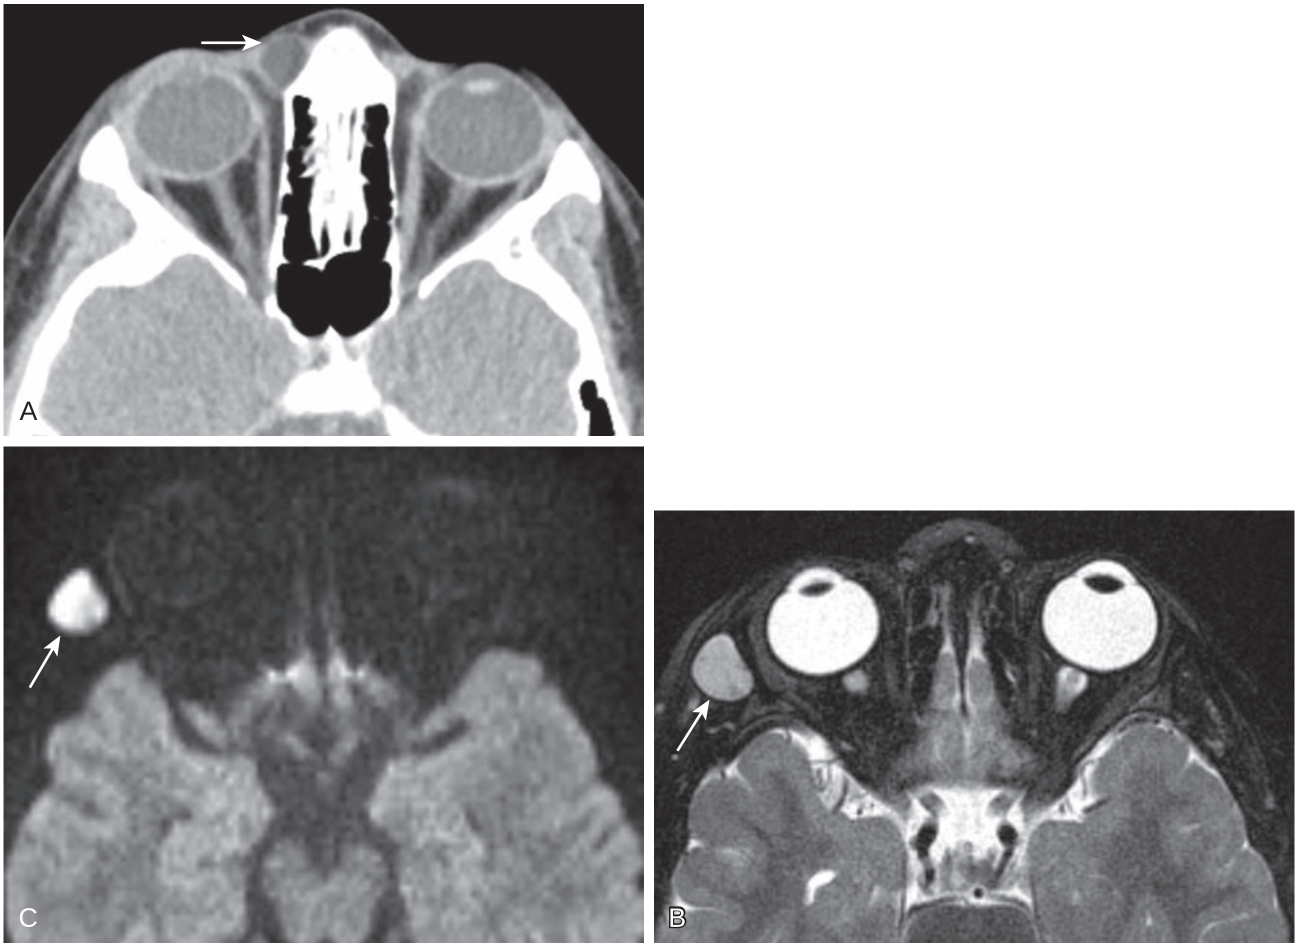

**Figure 7.19. Orbital epidermoid in two different patients.** (A) Axial noncontrast CT of the orbits demonstrates an ovoid area of low-attenuation (fat) within the anterior soft tissues medial to the right globe *(arrow)*. (B) Axial fat-saturated T2-weighted and (C) axial diffusion-weighted imaging MR images demonstrate a similar lesion along the right lateral orbital soft tissues *(arrows),* which is bright on T2-weighted imaging but exhibits restricted diffusion on DWI, as is typically seen with epidermoid cysts.

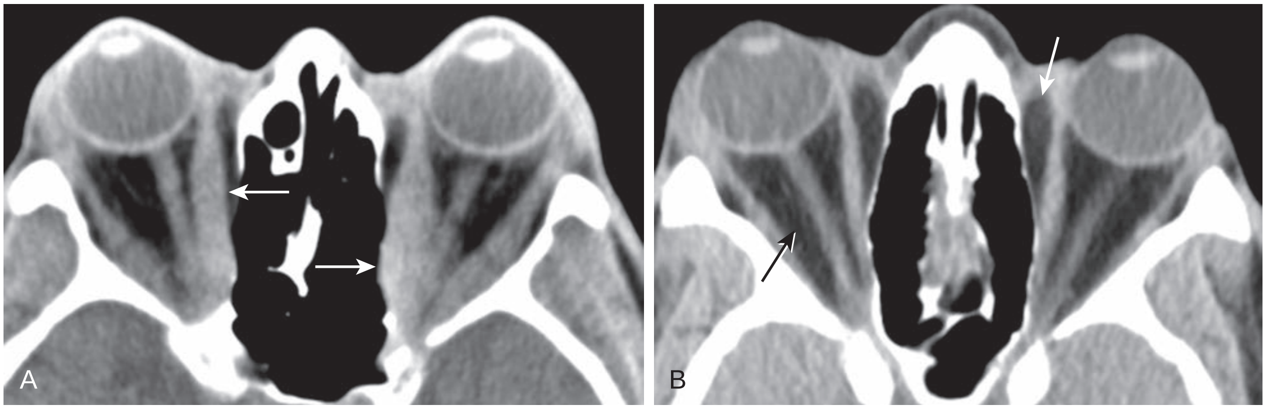
unclear. The disease may present as unilateral, isolated involvement of the EOMs but may also manifest with a more diffuse pattern involving multiple orbital sites. It can also present with neuritis or an extra bulbar mass. CT and MRI are equally effective in depicting the extent of disease (Figs. 7.20A and B). In children, orbital pseudotumor presents with an acute onset of painful proptosis and painful eye movement. The clinical presentation of orbital pseudotumor may be the best discriminator between this disease process and thyroid-associated orbitopathy (TAO). Orbital myositis usually appears as enlargement of the EOMs with mild surrounding inflammatory changes and anterior extension into the tendinous insertion. The imaging features of orbital myositis may be fairly similar to the early stage of TAO, although the tendinous portion/insertion of the EOMs is spared in patients with TAO. Excellent response to steroid treatment, with cessation of pain, is typical in cases of orbital pseudotumor. In rare cases, a biopsy is necessary to exclude malignancy.

## Thyroid-Associated Orbitopathy

TAO, previously referred to as thyroid ophthalmopathy, is an autoimmune disease that may or may not be contemporaneously associated with acute/active thyroid disease. This disease leads to thickening (usually symmetric) of the EOMs, but with sparing of the anterior musculotendinous junction, resulting in the so-called "coke-bottle"-like appearance (e-Fig. 7.21A). Patients usually present with disturbance of ocular motility, caused by swelling of rectus muscles at insertion sites into the globe, and injection of overlying vessels. Any EOM may be involved, with the inferior and medial rectus muscles being most commonly involved. EOMs may be infiltrated with lymphocytes, and fluid may accumulate in the periorbital tissues. Additionally, there is often increase in volume of the retrobulbar fat, which is associated with exophthalmos/proptosis. This condition is not common among pediatric patients but occasionally may be observed in teenagers (e-Fig. 7.21B). Eye findings in pediatric TAO are usually mild, and TAO-associated optic neuropathy has never been reported.

## Langerhans Cell Histiocytosis

Langerhans cell histiocytosis (LCH) is a granulomatous disease resulting from proliferation and infiltration of abnormal histiocytes within various tissues. Orbital lesions occur mainly in young children, ages 1 to 4 years. Orbital disease may accompany widespread disease, but occasionally it may be the first (and at times, the only) manifestation of LCH. The lesions arise from the orbital bone or bone marrow and spread directly to the orbit. Orbital disease may present clinically with proptosis and rapidly



**e-Figure 7.21. Thyroid-associated orbitopathy (TAO) in two different patients.** (A) Axial noncontrast CT of the orbit demonstrates fusiform thickening of the bilateral medial rectus muscles *(arrows)* with anterior tapering at the myotendinous junctions, the so-called "coke-bottle" appearance. (B) Axial noncontrast CT of the orbit demonstrates increase in orbital fat deposition *(arrows),* a known association of TAO.

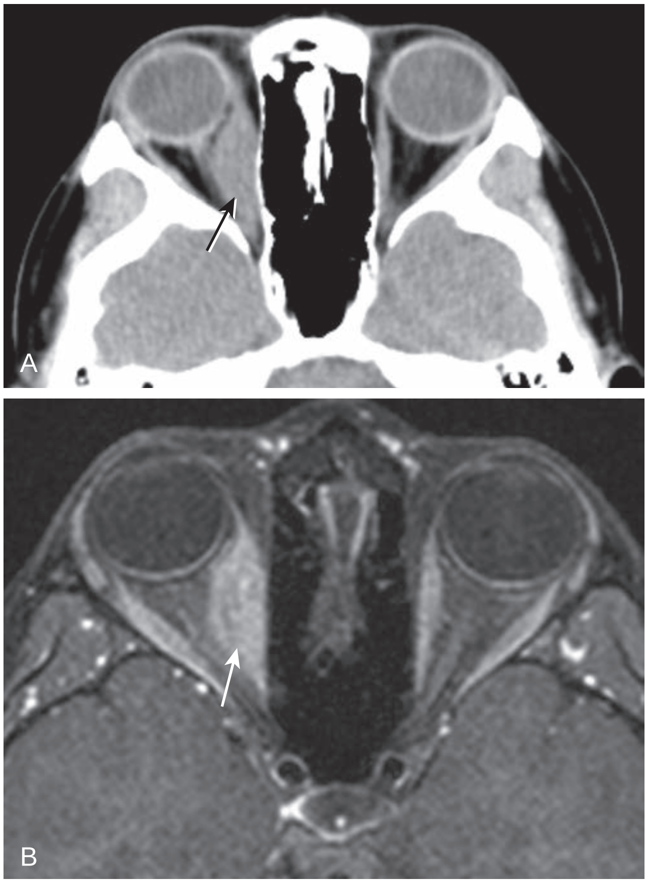


**Figure 7.20. Orbital pseudotumor.** (A) Axial contrast-enhanced CT and (B) axial contrast-enhanced fat-saturated T1-weighted MR images of the orbit in a patient with known right-sided inflammatory orbital pseudotumor. Note the fusiform enhancement and enlargement of the right medial rectus muscle *(arrows),* with extension to the myotendinous junction.

enlarging periorbital masses, or even with visual loss and destructive changes of the orbit.

CT and MRI are complimentary imaging techniques in the evaluation of LCH orbital lesions, and, in some cases, both may be indicated before treatment and when assessing for potential residual or recurrent disease. At times, the imaging features are often so typical for LCH that there is no need for biopsy. CT demonstrates expansile soft tissue masses in the posterolateral orbits, with a predilection for the frontosphenoid sutures. The lesions are usually associated with areas of osseous destruction, which show sharp and nonsclerotic ("punched out") margins typically without significant periosteal reaction (e-Fig. 7.22A). MRI demonstrates periorbital heterogeneous lesions that may contain blood-fluid levels (e-Fig. 7.22B) and foci of restricted diffusion. The masses exhibit diffuse enhancement on CT and MRI. Evaluation for intracranial extension is imperative, especially on contrast-enhanced sequences (e-Fig. 7.22C). Discovery of a solitary orbital LCH lesion necessitates additional imaging in search of other possible sites of involvement. LCH orbital masses may resemble NB metastases by certain imaging features; both lesions may demonstrate restricted diffusion, diffuse enhancement, and intraosseous and extraosseous components. The type of osseous involvement may help to distinguish the "clear-cut" margins of LCH from the permeative pattern and aggressive periosteal reaction of NB. Bone destruction in LCH typically is more pronounced than that seen with RMS.

### Granulomatosis With Polyangiitis and Sarcoidosis

Granulomatosis with polyangiitis (Wegener granulomatosis) is an autoimmune process that, in addition to pulmonary and paranasal involvement, may involve the orbit. Ocular involvement may be seen in 18% to 50% of cases, in which there is a propensity for lacrimal gland involvement (e-Fig. 7.23). The lesions are usually bilateral, with poor or no response to steroid treatment.

Sarcoidosis is an inflammatory, multisystem, granulomatous disease of unknown etiology, which, in addition to pulmonary and vascular involvement, affects the orbit in 25% of all patients. Any part of the orbit may be involved; a mass lesion within the lacrimal gland or the lacrimal sac can be the sole presentation of this disease (e-Fig. 7.24).

### Osteoma and Fibrous Dysplasia

Osteomas are benign, slow-growing, bone-forming tumors. Although osteomas of the facial region are not common, at times they may occur within the region of the paranasal sinuses, and, if allowed to grow large, may break through into the orbit and even intracranially. Osteomas within the orbits demonstrate typical imaging features of a broad-based expansile osseous mass, sometimes with an inner ground-glass lucent area, surrounded by dense compact bone. Osteomas usually do not cause bony destruction, even when these lesions are large. CT is the best imaging modality to delineate the lesion's characteristics and extension. MRI findings may be confusing, as the mature dense bone of the osteoma, representing most of the lesion's volume, may not be distinguishable from the air in the paranasal sinuses, as air and compact bone lack the MRI excitable protons of water molecules. These lesions are very dense, thereby appearing very "white" on CT and very "black" on MRI (e-Fig. 7.25).

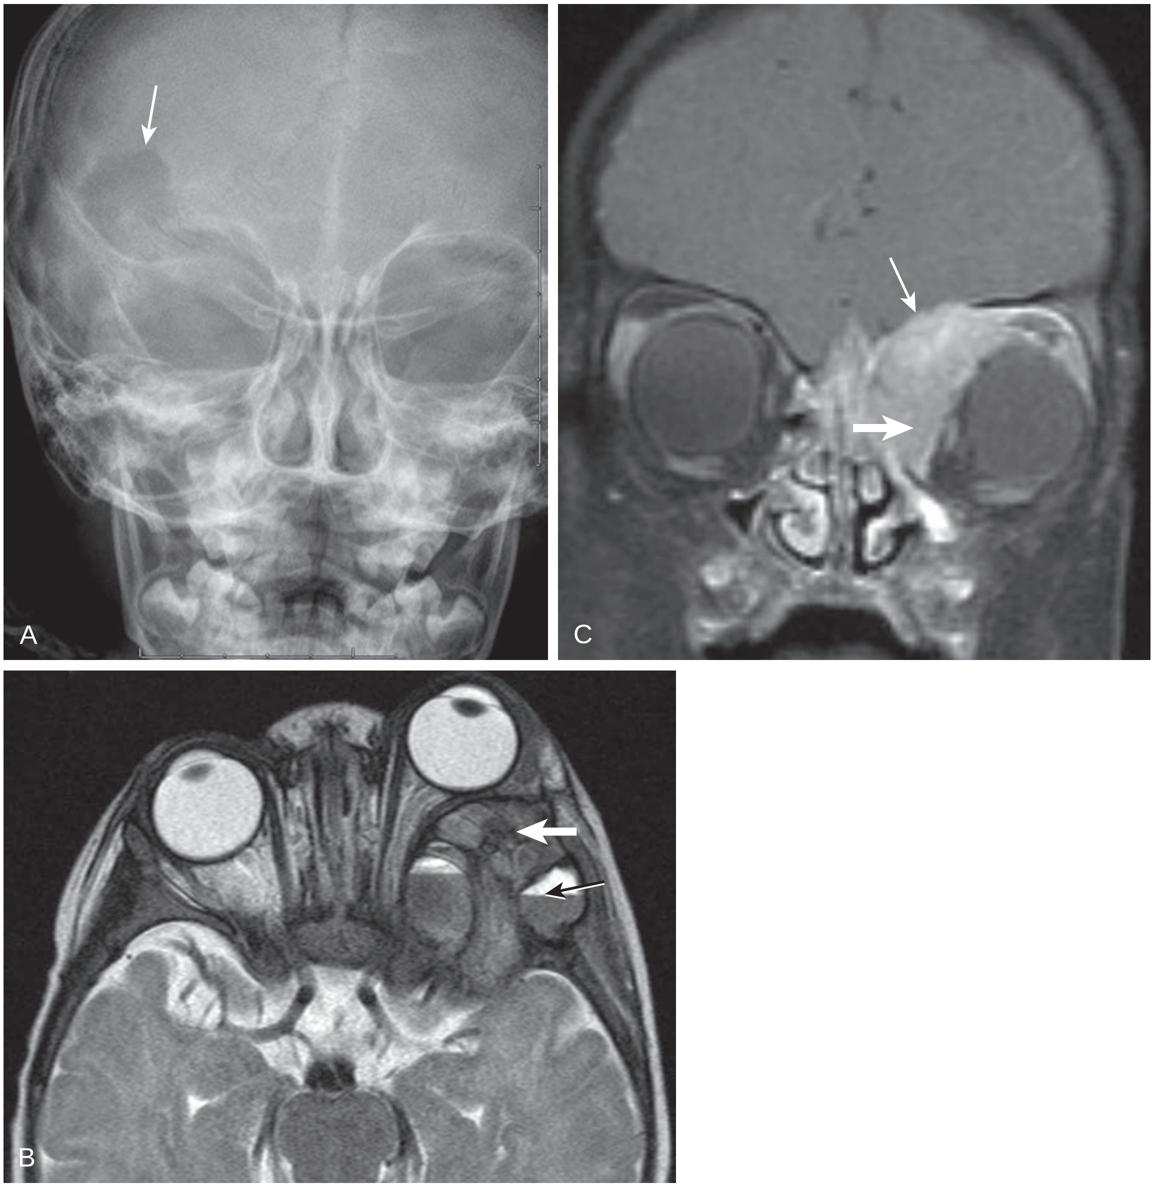
Fibrous dysplasia is a systemic osseous disease that often involves the skull. Although usually sclerotic in appearance, with a "ground-glass" appearance, there are phases of this disease in which lysis/lucency may be a predominate feature, thereby mimicking LCH. The MRI features may be confusing, with intermediate signal on T1W and T2W imaging, with an appearance more typical and characteristic on CT (e-Fig. 7.26).

## METASTATIC LESIONS INVOLVING THE ORBITS

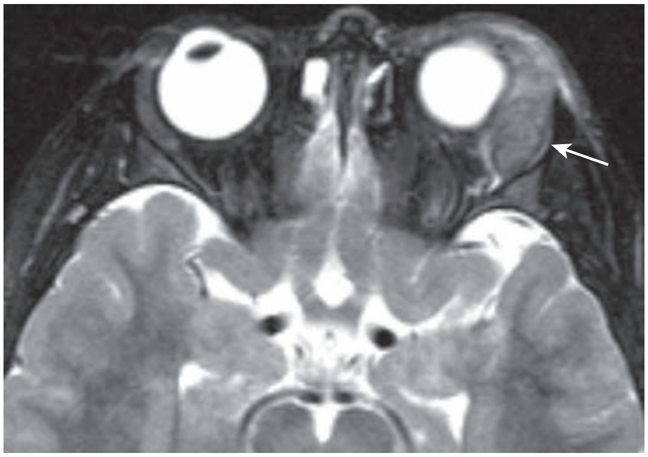
Orbital metastases are less common in children than in adults. Primary tumors that may metastasize to the bony orbit are NB, lymphoma and leukemia, and very rarely Wilms tumor and Ewing sarcoma. Ocular choroid metastases, which are quite common in adults, are exceedingly rare in children. However, leukemic deposits may infiltrate the optic nerve, which represents an emergency, as vision may decline precipitously.

### Neuroblastoma

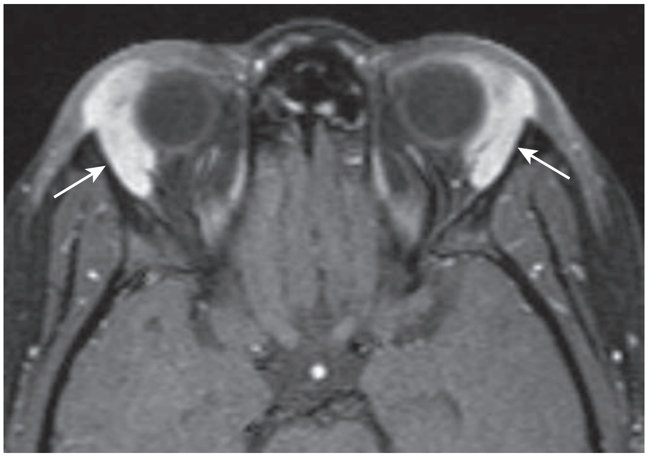
NB is the most common metastatic tumor of young pediatric patients. In 8% of cases, NB first presents with acute orbital symptoms related to tumoral hemorrhage, sudden proptosis, and ecchymosis (so-called "raccoon eyes"). NB metastases are bilateral in 50% of cases and originate in the osseous walls of the orbits. Permeative bony destruction or spiculated thickening with aggressive periosteal reaction of the lateral wall and roof of the orbit are characteristic findings (Fig. 7.27A). Epidural tumor deposits may extend to the sutural margins and cause sutural diastasis (Fig. 7.27B) without elevation of intracranial pressure. Soft tissue masses often contain calcifications. Infiltration of the deep spaces of the face and neck and intracranial extension is often seen. Lesions may be heterogeneous on T1W and T2W images when compared with muscle. Marked heterogeneity of contrast enhancement can be seen due to hemorrhage and necrosis (Fig.



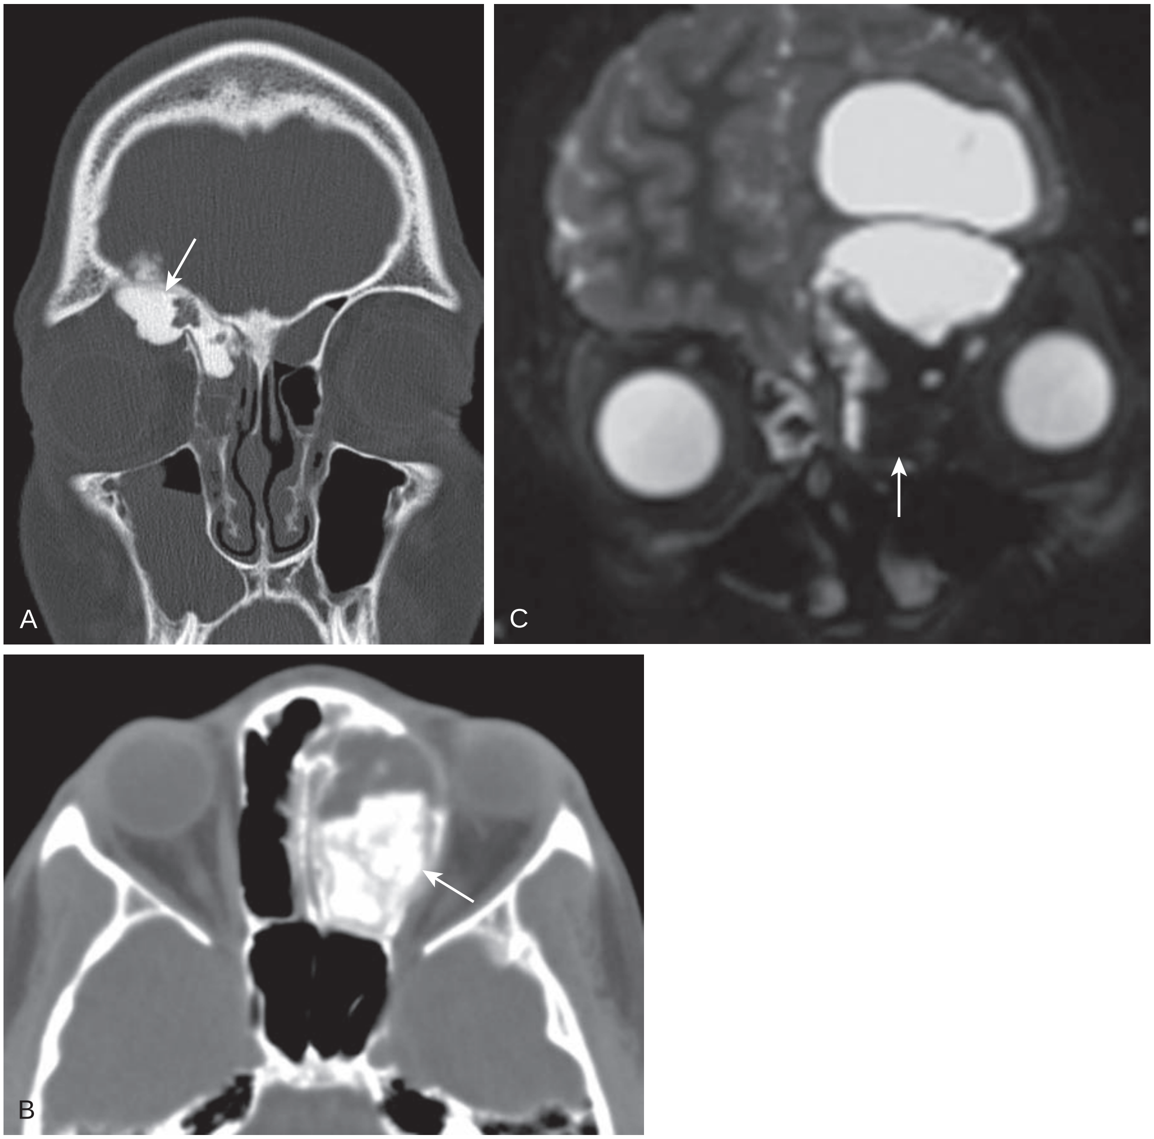
**e-Figure 7.22. Langerhans cell histiocytosis (LCH) in three different patients.** (A) Frontal radiograph of the skull demonstrates a right-sided supraorbital lucent lesion with beveled edges *(arrow),* typical of LCH. (B) Axial T2-weighted MR image demonstrates marked left-sided proptosis, associated with a posterior bony lesion along the greater wing of the sphenoid *(white arrow)* and with associated fluid-fluid levels *(black arrow)*. Although these findings are more commonly seen with aneurysmal bone cysts and telangiectatic osteosarcomas, they also are seen in LCH lesions. (C) Coronal contrast-enhanced fat-saturated T1-weighted MR image demonstrates an avidly enhancing, left-sided medially based LCH lesion *(thick arrow)* with a propensity for invasion of the skull base and thickening and enhancement of the adjacent dura *(thin arrow)*.



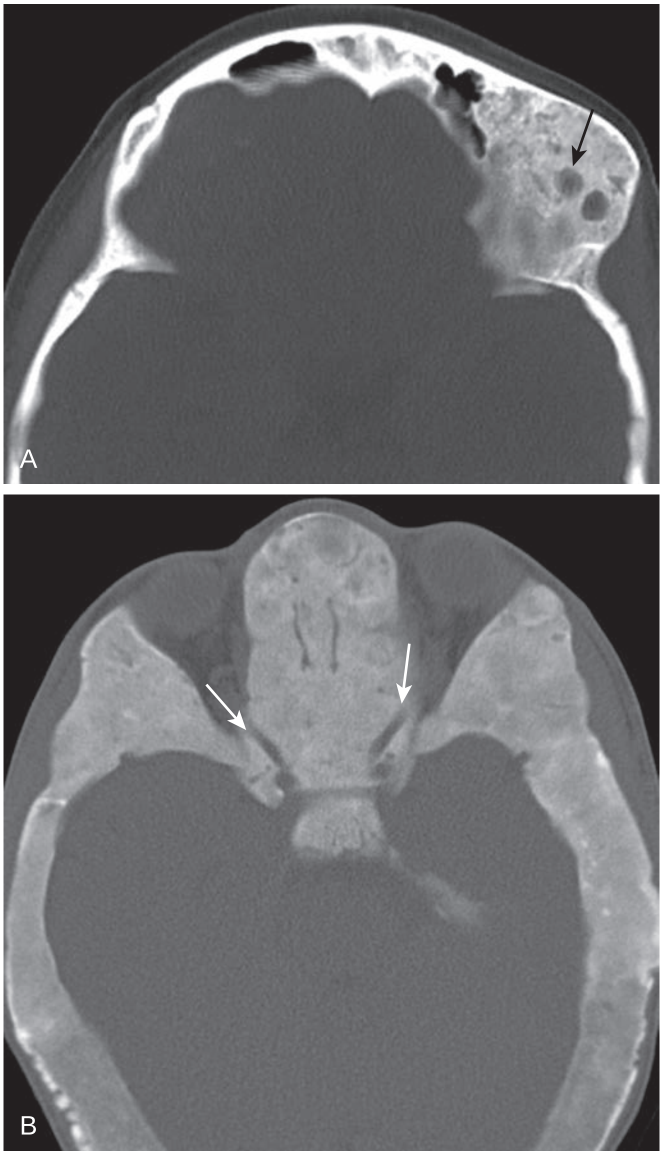
**e-Figure 7.23. Granulomatosis with polyangiitis (Wegener granulomatosis).** Axial fat-saturated T2-weighted MR image demonstrates enlargement of the left lacrimal gland *(arrow)*.



**e-Figure 7.24. Sarcoidosis.** Axial contrast-enhanced fat-saturated T1-weighted MR image demonstrates symmetric, bilaterally enlarged lacrimal glands, with avid contrast enhancement *(arrows)*.



**e-Figure 7.25. Orbital osteoma in two different patients.** (A) Coronal noncontrast CT of the orbit and sinus region in a patient with a known right frontal sinus osteoma demonstrates a markedly dense lesion emanating from the right frontal sinus, similar in attenuation to that of enamel and dense bone *(arrow),* in keeping with a right frontal osteoma, with extension into the right orbit via a breach of the right orbital roof *(arrow)*. (B) Axial noncontrast CT and C, coronal fat-saturated T2-weighted MR images of the orbits demonstrate a markedly CT dense (bone-producing) lesion *(arrows)* with corresponding marked MRI signal loss, in keeping with a left ethmoid sinus region osteoma.



**e-Figure 7.26. Fibrous dysplasia (FD).** (A) Axial noncontrast CT at the level of the supraorbital frontal bone demonstrates ground-glass sclerosis with central areas of cystic lucencies *(arrow),* in keeping with FD. (B) Axial noncontrast CT of the head at the level of the orbits demonstrates diffuse marrow expansion and sclerosis associated with bilateral optic canal narrowing/impingement *(arrows)*.

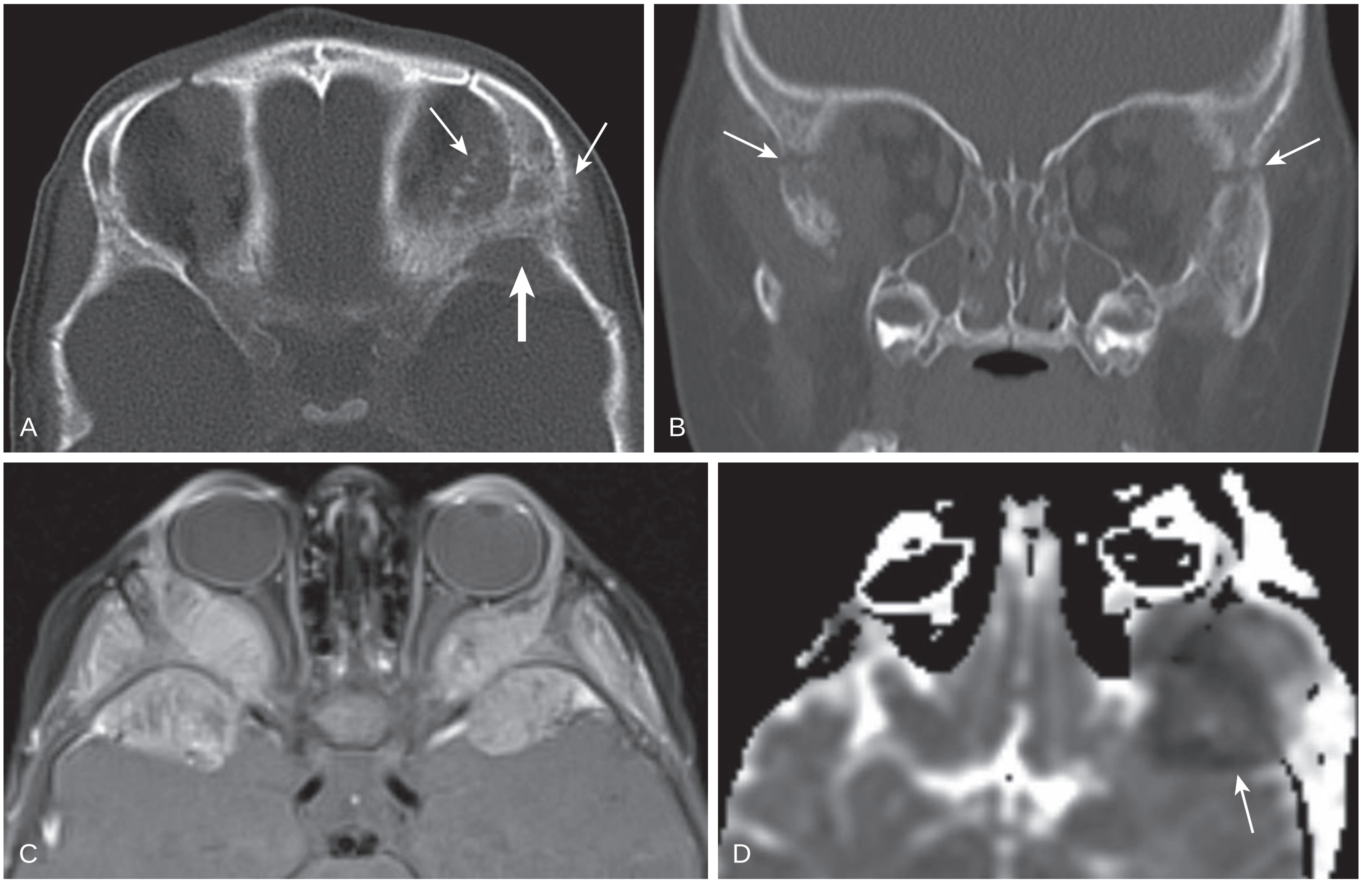


**Figure 7.27. Orbital neuroblastoma (NB) metastases in four different patients.** (A) Axial noncontrast CT image of the orbits demonstrates a moth-eaten, spiculated appearance of the bone surrounding the left orbit, which is a typical appearance of a NB that has metastasized to the orbits/skull base *(arrows)*. (B) Coronal reformatted noncontrast CT image demonstrates bilateral sutural irregularity and widening *(arrows),* highly suggestive of NB metastases (especially in the absence of an intracranial cause for increased intracranial pressure). (C) Axial contrast-enhanced fat-saturated T1-weighted MR image of the orbits demonstrates bilaterally symmetric lobulated enhancing soft tissue masses, around the bony orbit, with a speculated appearance, in the vicinity of cranial sutures, highly suggestive of metastatic NB. (D) Axial ADC MR image demonstrates marked restricted diffusion *(arrow pointing to dark signal)* along the posterolateral aspect of the orbit, with involvement of temporal bone, indicating marked cellularity of the tumor.

7.27C). NB metastases demonstrate restricted diffusion on DWI (Fig. 7.27D).

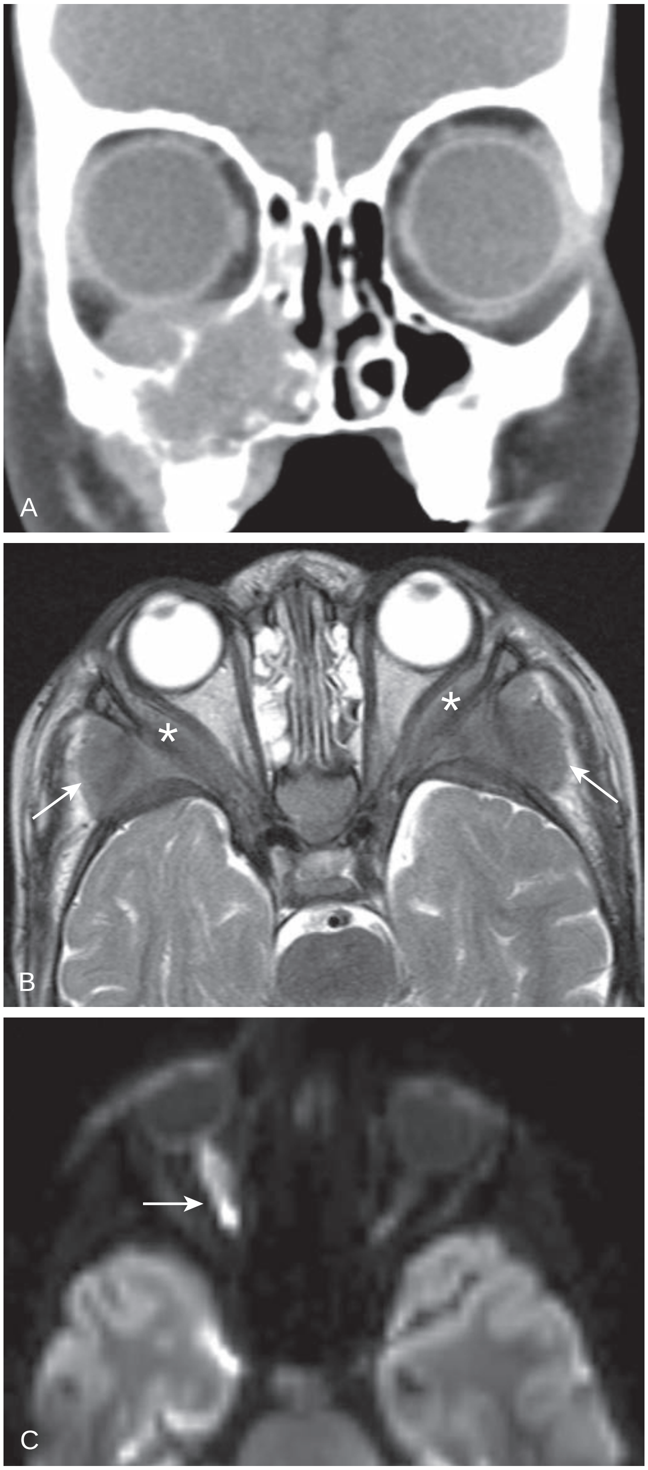
## Leukemia and Lymphoma

Marrow malignancies, lymphoma and leukemia, account for 10% to 15% of orbital masses. Extramedullary metastases to the orbits are most often associated with acute myelogenous leukemia (AML) in younger children and non-Hodgkin lymphoma (NHL) in older children. In patients with AML, the metastatic focus is referred to as a chloroma (derived from the Greek word *chloros* meaning “green”) due to their green tint.

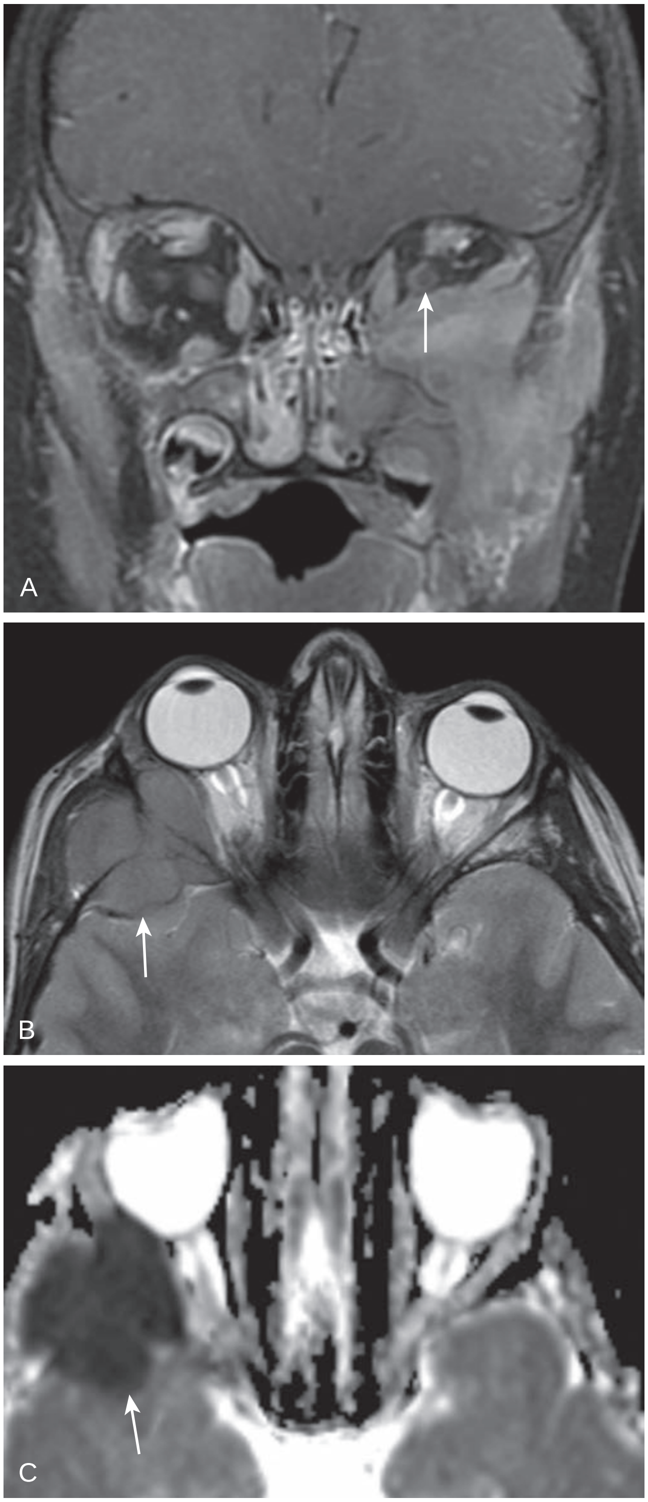
Rarely, leukemic deposit is the initial presenting sign of AML, although it more commonly occurs in the setting of recurrent disease. The subperiosteal space along the lateral orbital wall is often a location of involvement; however, any location in the orbit may be involved. Imaging features resemble the bony metastases of NB, including invasion of the sutures of the orbital walls as well as periosteal reaction. Bilateral disease is seen in approximately one-third of cases. Invasion of the orbital fat and extension to the eyelid are common. Masses are isoattenuating to hyperattenuating on CT (e-Fig. 7.28A), isointense on T1W and T2W imaging (e-Fig. 7.28B) when compared with muscle, and demonstrate variable degrees of enhancement. Calcification is not a feature of leukemic disease. DWI demonstrates restricted diffusion in the soft tissue masses and the involved bony structures.

Imaging plays a crucial role in the detection of optic nerve involvement (e-Fig. 7.28C) and in guiding therapy to prevent irreversible visual loss. Compressive neuropathy (e-Fig. 7.29A) of the optic nerve is a known complication of orbital chloroma and lymphoma, even without direct infiltration of the optic nerve/sheath complex. Radiation to the optic nerves and intrathecal chemotherapy should be initiated promptly to preserve vision.

NHL (a tumor composed of B cells) often presents with extranodal disease. Most patients with orbital lymphoma also have systemic disease. NHL commonly involves the lacrimal gland and encases the globe. CT may demonstrate a hyperattenuating mass with sharply defined margins. MRI findings include T2W hypointense masses (e-Fig. 7.29B), with restricted diffusion (e-Fig. 7.29C). Orbital lymphoma ranges from very malignant tumors to much less malignant, indolent lesions, such as ocular adnexal Mucosa Associated Lymphoid Tissue (MALT) lymphoma. Imaging features as well as histologic features of different lymphoma types may overlap significantly.



**e-Figure 7.28. Leukemia in three different patients.** (A) Coronal reformatted contrast-enhanced CT in a patient with AML demonstrates soft tissue opacification of the right maxillary sinus with bony breakthrough into the floor of the left orbit and inferolateral wall of the right maxillary sinus. (B) Axial T2-weighted MR image of the orbits in a patient with acute myelogenous leukemia (AML) demonstrates T2 dark soft tissue masses surrounding the posterolateral aspects of both orbits *(arrows),* with soft tissue extending to involve the inner tables of the posterior bony walls of both orbits *(asterisks)*. (C) Axial diffusion-weighted imaging MR image in a leukemic patient with direct optic nerve involvement as evidenced by restricted diffusion *(arrow)*.



**e-Figure 7.29. Lymphoma.** (A) Coronal contrast-enhanced fat-saturated T1-weighted MR image of the orbit in a patient with lymphoma demonstrating a large enhancing facial mass extending into the orbit, causing upward displacement of the left optic nerve *(arrow)*. (B) Axial T2-weighted and (C) apparent diffusion coefficient (ADC) MR images demonstrate a lobulated T2 isointense mass about the right orbit, on both sides of the greater wing of the sphenoid, associated with diffusion restriction *(arrows)*.

## KEY POINTS

- Retinoblastoma is the most common intraocular pediatric tumor. Leukocoria is the most common presenting clinical sign.
- Optic nerve glioma is the most common pediatric primary neoplasm of the ocular nerve, often associated with NF type I.
- Orbital hemangiomas affect 2.5% to 10% of infants and are almost solely benign IHs.
- Rhabdomyosarcoma is the most common malignant soft tissue tumor in childhood, and the orbits and paranasal sinuses are the second-most common site of occurrence.
- Dermoid and epidermoid cysts are congenital developmental ectodermal inclusion cysts, constituting up to 5% of all orbital masses.
- Orbital metastatic disease may be due to NB, leukemia, or lymphoma.

# Nose and Sinonasal Cavities

*Diana P. Rodriguez*

## DEVELOPMENT AND ANATOMY OF THE NOSE AND SINONASAL CAVITIES

The craniofacial structures form from a complex sequence of events dictated by molecular changes during the third to 10th gestational weeks. The nose forms in the fourth gestational week from the frontonasal processes and two nasal placodes that develop dorsal to the stomodeum. The nose derives from ectoderm, mesoderm, and a deep cartilaginous capsule. The posterior nasal septum and the sphenoid and ethmoid bones form from neural crests. The skull base and nose are formed by mesenchymal structures that later fuse and ossify.[1,2] Neural tube closure anomalies of the anterior neuropore (primitive frontonasal region) may result in developmental frontonasal midline masses.[2] A temporary fontanelle, *the fonticulus nasofrontalis*, forms between the nasal bones and inferior frontal bones and later fuses to form the frontonasal suture in the eighth gestational week. The *pre-nasal space* is another transient space located between the posterior aspect of the frontal and nasal bones, and anterior aspect of the nasal cartilage. This space extends from the foramen cecum, a midline opening just anterior to the crista galli of the ethmoid bone, to the osteocartilaginous junction. The dura extends through the foramen cecum and comes in close contact to the skin and later involutes and obliterates, while the nasal process of the frontal bone grows. Failure of regression of these structures may result in midline developmental anomalies such as nasal dermoids, cephaloceles, and nasal neuroglial heterotopia.[3]

The nasal cavity is triangular and separated in the midline by the nasal septum. The nasal cavity is composed of a cartilaginous portion anteriorly and an osseous portion posteriorly, which is formed by the perpendicular plate of the ethmoid posterosuperiorly and the vomer posteroinferiorly. The opening to each nasal cavity is known as the vestibule, which is bounded medially by the columella and nasal septum and laterally by the nasal alae. The cribriform plate is the roof of the nasal cavity, and the floor is the hard and soft palate. Posteriorly, the nasal cavity communicates with the nasopharynx via the choanae, after rupture of the oronasal membrane during the fetal period. From the lateral wall of the nasal cavity, three pairs of turbinates (superior, middle, and inferior) project into the nasal cavity, each with a corresponding meatus below them. The middle turbinate is attached to the cribriform plate via the vertical lamella and to the lamina papyracea via the basal lamella (Fig. 8.1).

### Paranasal Sinuses

The paranasal sinuses form as diverticula from the walls of the nasal cavities and become air-filled extensions in the adjacent bones—maxilla, ethmoid, frontal, and sphenoid. The original openings of the diverticula persist as the ostia of the sinuses that communicate with the nasal cavity (Figs. 8.2A and B).

The mucosal lining of the nasal cavities is contiguous with the paranasal sinuses and consists of pseudostratified, columnar, ciliated epithelium containing mucinous and serous glands,[4] whereas the nasal septum is lined by squamous mucosa.[5] In the human embryo, ethmoidal and maxillary sinus budding can be detected at 11 to 12 gestational weeks and at 14 to 15 gestational weeks, respectively.[6] In general, only rudimentary maxillary and ethmoid sinuses, which continue to expand until puberty or early adulthood, are present at birth.[7] The sinuses also are linked to facial growth and dentition.[7–14]

### Ethmoid Sinuses

The ethmoid sinuses are already developed in number and pneumatized at birth but continue to expand, reaching adult proportions at about 12 years of age (Fig. 8.3).[15] The ethmoid sinuses consist of a paired group of a variable number of cells (3–18) within the lateral masses of the ethmoid bone. The ethmoid bone also consists of the cribriform plate superiorly and the perpendicular plate, which is part of the nasal septum. The ethmoid sinus is bordered medially by the nasal cavity and laterally by the lamina papyracea; its roof is formed by the cribriform plate and fovea ethmoidalis (see Fig. 8.1). The anterior and posterior ethmoid air cells are separated by the basal lamella (see Fig. 8.3C), which is the lateral attachment of the middle turbinate to the lamina papyracea. Drainage of the anterior ethmoid air cells occurs via the ethmoid bulla into the hiatus semilunaris and middle meatus. The posterior ethmoid air cells drain into the superior meatus and then into the sphenoethmoid recess (see Fig. 8.2A).

The anterior ethmoidal artery arises from the ophthalmic artery in the orbit, pierces the lamina papyracea, and exits through the ethmoid roof in the superomedial wall of the orbit, 2 to 3 mm behind the anterior wall of the bulla ethmoidalis. Occasionally, the anterior ethmoidal artery passes within the bony septae of the ethmoid sinuses and is suspended in a mesentery without a bony cover (e-Fig. 8.4).[16]

#### Anatomic Variants

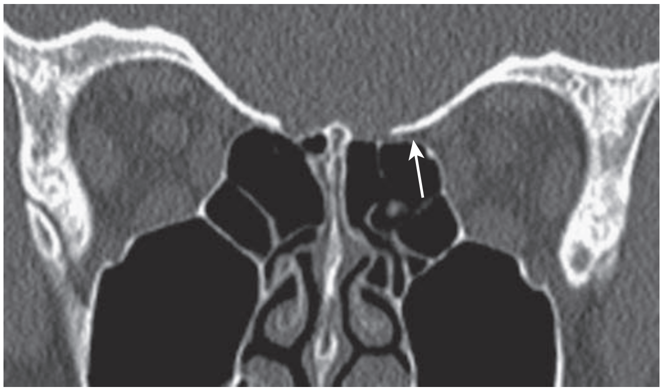
Any asymmetry in the height of the ethmoid roof should be documented by the radiologist due to risk of surgical penetration during endoscopic surgery on the side where the roof is lower.[17,18]

Concha bullosa refers to the pneumatization of the middle turbinate as a result of intramural extension of posterior ethmoid air cells (Fig. 8.5B). A large concha bullosa can eventually cause obstruction of the nasal cavity.

Extramural expansion of ethmoid air cells can result in anatomic variants, including the following: Agger nasi cells (Fig. 8.5A), which are the most anterior and inferior cells involving the lacrimal bone or maxilla; Haller cells, which are middle ethmoid air cells extending into the inferomedial floor of the orbit (Fig. 8.5C); and Onodi cells, which are posterior sphenoethmoid air cells with prominent superolateral pneumatization in close relationship to the optic nerve canal.[16]

### Maxillary Sinuses

The maxillary sinuses are very small and pneumatized at birth and undergo rapid inferolateral expansion during the first years of life, reaching full size between 15 to 18 years of age. The floor of the maxillary sinus is seen usually at the level of the middle



**e-Figure 8.4. Anterior ethmoidal artery canal.** Coronal CT image shows the normal bony canal for the anterior ethmoidal artery on the left side *(arrow)*.

meatus during infancy; it reaches the level of the nasal floor by 8 to 9 years of age, and by age 12 years, it is located at the level of the hard palate.[9] The maxillary floor lies below the level of the nasal floor in 65% of adults (e-Fig. 8.6).[19]

The maxillary sinus is the largest of the sinuses. Its roof is formed by the orbital floor, which carries the bony canal for the infraorbital nerve; the medial wall is formed by the lateral nasal wall. The posterior wall of the maxillary sinus forms the pterygopalatine fossa (Fig. 8.7A). The maxillary sinus drains via the maxillary ostium located superomedially into the infundibulum, the hiatus semilunaris, and the middle meatus (see Fig. 8.2A).

Developmental variations of the maxillary sinus include an accessory ostium, unilateral hypoplasia, and septations that can compartmentalize the sinus cavity. Maxillary molar roots may impinge on the walls of the sinuses.

## Sphenoid Sinus

The sphenoid sinus pneumatizes in a ventrodorsal direction from 7 months to 2 years of age. Significant sinus expansion occurs between 3 and 8 years of age, with complete pneumatization usually present by age 10 years (e-Fig. 8.8).[12] Its superior border is formed by the sella turcica, posteriorly by the clivus, anteriorly by the ethmoid sinus, and inferiorly by the nasopharynx (see Figs. 8.2A and B). This sinus drains anteriorly via the sphenoethmoid recess. Lateral recesses of the sphenoid sinus are formed from pneumatization of the pterygoid process in 44% of people (see Fig. 8.7A). Benign sphenoid marrow variants, which sometimes are mistaken for lesions, can be seen adjacent to the pneumatized sphenoid sinus (e-Fig. 8.9).

Important anatomic relationships of the sphenoid sinus include the optic canal and nerve located superolaterally; the foramen rotundum with the maxillary nerve that courses along the inferolateral margin of the sphenoid sinus; the vidian canal, which usually runs along the floor of the sphenoid sinus; and the cavernous portion of the internal carotid artery, which protrudes laterally into the sinus (see Fig. 8.7B). The sphenoid sinus septum usually is aligned anteriorly with the nasal septum but can deviate posteriorly, forming unequal sphenoid cavities (see Fig. 8.7C). Absent pneumatization in a child older than 9 years is usually abnormal and warrants clinical investigation (see Fig. 8.7D).

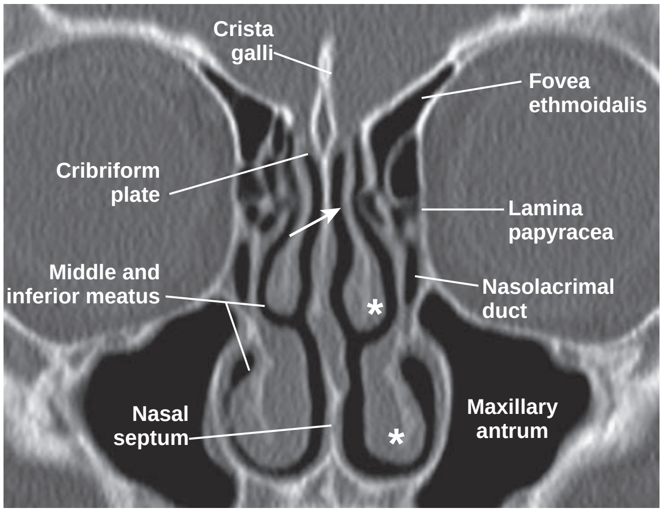


**Figure 8.1. Anatomy of the nasal cavity demonstrated in a 13-year-old.** Coronal CT image shows middle and inferior turbinates *(asterisks)* and vertical lamella of the middle turbinate *(arrow)* attached to the cribriform plate.

## Frontal Sinuses

The frontal sinuses are absent at birth and are the last to develop once bone marrow conversion has occurred. The frontal sinus is considered an extension of the anterior ethmoid air cells, pneumatizes between 2 to 8 years, and continues to expand until the second decade of life.[9,14] The frontal sinuses consist of paired, often asymmetric cells. The anterior wall corresponds to the outer cortical table of the frontal bone, and its posterior wall separates this sinus from the anterior cranial fossa. This sinus drains via the frontal recess, which is an hourglass-like narrowing between the frontal sinus and the anterior middle meatus (see Fig. 8.2A). Hypoplasia and aplasia of the frontal sinus can be seen in 4% and 5% of the population, respectively.

# IMAGING OF THE PARANASAL SINUSES

## Radiography

Although plain radiography is less costly and more widely available than computed tomography (CT), it has significant limitations. Plain radiography often overestimates or underestimates findings, does not localize pathology well, and does not provide important

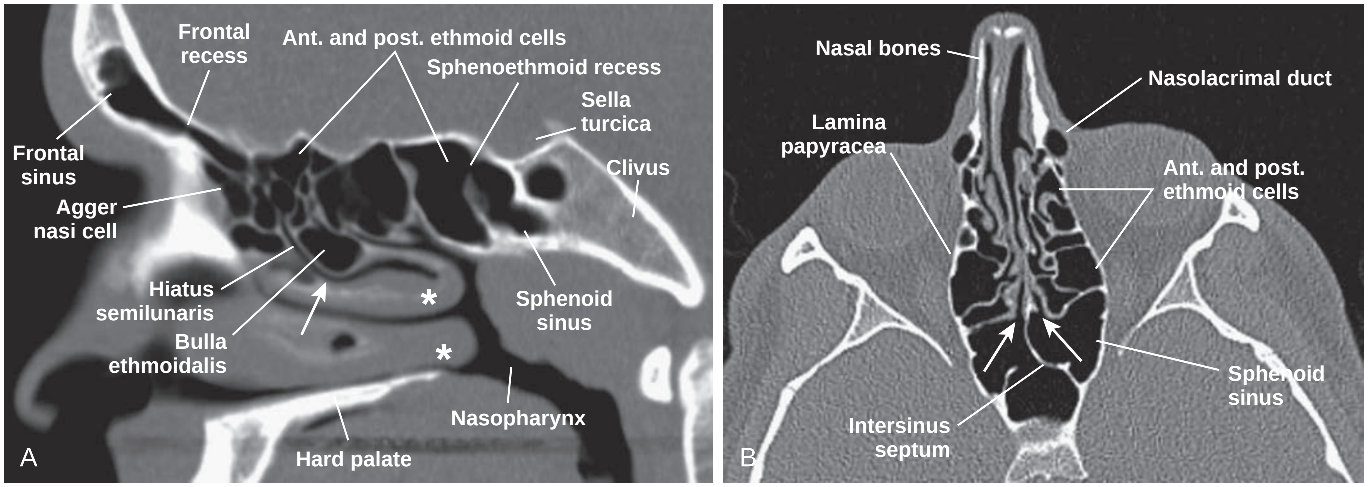

**Figure 8.2. Normal sinus openings.** (A) Sagittal CT image shows frontal recess of the frontal sinus, hiatus semilunaris, middle meatus *(arrow),* sphenoethmoid recess, and middle and inferior turbinates *(asterisks)*. (B) Axial CT image shows sphenoethmoid recesses *(arrows)*.

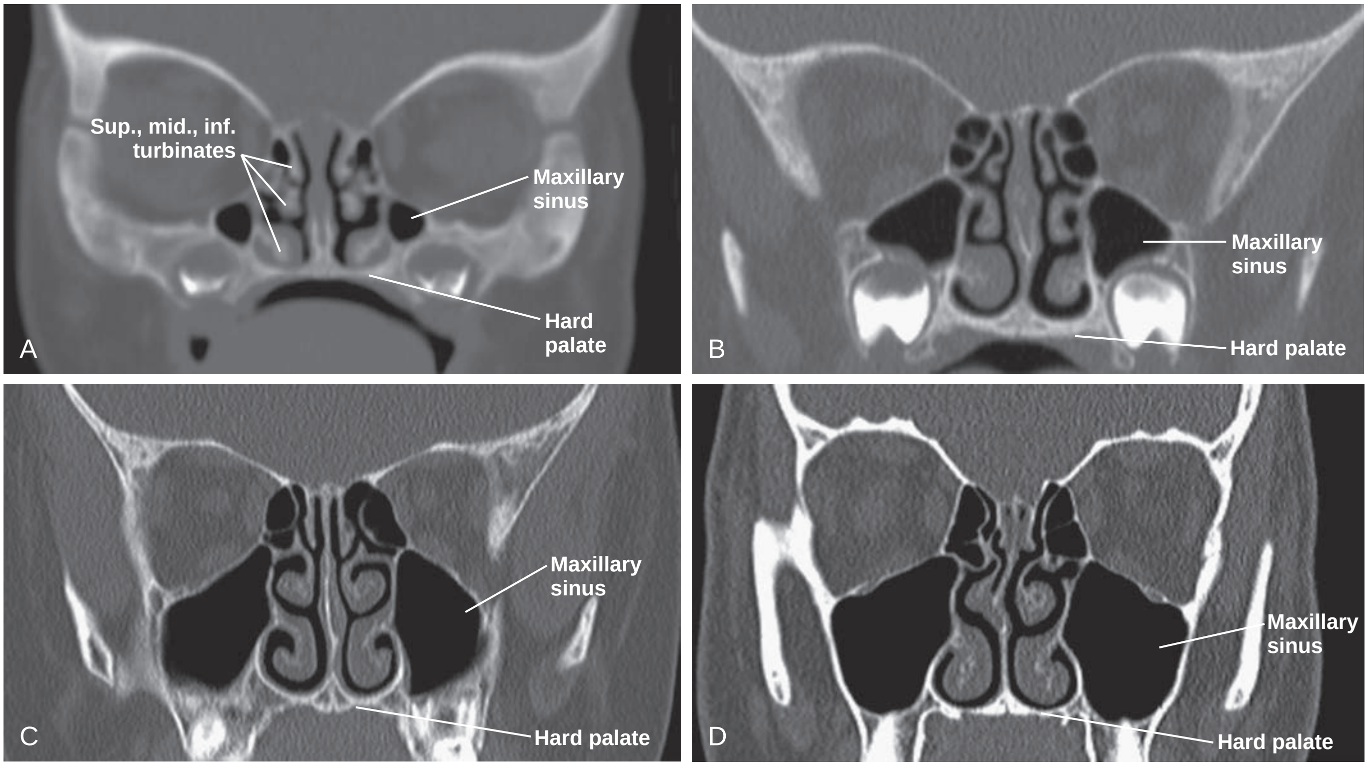
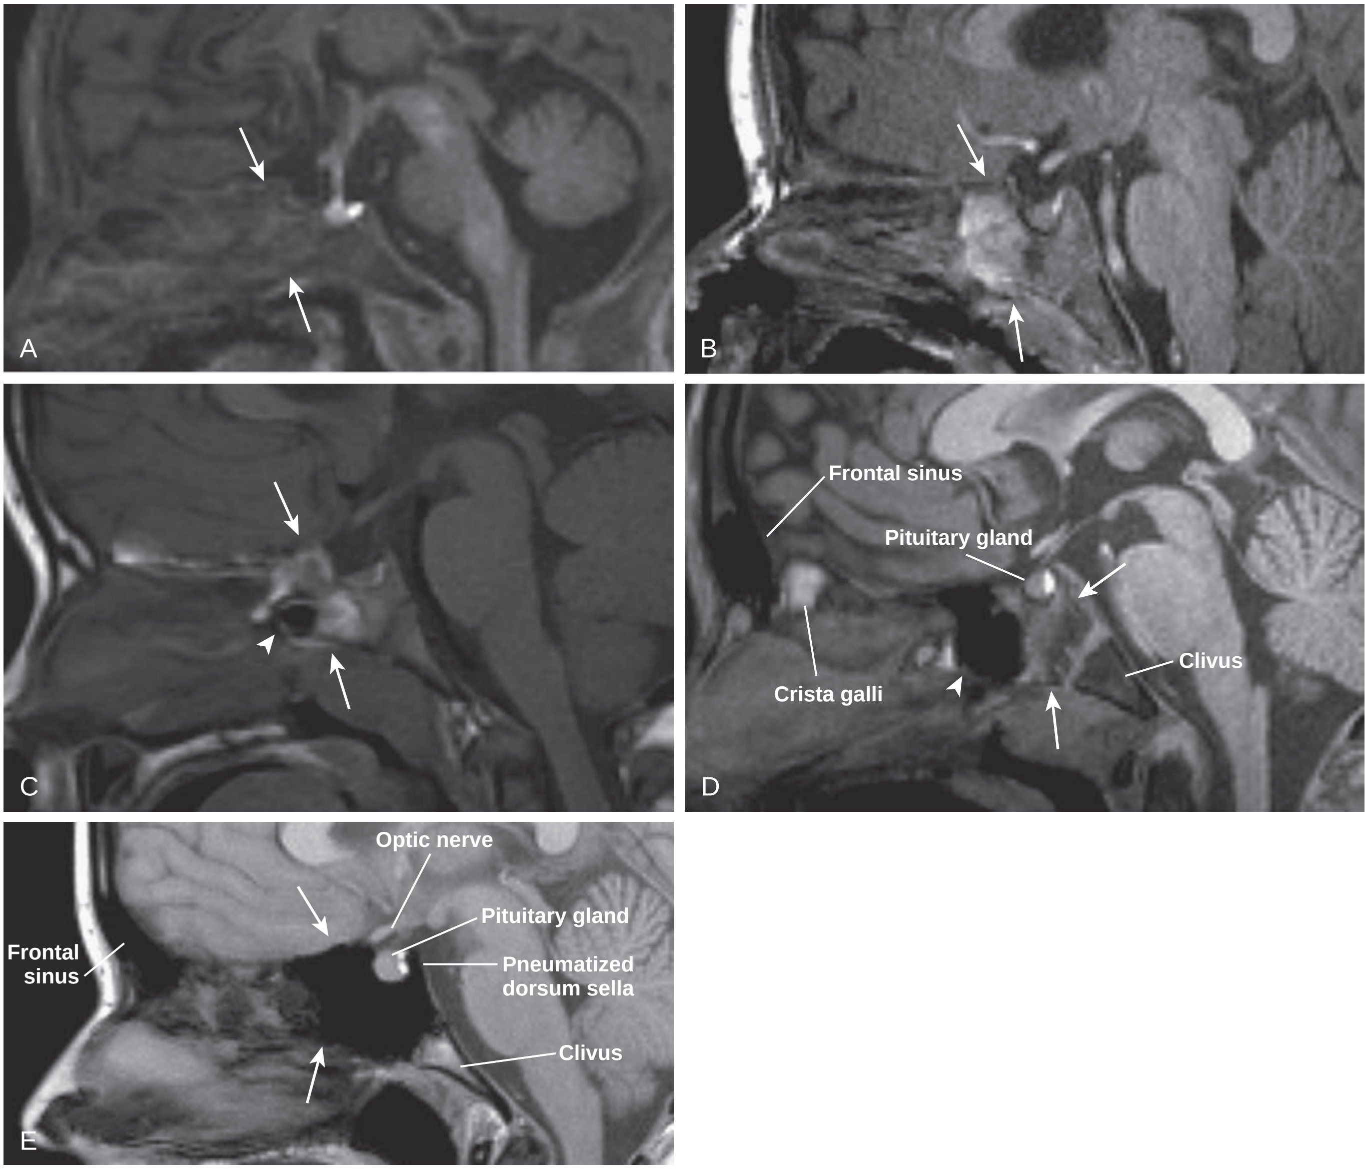
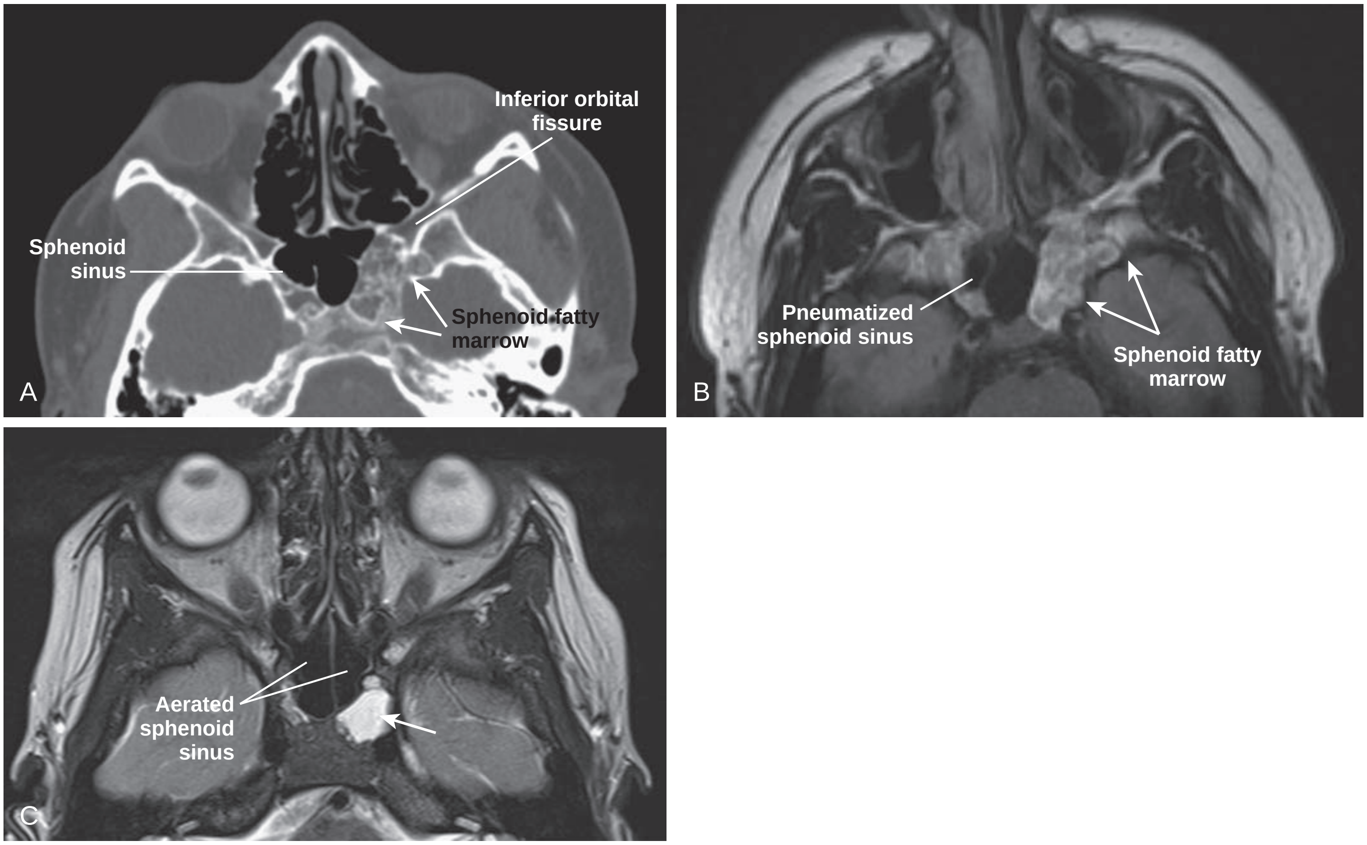


**e-Figure 8.6. Maxillary sinus development.** Coronal CT images show maxillary sinuses at (A) 1 month, (B) 3 years, (C) 7 years, and (D)15 years.



**e-Figure 8.8. Sphenoid sinus development.** Sagittal T1-weighted MR images. (A) Hematopoietic marrow (T1 hypointense) of the sphenoid bone in a newborn *(thin arrows)*. (B) Fatty transformation of the anteroinferior aspect of the sphenoid bone in a 12-month-old *(arrows)*. (C) Pneumatization of the anteroinferior aspect of the sphenoid sinus in a 3-year-old *(arrowhead)* with fatty sphenoid marrow *(arrows)*. (D) Further pneumatization of the sphenoid sinus *(arrowhead)* and fatty transformation of the sphenoid bone *(arrows)*. (E) Fully pneumatized sphenoid sinus *(arrows),* including the dorsum sella in a 14-year-old boy.



**e-Figure 8.9. Benign sphenoid marrow variants.** (A) Axial CT image shows asymmetric fatty marrow of nonpneumatized sphenoid bone on the left side. (B) Axial T1-weighted MR image shows correlation of T1-hyperintense normal marrow of the sphenoid bone, which can simulate mass (neoplasm/erosion). (C) Axial CT image in another patient shows retained fluid in the left lateral recess of the sphenoid sinus.

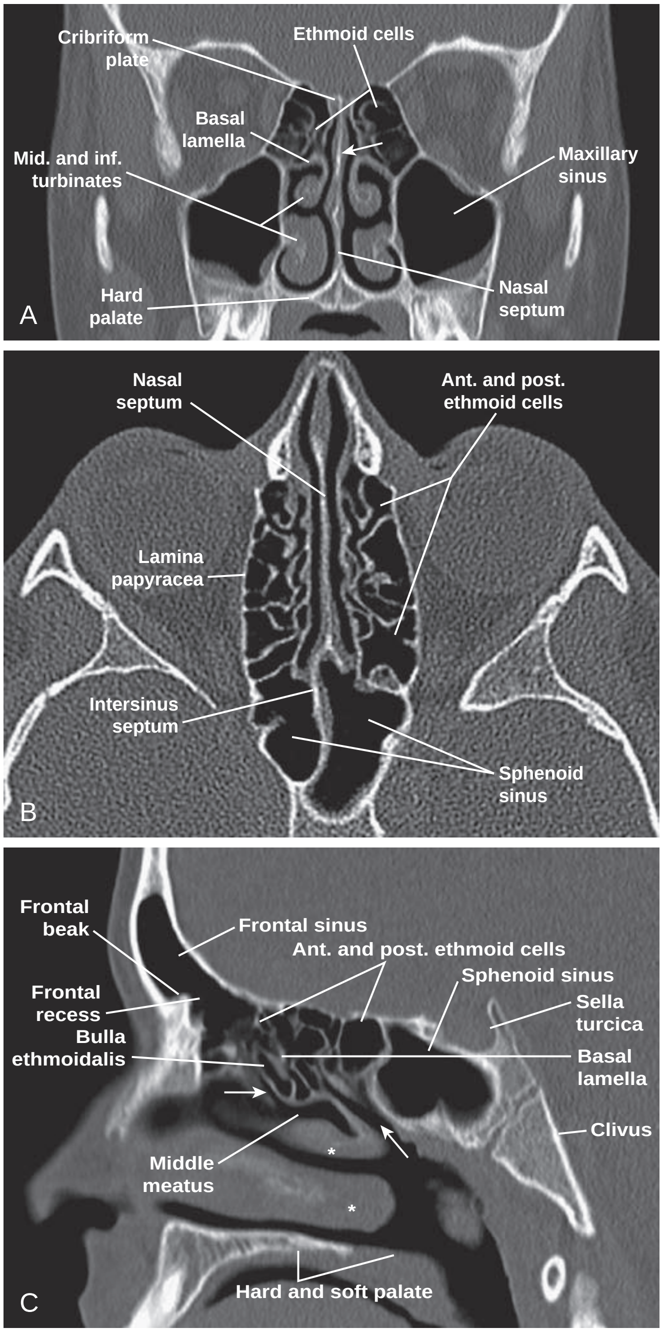


**Figure 8.3. Normal anatomy of the sinuses demonstrated by fully developed sinuses in a 13-year-old boy.** (A) Coronal CT image shows the perpendicular plate of the ethmoid bone *(arrow)*. (B) Axial CT image and (C) sagittal CT image shows hiatus semilunaris *(arrow at left),* drainage passage of posterior ethmoid cells *(arrow at right),* and middle and inferior turbinates *(asterisks)*.

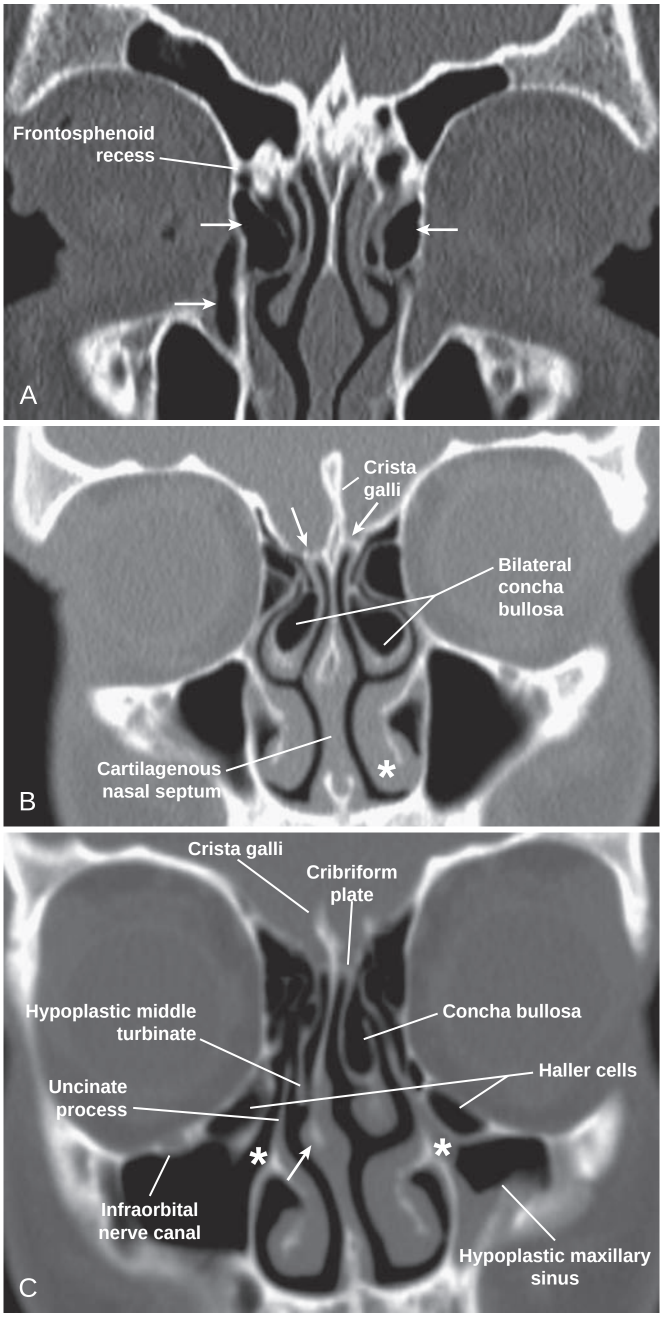

**Figure 8.5. Anatomic variants.** (A) Coronal CT image shows bilateral Agger nasi cells *(top arrows),* the nasolacrimal canal *(bottom arrow),* and the right frontoethmoidal recess. (B) Bilateral concha bullosa, asymmetric height of the ethmoid roofs *(arrows),* and the inferior turbinate *(asterisk)* are shown. (C) A hypoplastic right middle turbinate, rightward nasal septal deviation, Haller cells, and infundibulum *(asterisks)* are shown.

anatomic detail.[20] The paranasal sinus series traditionally consists of four views (Caldwell, Waters, posteroanterior, and lateral) that are technically difficult to perform in children. The Waters view is obtained by angulating the beam in 5-degree increments per year (up to age 6 years) to compensate for the progressive enlargement of the maxillary antra throughout childhood (Fig. 8.10). This approach improves visualization of the maxillary sinuses by projecting them over the petrous pyramids but can create double contours that simulate mucosal thickening. Air fluid levels also can be obscured as a result of beam angulation. Using only the Waters view radiograph has been shown to have 32% false-negative results and 49.2% false-positive results when compared with CT. Abnormalities in the ethmoid and sphenoid sinuses are not detected on a Waters radiograph.[21] Ethmoid disease on the Caldwell projection is limited, and the lateral view for evaluating the sphenoid sinus is of little value in children younger than 4 years.[20,23]

Sinusitis is considered a clinical diagnosis that should not be made on the basis of imaging findings alone.[23] The American

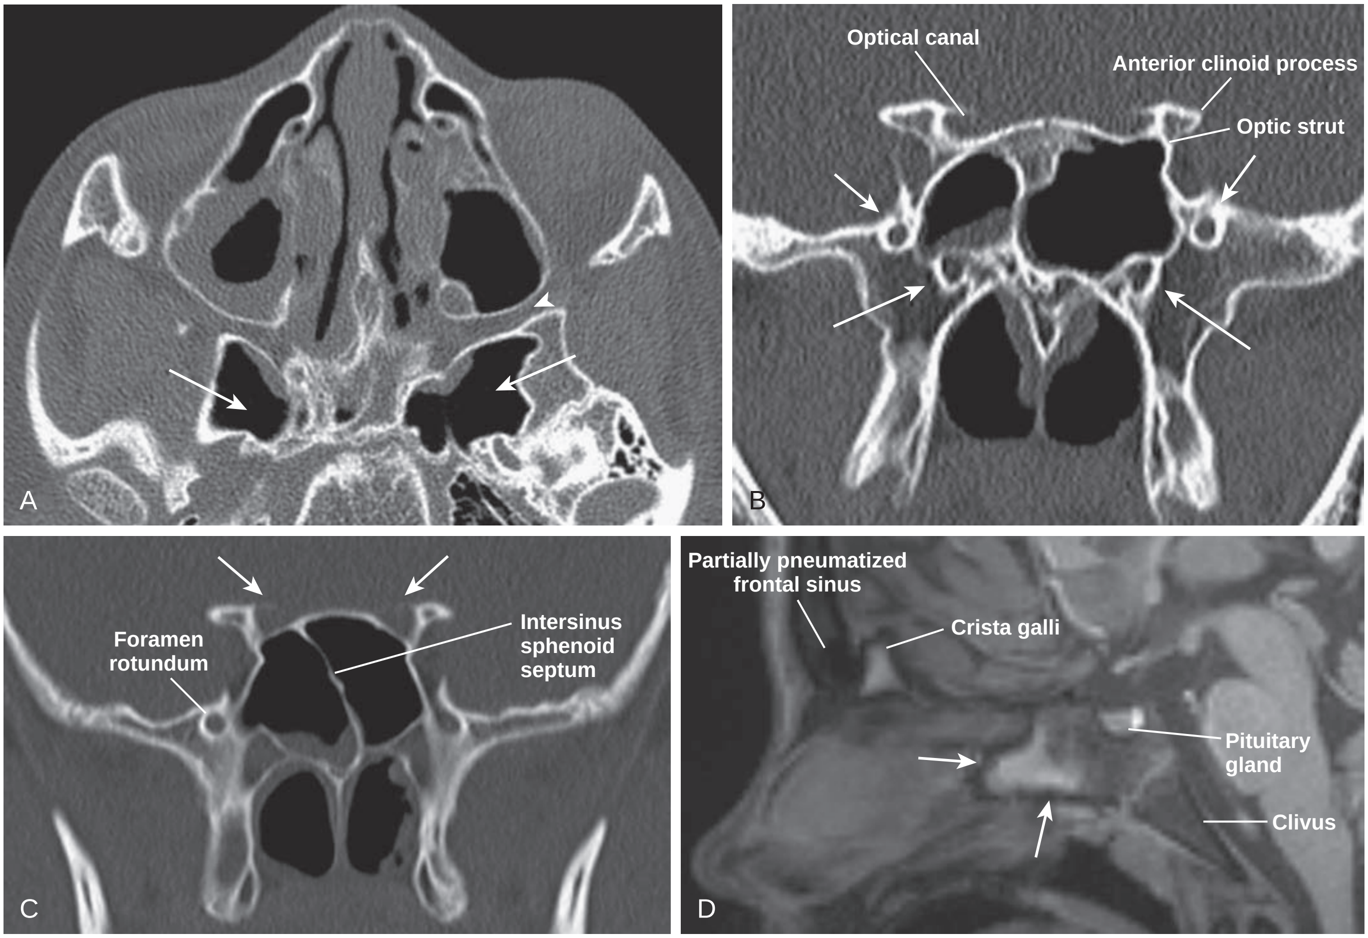

**Figure 8.7. Sphenoid sinus anatomy and variants.** (A) Axial CT image shows hyperpneumatization of the sphenoid sinus involving the pterygoid plates bilaterally *(arrows);* the pterygopalatine fossa *(arrowhead)* also is shown. (B) Coronal CT image shows foramen rotundum *(short arrows)* and the vidian canal *(long arrows)* bilaterally. (C) Coronal CT image shows insertion of the intersinus septum into the right optic canal *(arrows)*. (D) Sagittal T1-weighted MR image demonstrates a nonpneumatized sphenoid sinus in an 11-year-old boy with fatty transformation of its anteroinferior portion *(arrows)*.

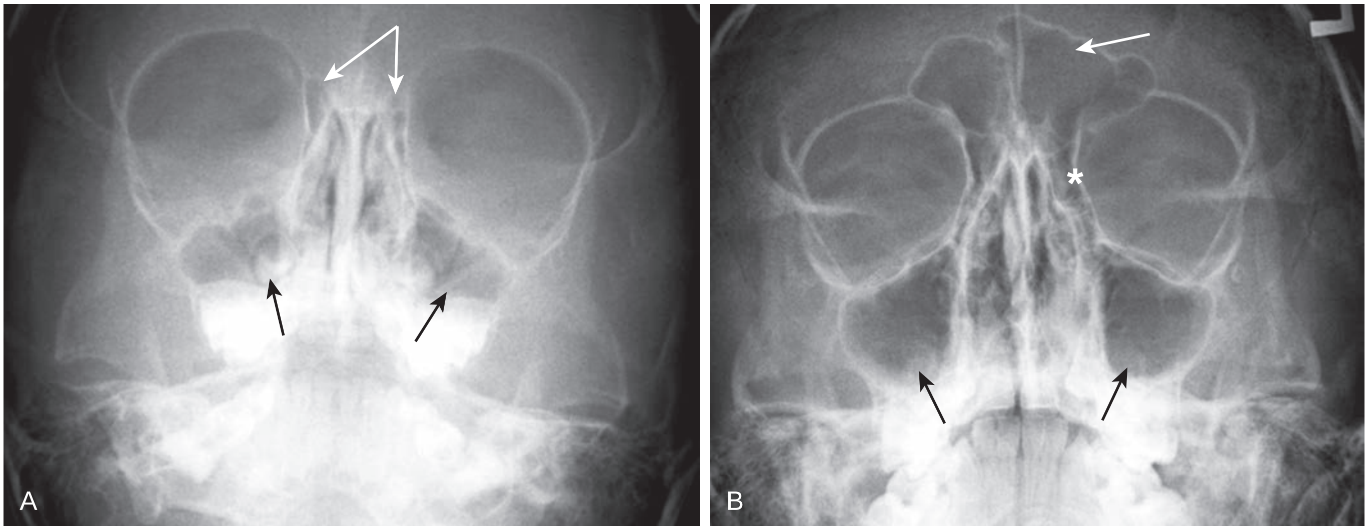

**Figure 8.10. Waters view radiograph.** (A) Maxillary sinuses *(black arrows)* and ethmoid air cells *(white arrows)* in a 3-year-old child. (B) Maxillary sinuses *(black arrows),* frontal sinus *(white arrow),* and ethmoid air cells *(asterisk)* in an 11-year-old child.

College of Radiology does not recommend the use of plain radiography in diagnosing sinusitis in children,[23] and similarly, American Academy of Pediatrics (AAP) guidelines state that plain radiographs are unnecessary for diagnosing sinonasal disease in children younger than 6 years.[7,24] Plain films do not play a role in evaluating sinonasal masses or complications of sinusitis.

## Computed Tomography

CT nicely demonstrates paranasal sinus bony anatomy, soft tissue changes, lesion calcification, and osseous changes. Coronal images best demonstrate the anatomy of the ostiomeatal unit, as well as important anatomic landmarks and variants, effectively providing a road map for functional endoscopic sinus surgery. For these reasons, CT is considered the imaging modality of choice for evaluating inflammatory disease of the paranasal sinuses (i.e., recurrent and chronic sinusitis). CT plays an important role in detecting orbital and intracranial complications of sinusitis. Along with magnetic resonance imaging (MRI), CT is an excellent tool for evaluating sinonasal masses.

Currently, multidetector CT with volume isometric imaging allows axial image acquisition with the patient in a neutral supine position. Images are subsequently reformatted in the coronal and sagittal planes. Slice thickness is usually 2.5 mm, and anatomic coverage extends from the upper teeth to 2 cm above the frontal sinus. If orbital or intracranial complications of sinusitis are suspected clinically, the study should be performed after the intravenous (IV) administration of contrast material, and imaging of the brain should be considered. Images are displayed in both soft tissue and bone algorithms.

Awareness of and concern about the potentially harmful radiation side effects is particularly important in children.[25,26] The practice of the "as low as is reasonably achievable" (ALARA) principle among the radiologic community is critical, with special attention given to CT protocols and parameters.[25,27] In evaluating paranasal sinuses, it is possible to reduce radiation techniques for maxillofacial CT imaging, even to a level comparable to that used for standard radiographic images, without sacrificing diagnostic image quality.[28]

## Magnetic Resonance Imaging

MRI is valuable in evaluating complications of sinusitis (e.g., intracranial extension), as well as inflammatory disease associated with sinus or parasinal neoplasm. Although MRI detects bone marrow involvement, it is less sensitive for bony erosions than CT. Other limitations include its availability, higher costs, and the frequent need for sedation in young children.

The normal nasal cycle of vasodilation and mucosal edema, followed by vasoconstriction and mucosal shrinkage, varies from 50 minutes to 6 hours. The signal intensity during the edematous phase is indistinguishable from that of inflammatory change. As with CT and plain radiographs, sinus MRI typically shows a high incidence of findings in asymptomatic persons (13%–37%) and mucosal thickening of less than 3 mm that is likely insignificant.[5] MRI can differentiate mucosal thickening from sinus secretions (Fig. 8.11).

MRI is very useful in evaluating neoplasms. An estimated 90% to 95% of tumors in the sinuses or nasal cavity exhibit moderately lower signal intensity on T2-weighted images (from hypercellularity) compared with most acute inflammatory diseases (including polyps, mucoceles, and retention cysts), which produce a bright signal on T2-weighted images. However, more mature granulation tissue and fibrosis also have a lower T2 signal, making it difficult to distinguish from tumor. Certain fungal infections, in contrast to other types of acute inflammatory disease, also have a lower T2 signal.

# IMAGING ANATOMY OF THE SINONASAL CAVITIES

## Ostiomeatal Unit

Regarded as an important anatomic region for potential surgical intervention, the ostiomeatal unit is a complex anatomic structure at the crossroads of mucociliary drainage from the frontal, anterior ethmoid, and maxillary sinuses.[29] It includes the uncinate process, infundibulum, ethmoid bulla, hiatus semilunaris, and middle meatus (Fig. 8.12).[16]

The uncinate process arises from the upper medial maxillary wall and defines the wall of the infundibulum.[30] The infundibulum is the channel defined laterally by orbit or Haller cells and medially by the uncinate process. The ethmoid bulla is a dominant middle ethmoid air cell that protrudes inferomedially into the infundibulum and hiatus semilunaris. The hiatus semilunaris is a semilunar region between the tip of the uncinate process and ethmoid bulla.

# CONGENITAL LESIONS OF THE NOSE

## Choanal Atresia

Choanal atresia, the most common congenital abnormality of the nasal cavity, is thought to result from failure of rupture of the oronasal membrane during the sixth week of fetal life. It consists of obstruction of the posterior opening of the nasal cavity, which is mixed bony-membranous in approximately 70% of cases and pure bony atresia in 30% of cases. The existence of a purely membranous atresia is questionable.[31] Choanal atresia can be unilateral (in 50%–60% of cases) or bilateral, and it is twice as common in girls.

***Clinical Presentation.*** Bilateral choanal atresia presents with severe immediate onset of respiratory distress in the newborn, because infants are obligate nasal breathers. Symptoms are aggravated by feeding and relieved by crying. The inability to pass a nasogastric tube in a neonate with well-aerated lungs suggests the diagnosis. Unilateral choanal atresia usually is diagnosed later in childhood and presents with unilateral purulent rhinorrhea.

***Imaging.*** Noncontrast CT is the imaging modality of choice. Nasal secretions should be suctioned before imaging is performed; administration of a nasal topical vasoconstrictor spray helps in reducing mucosal thickening. High-resolution imaging in bone algorithm will aid in delineating the bone margins. Findings consist of narrowing of the posterior choana (<0.34 cm in children <2 years of age) and enlargement and thickening of the vomer (>0.23 cm), which sometimes is fused to the maxilla.[32] Medial bowing and thickening of the posterior aspect of the lateral wall of the nasal cavity also is seen. The nasal cavity often is filled with air, soft tissue, and fluid (Fig. 8.13). CT will identify other causes of bilateral nasal obstruction, such as pyriform aperture stenosis and bilateral nasolacrimal duct (NLD) mucoceles. Bilateral choanal atresia can be associated with other congenital abnormalities in 75% of cases, such as CHARGE syndrome.

***Treatment.*** The oral airway should be secured and surgical correction of bilateral atresia should be performed as soon as possible after diagnosis. Transpalatal or transnasal endoscopic surgical techniques may be used.

## Congenital Nasal Pyriform Aperture Stenosis

Congenital nasal pyriform aperture stenosis is a rare form of nasal obstruction that consists of narrowing of the nasal pyriform aperture as a result of bony overgrowth of the nasal process of the maxilla.[33] It should be suspected in any neonate with upper respiratory obstruction and must be differentiated from choanal atresia and other congenital nasal masses.

***Clinical Presentation.*** Symptoms depend on the severity of the stenosis and are similar to those in patients with choanal

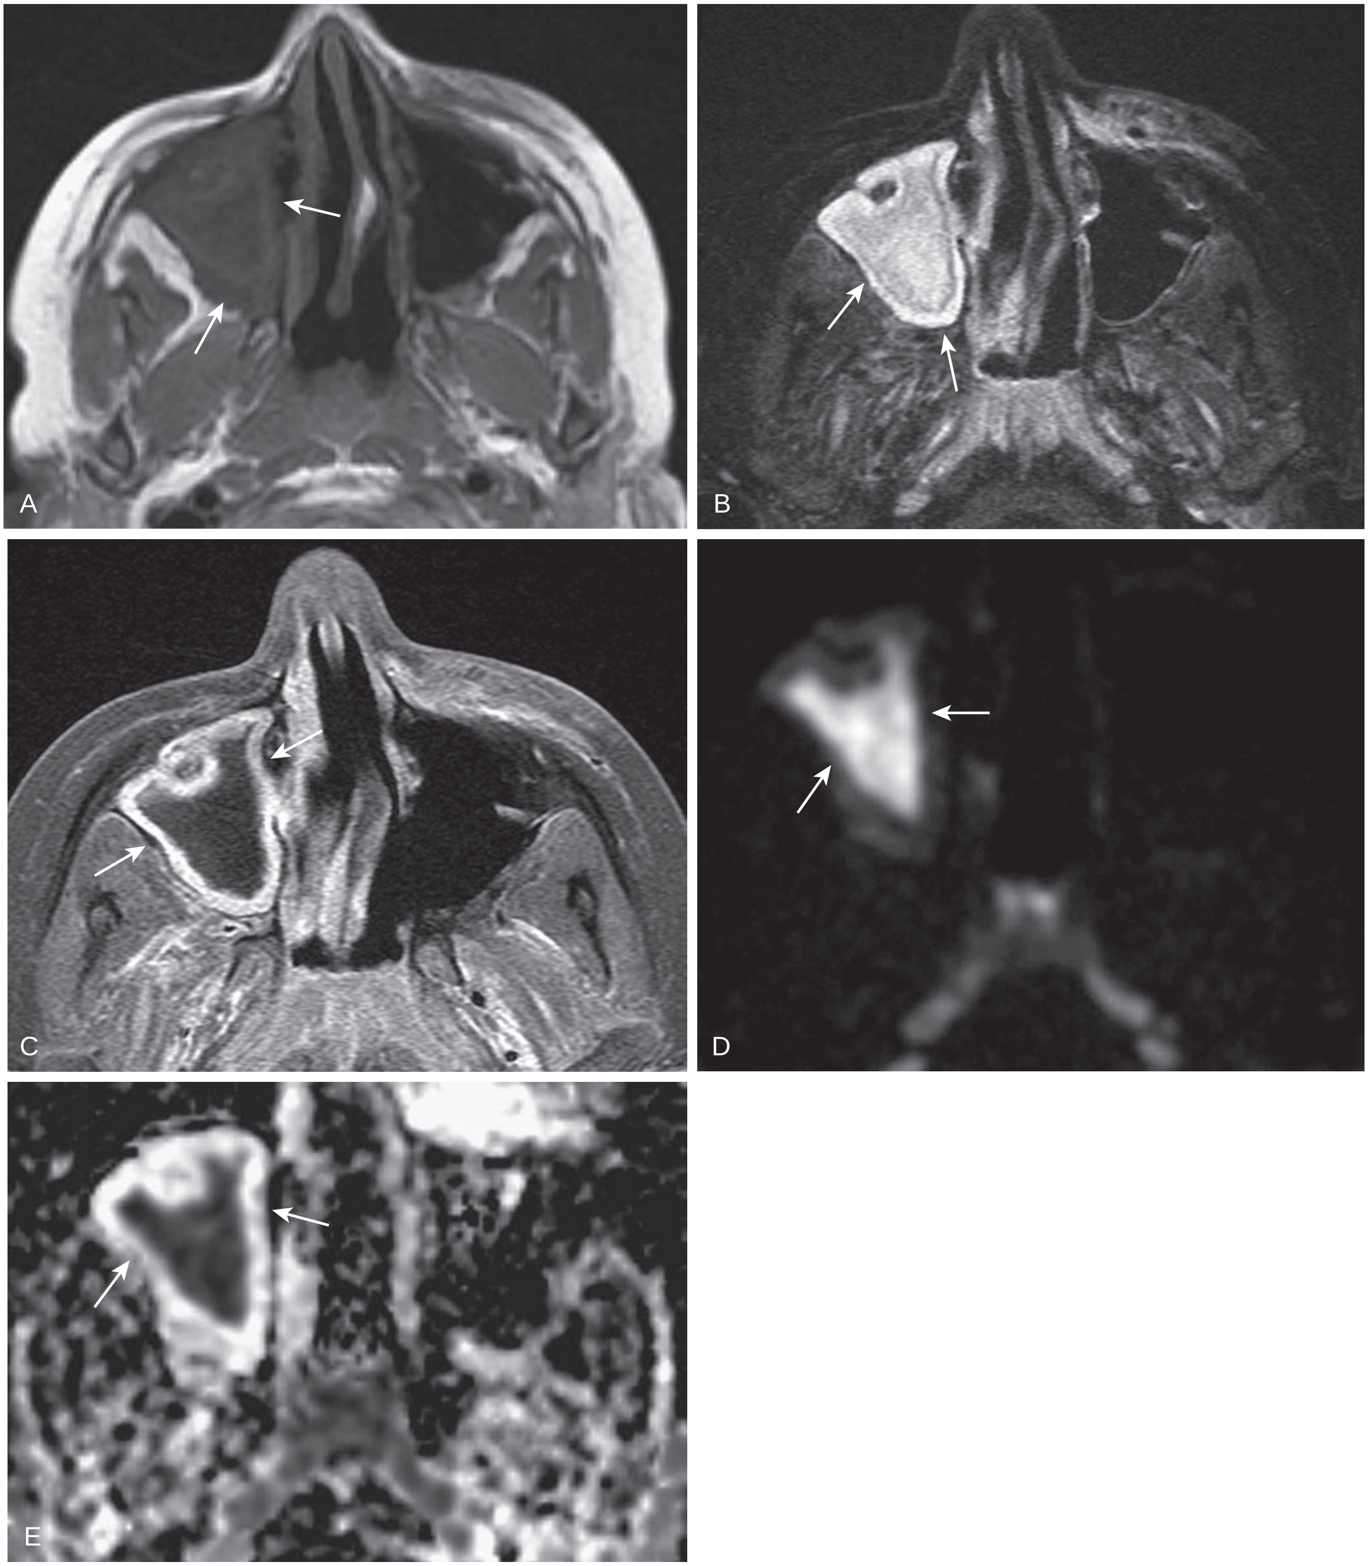

**Figure 8.11. Acute bacterial sinusitis in a 10-year-old boy.** (A) Axial T1-weighted MR image shows hypointense material in the right maxillary sinus *(arrows)*. (B) Axial T2-weighted MR image shows corresponding T2-hyperintense material *(arrows)*. (C) Axial T1-weighted MR image with fat saturation and contrast shows circumferential mucosal enhancementl *(arrows)*. (D and E) Corresponding decreased diffusivity in the right maxillary sinus is shown on diffusion-weighted imaging (D) and apparent diffusion coefficient maps (E) consistent with purulent materiall *(arrows)*.

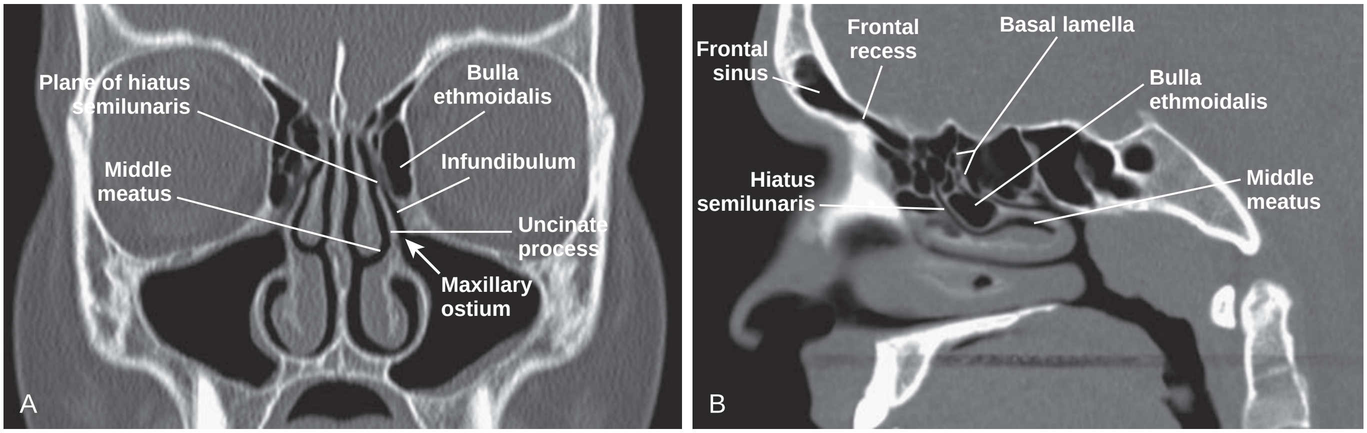

**Figure 8.12. Ostiomeatal unit (OMU).** (A) Coronal CT image shows the OMU components: middle meatus, uncinate process, infundibulum, bulla ethmoidalis, maxillary ostium, and plane of the hiatus semilunaris. (B) Sagittal CT image demonstrates the hiatus semilunaris.

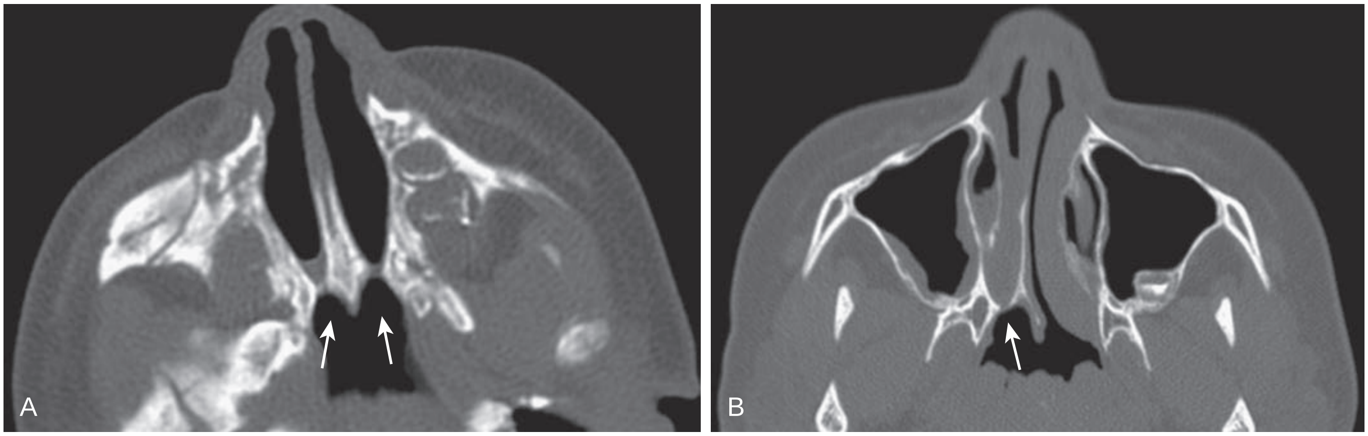

**Figure 8.13. Choanal atresia.** (A) Axial CT image in a 1-day-old neonate with severe respiratory distress shows bilateral bony choanal atresia with retained fluid in the right nasal cavity, medial bowing of the lateral nasal wall, and a thickened vomer *(arrows)*. (B) Axial CT image in a 12-year-old child with chronic nasal obstruction and purulent rhinorrhea shows unilateral (right) bony atresia with fluid in the nasal cavity *(arrow)*.

atresia, including cyanosis in the neonatal period that is exacerbated with feeding and relieved by crying. Congenital nasal pyriform aperture stenosis can present in association with other congenital anomalies such as holoprosencephaly, hypopituitarism, a single mega-incisor, hypotelorism, cleft palate, clinodactyly, or absent olfactory bulbs.[34,35] A central mega-incisor often is associated with intracranial abnormalities, and thus further evaluation with MRI of the brain is indicated in these cases.

***Imaging.*** Congenital nasal pyriform aperture stenosis is confirmed with CT and is characterized by overgrowth of the medial nasal process of the maxilla, resulting in narrowing of the anterior bony nasal cavity, and is usually bilateral. A pyriform aperture of less than 11 mm in a term infant is diagnostic.[33] The choanae are usually normal in caliber, but choanal atresia may coexist.[34] The hard palate is usually hypoplastic and triangular-shaped with the presence of a median maxillary single incisor tooth (mega-incisor) (Fig. 8.14).

***Treatment.*** Treatment consists of securing the airway, with surgical intervention required in severe cases.

## Congenital Nasolacrimal Duct Mucocele

Congenital NLD mucocele consists of a cystic dilatation of the NLD due to obstruction of its distal opening. This results in the classic triad: dacryocystocele (dilated nasolacrimal sac) located in the medial canthus, dilated NLD with expansion of its osseous canal, and an intranasal mass (mucocele). In contrast, a classic dacryocystocele results from proximal obstruction secondary to failure of canalization during the sixth month of fetal life. Congenital NLD mucoceles and classic dacryocystoceles can be unilateral or bilateral.

***Clinical Presentation.*** A dacryocystocele presents clinically as a round, bluish, medial, canthal mass usually identified at birth, and may vary in size from 5 to 10 mm. The classic NLD mucocele triad usually presents in the neonatal period as an intranasal mass causing airway obstruction if it is bilateral. Neonates also can present with difficulty breathing while feeding.

***Imaging.*** CT findings include a well-circumscribed, rounded, unilateral or bilateral hypodense "cystic" lesion in the medial canthus and/or anteroinferior nasal cavity. The cyst can communicate with an enlarged NLD and canal (Fig. 8.15A). Large cysts may cause nasal septal deviation. Association with choanal atresia has been described. Contrast-enhanced CT will show no enhancement or minimal thin wall enhancement. Infected dacryocystoceles present with thick rim enhancement.

MR findings include a T1-weighted hypointense and T2-weighted hyperintense well-circumscribed mass at the medial canthus and/or nasal cavity with no enhancement or minimal wall enhancement

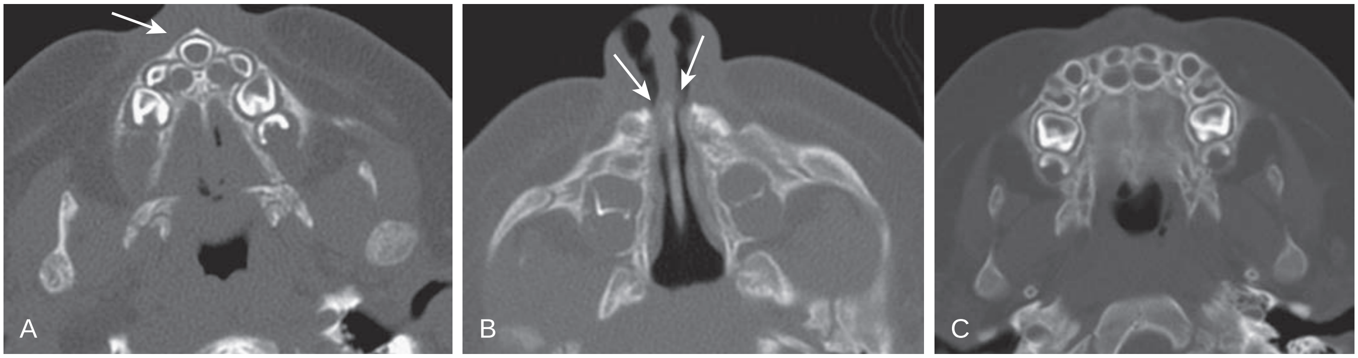

**Figure 8.14. Congenital nasal pyriform aperture stenosis in a 1 1/2-month-old infant with episodes of respiratory distress during breastfeeding.** (A) Axial CT image shows a triangular hard palate and solitary central maxillary mega-incisor *(arrow)*. (B) An axial CT image shows narrowing of the anterior and inferior nasal passages *(arrows)*. (C) Axial CT of a normal infant maxilla for comparison.

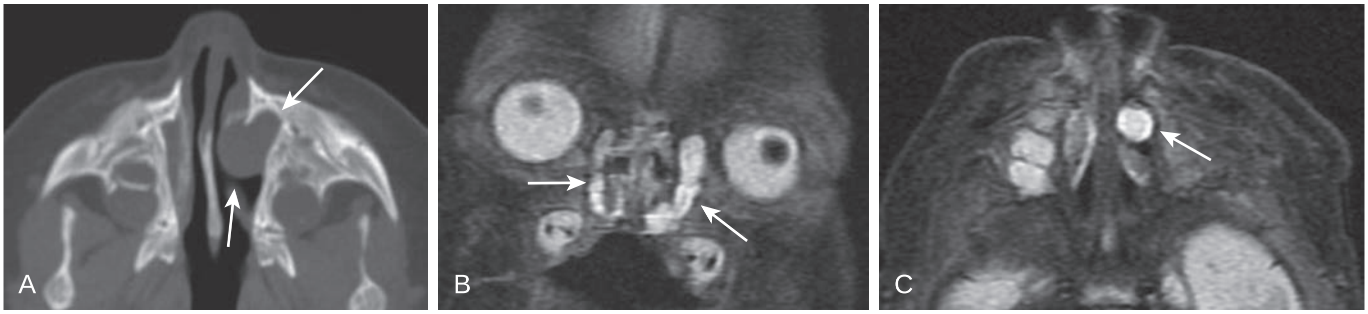

**Figure 8.15. Congenital nasolacrimal duct mucoceles in a 1-day-old neonate.** (A) Axial CT image shows a left nasal round soft tissue mass with enlargement of the ipsilateral nasolacrimal duct and canal *(arrows)*. (B and C) Coronal and axial fast spin-echo inversion recovery MR images show bilateral cystic enlargement of the nasolacrimal sacs and ducts *(arrows)*.

(Figs. 8.15B and C). NLD mucoceles and dacryocystoceles can be diagnosed prenatally with fetal ultrasound or MRI.[36]

***Treatment.*** Congenital dacryocystoceles may resolve with conservative treatment, but many become infected and require treatment; most need surgical intervention.[36]

## OTHER CONGENITAL/DEVELOPMENTAL NASAL MIDLINE MASSES

Frontonasal or intranasal developmental masses that result from anomalies of the anterior neuropore can present similarly and should be in the differential diagnosis. These include anterior cephaloceles, nasal neuroglial heterotopia, and nasal dermoids.

Cephaloceles consist of herniation of intracranial contents (meninges, cerebrospinal fluid [CSF], and brain) through a skull defect that occurs from failure of neural tube closure and are classified by location. Anterior cephaloceles include subtypes such as basal, frontoethmoidal, and nasopharyngeal. Frontoethmoidal (sincipital) cephaloceles present as an external nonenhancing soft tissue mass contiguous with the intracranial brain that extends through a bony defect. The adjacent meninges may enhance. These include frontonasal, nasoethmoidal, and naso-orbital cephaloceles. On the other hand, basal cephaloceles are occult, result from failed ossification of neural crest cells through the osseous defect, and may contain pituitary tissue, optic nerves, or vascular structures (e-Fig. 8.16E). These present with nasal or nasopharyngeal obstruction and include transethmoidal, sphenoethmoidal, and sphenopharyngeal types (e-Fig. 8.16A).

Nasal neuroglial heterotopia is a nonenhancing extranasal (along the nasal dorsum) or intranasal solid soft tissue mass without connection between the mass and intracranial contents. It consists of sequestered dysplastic, nonneoplastic neurogenic brain tissue (e-Figs. 8.16B and C).

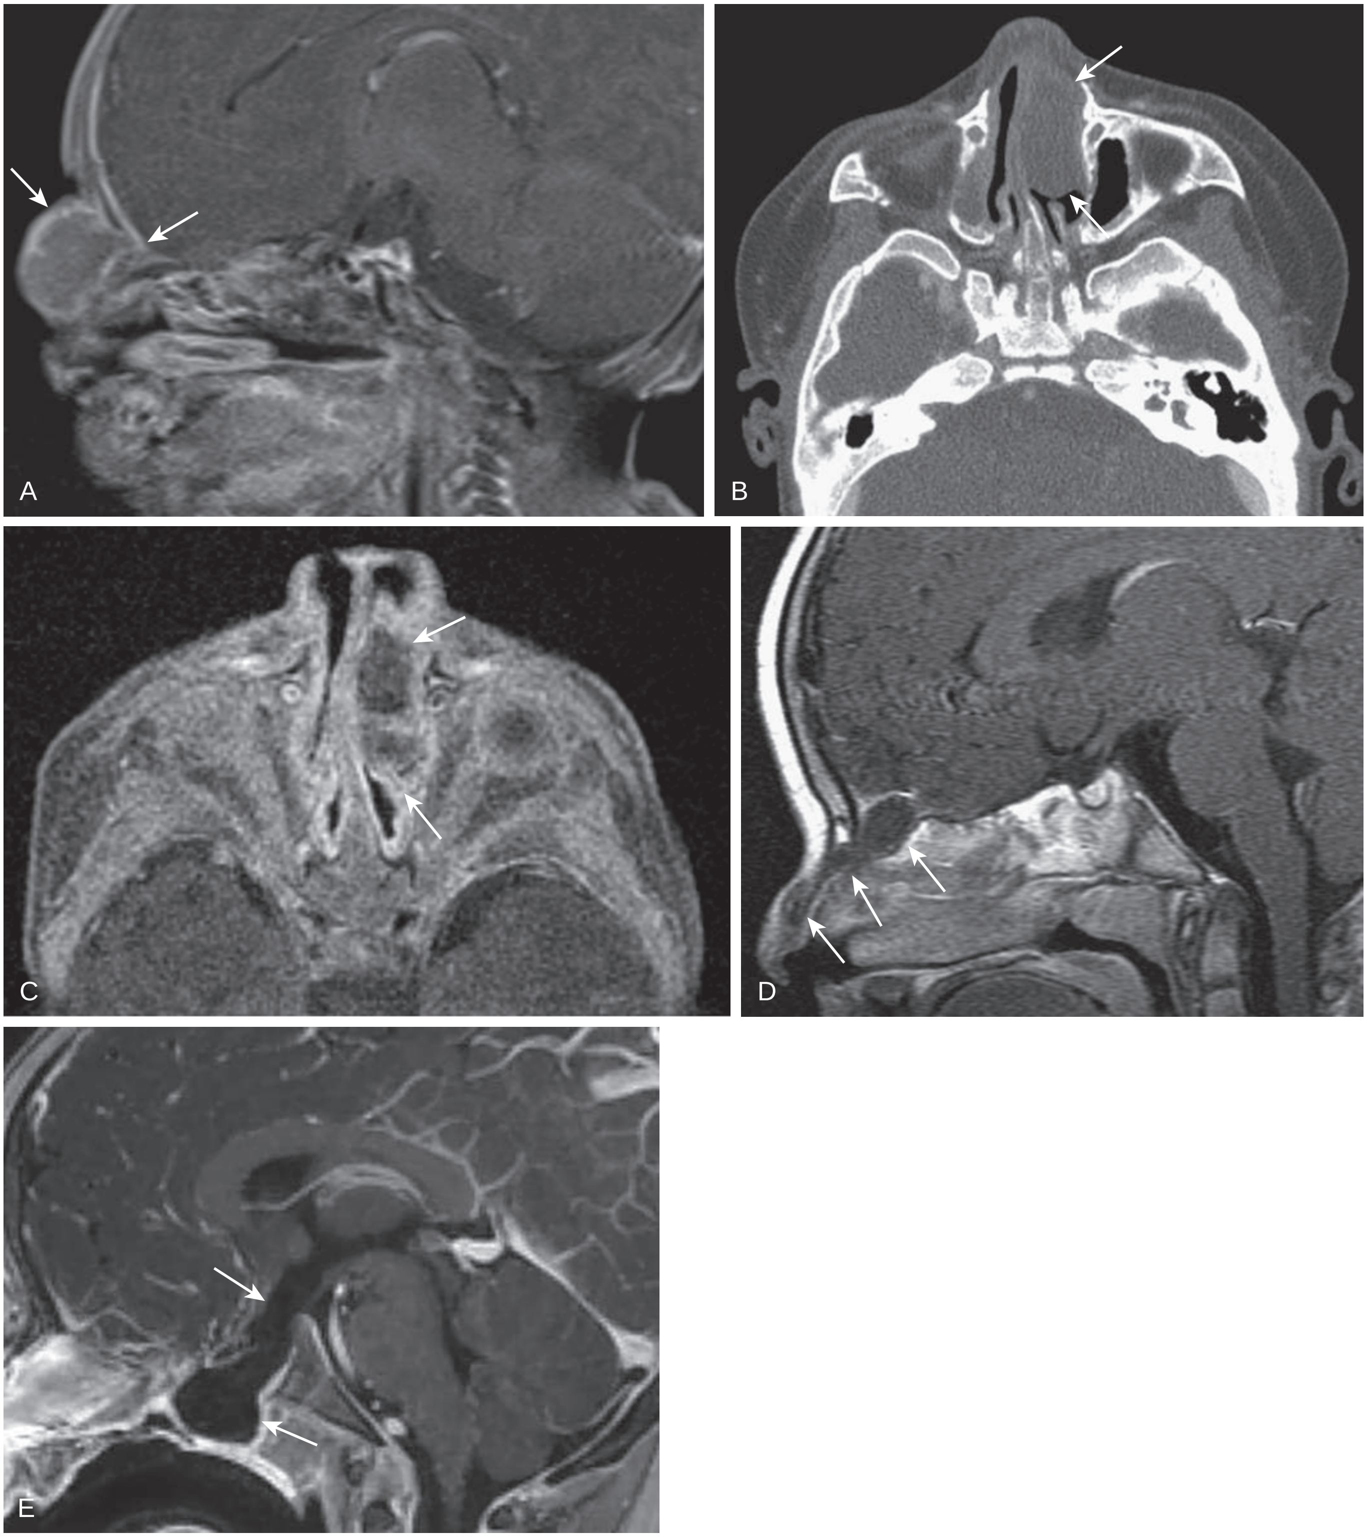
Nasal dermoid may present as an enhancing tract or fistula from the tip of the nose to the foramen cecum (intracranially) just anterior to the crista galli with or without a dermoid/epidermoid cysts along its tract (e-Fig. 8.16D). On diffusion-weighted imaging, the cyst can demonstrate restricted diffusion.

## IMAGING OF INFECTIOUS AND INFLAMMATORY SINONASAL DISEASE

### Sinusitis

Rhinosinusitis is characterized by inflammation of the sinonasal mucosa, usually after an upper respiratory infection (URI). Children contract an average of three to eight viral URIs per year that are generally self-limited, with no antimicrobial therapy required.[37] However, acute bacterial sinusitis (ABS) can complicate viral rhinosinusitis in up to 6% to 7% of affected children.[24] Other predisposing conditions for sinusitis are allergic rhinitis, immunoglobulin deficiency, immotile cilia syndrome, cystic fibrosis (CF), and anatomic abnormalities causing obstruction of the drainage pathways. The AAP has defined five categories of bacterial rhinosinusitis: acute, subacute, recurrent acute, ABS superimposed on chronic disease, and chronic sinusitis.[24]

Bacterial sinusitis remains a challenging clinical diagnosis because the signs and symptoms of sinusitis typically seen in adults are noted less frequently in children. Because specific clinical signs in children are generally few, and symptoms overlap between ABS



**e-Figure 8.16. Developmental nasal midline masses.** (A) Naso-orbital cephalocele in a newborn. Sagittal contrast-enhanced T1-weighted MR image shows a nonenhancing frontonasal mass with intracranial dural connection *(arrows)*. (B) Nasal glial heterotopia in a neonate *(arrows)*. Axial contrast-enhanced CT image shows a nonenhancing left intranasal mass. (C) Axial contrast-enhanced T1-weighted MR image in the same patient shows a T1-hypointense nonenhancing mass without intracranial connection *(arrows)*. (D) Nasal dermoid cysts in a 3-year-old. Sagittal contrast-enhanced T1-weighted MR image shows a dermal sinus tract with nasal and intracranial dermoid cysts *(arrows)*. (E) Basal cephalocele in a 3-year-old. Sagittal contrast-enhanced T1-weighted MR image shows a large nasopharyngeal CSF-filled mass lesion *(top arrow),* which extends through the sphenoid bone into the nasopharynx with peripheral meningeal enhancement *(bottom arrow)*.

and uncomplicated viral URI, it is often difficult to differentiate these two. A presumptive clinical diagnosis of ABS should be made when a child with an acute URI presents with the following: persistent illness, that is, nasal discharge (of any quality) or daytime cough, or both lasting more than 10 days without improvement; or worsening course, that is, worsening or new onset of nasal discharge, daytime cough, or fever after initial improvement; or severe onset, that is, concurrent fever (temperature ≥39°C/102.2°F) and purulent nasal discharge for at least 3 consecutive days.[24,37]

The gold standard for diagnosis of acute or chronic sinusitis remains aspiration from the sinus cavities with the recovery of bacteria in a high density (>10 colony-forming units/mL).[24] However, this method is impractical, invasive, and time-consuming and is rarely performed.

## Acute Sinusitis

The most common causative microorganisms of ABS are *Streptococcus pneumoniae* (30% of ABS cases), nontypeable *Haemophilus influenzae* (30%), and *Moraxella catarrhalis* (10%). *Staphylococcus aureus* is a rare cause of ABS but is isolated in children with orbital and intracranial complications of ABS.

The updated AAP practice guideline for the diagnosis and management of ABS in children and adolescents contains changes including a clinical presentation designated "worsening course," inclusion of new data on the effectiveness of antibiotics in children with acute sinusitis, and a review of evidence indicating that imaging is not necessary to identify those children who will benefit from antimicrobial therapy.[24]

***Imaging.*** Imaging of the paranasal sinuses in children with uncomplicated ABS is unnecessary because the results will not affect treatment decisions. Imaging cannot differentiate between viral and bacterial sinusitis. Mucosal abnormalities are reported routinely on radiographs, CT, and MRI in asymptomatic patients who undergo imaging for other indications. The incidence of abnormal findings is very high in infants and young children, and soft tissue changes can persist for months on MRI after an acute infection.[23] For these reasons, clinical correlation is vital when evaluating imaging findings in children.

***Treatment.*** A course of antibiotics is recommended to speed resolution of symptoms and to prevent possible complications. In uncomplicated ABS, amoxicillin remains the antimicrobial agent of choice. Amoxicillin-clavulanate is indicated in children with moderate to severe illness or when resistance is suspected, children less than 2 years of age, children that attend child care, or recently treated patients. Reassessment should occur if there is symptom progression worsening or failure to improve within 72 hours of initial management.[24]

## Chronic Sinusitis

The AAP defines chronic sinusitis as episodes of inflammation of the paranasal sinuses lasting more than 90 days. Patients have persistent residual respiratory symptoms such as cough, rhinorrhea, and/or nasal obstruction. Children who experience chronic sinusitis usually are older (at least 4–7 years of age) and often have a history of recurrent ABS. Other associated factors are recurrent viral URIs, allergic and nonallergic rhinitis, CF, immunodeficiency, ciliary dyskinesia, sinus and facial anatomic abnormalities, and gastroesophageal reflux.[38]

Clinical findings are similar to those of acute infection but are characterized mostly by a continuous nasal discharge and congestion with a persistent nighttime cough. Other symptoms include chronic headache, chronic halitosis, intermittent fever, sleep deprivation, and general malaise. In chronic sinusitis, *Staphylococcus aureus*, coagulation negative *Staphylococcus*, anaerobic organisms, gram-negative bacteria, and fungi are the most commonly encountered colonizing organisms.[38]

***Imaging.*** Radiography can show mucosal thickening or sinus opacification, and occasionally, sclerotic, thickened walls. CT findings include peripheral mucosal thickening in a hypoaerated or contracted sinus with sclerotic thickened walls, although these findings are uncommon in children. Calcifications may be seen occasionally, and sinonasal polyposis also may be present. Secretions can be dense depending on their content. MR findings include mucosal thickening that enhances with administration of contrast material. Retained secretions will vary in signal intensity depending on content (see Fig. 8.11). Desiccated secretions are hypointense on T2-weighted imaging.

***Treatment.*** Initial trial therapy includes environmental control, allergic therapy if indicated, antibiotics for 21 days directed to resistant organisms, nasal saline solution irrigation, and topical nasal steroids. Second-line therapy includes oral decongestants and oral steroids. Initial surgical therapies include adenoidectomy, sinus lavage, and, less frequently, balloon catheter dilation and endoscopic sinus surgery (ESS). In the case of failed initial surgical treatment, ESS is performed in most patients (85%) as definitive therapy.[39]

## Complications of Rhinosinusitis

Orbital and intracranial complications of rhinosinusitis can result from delayed diagnosis and treatment, antibiotic-resistant or aggressive organisms, or incomplete treatment. Signs and symptoms of orbital complications include periorbital edema, proptosis, chemosis, decreased visual acuity, and/or limited ocular motility. Potential intracranial complications should be suspected when a patient has a history of acute sinusitis combined with severe intractable headache, an altered level of consciousness, focal neurologic deficits, or signs of meningitis.[40]

Orbital complications usually result from the spread of ethmoid infection that occurs via valveless ethmoid veins that traverse the lamina papyracea. Extension of disease also can arise (in order of frequency) from the sphenoid, frontal, and maxillary sinuses. Complications include orbital cellulitis with inflammatory edema, preseptal cellulitis, postseptal cellulitis, subperiosteal abscess (Fig. 8.17), orbital abscess (e-Fig. 8.18), optic neuritis, and cavernous sinus thrombosis.

Intracranial complications include epidural empyema, subdural empyema, meningitis, cerebritis, and parenchymal abscess (e-Fig. 8.19). Subgaleal involvement, such as with Pott puffy tumor and

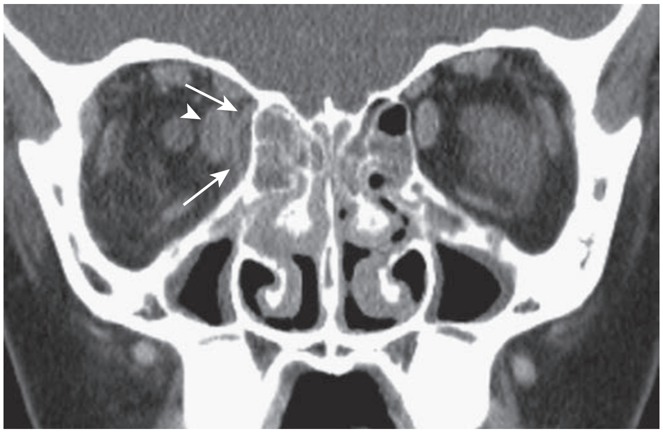


**Figure 8.17. Orbital subperiosteal abscess in a 9-year-old girl.** Coronal contrast-enhanced CT image shows a small, low-attenuation, rim-enhancing fluid collection consistent with an abscess *(arrows)* in the medial aspect of the orbit with mass effect on the medial rectus muscle *(arrowhead),* which is thickened. Bilateral ethmoid sinus disease with infiltration of the right retro-orbital fat is demonstrated.

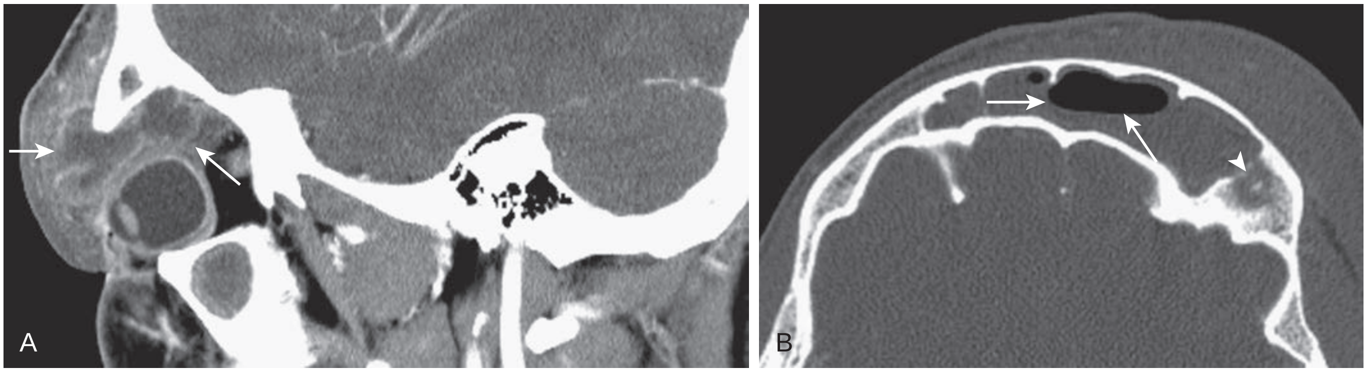
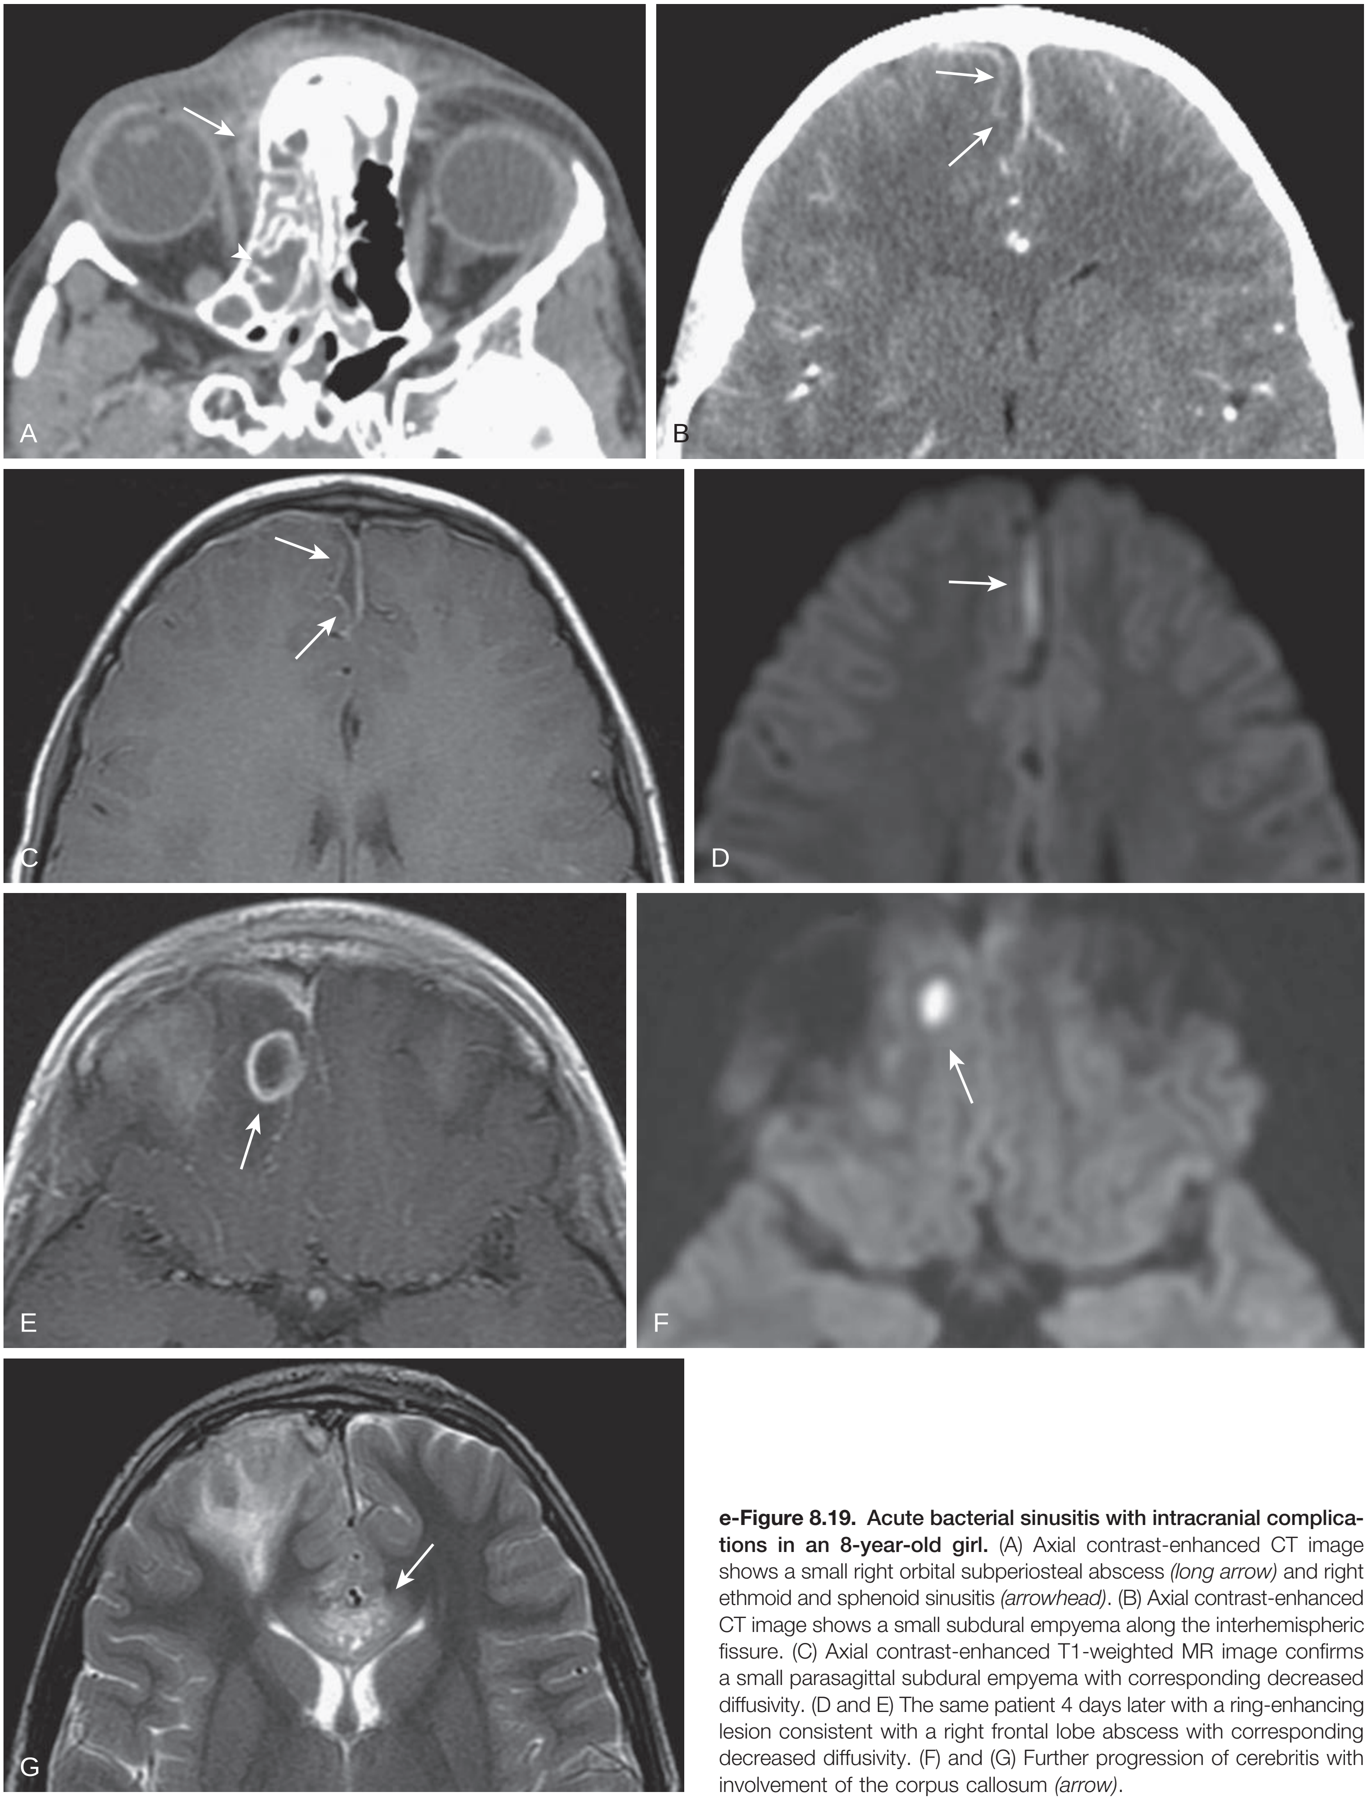


**e-Figure 8.18. Intraorbital abscess and frontal bone osteomyelitis in a 14-year-old boy.** (A) Sagittal reformat contrast-enhanced sagittal CT image shows a large, multiloculated, intraorbital abscess with significant effect of the mass on the globe *(arrows)*. (B) Axial CT image shows an osteolytic lesion in the frontal bone consistent with osteomyelitis *(arrowhead)* and an air-fluid level in the frontal sinus *(small arrows)*.



**e-Figure 8.19. Acute bacterial sinusitis with intracranial complications in an 8-year-old girl.** (A) Axial contrast-enhanced CT image shows a small right orbital subperiosteal abscess *(long arrow)* and right ethmoid and sphenoid sinusitis *(arrowhead)*. (B) Axial contrast-enhanced CT image shows a small subdural empyema along the interhemispheric fissure. (C) Axial contrast-enhanced T1-weighted MR image confirms a small parasagittal subdural empyema with corresponding decreased diffusivity. (D and E) The same patient 4 days later with a ring-enhancing lesion consistent with a right frontal lobe abscess with corresponding decreased diffusivity. (F) and (G) Further progression of cerebritis with involvement of the corpus callosum *(arrow)*.

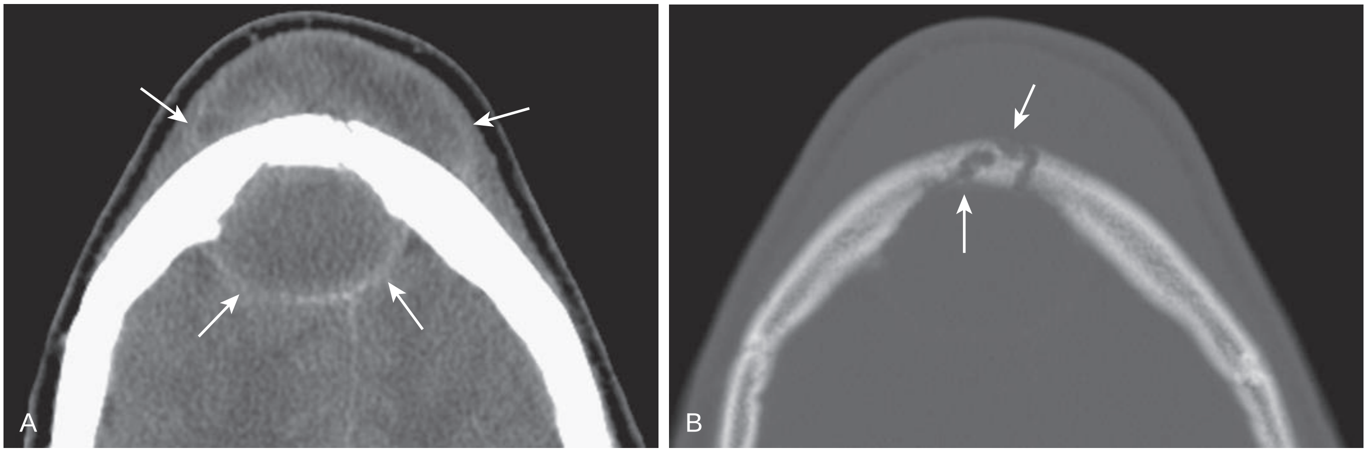


**Figure 8.20. Pott puffy tumor and epidural abscess in a 16-year-old boy.** (A) Contrast-enhanced CT image in a soft tissue window shows a large subperiosteal abscess *(top arrows)* and a large epidural abscess *(bottom arrows)*. (B) Axial CT image in a bone window shows erosion of the frontal bone consistent with osteomyelitis *(arrows)*.

osteomyelitis, also can occur (Fig. 8.20). Vascular complications are infrequent and include mycotic aneurysm, stenosis of the cavernous segment of the internal carotid artery (which, in very rare instances, can result in brain infarction[41]), and venous sinus thrombosis. Superior sagittal thrombosis usually results from frontal sinusitis, whereas sigmoid sinus thrombosis and cavernous sinus thrombosis are associated more often with sphenoid sinusitis.

***Imaging.*** Imaging enables diagnosis and accurate presurgical planning when necessary. For the initial evaluation, contrast-enhanced CT is the imaging modality of choice and should include both the paranasal sinuses and brain. Noncontrast CT should not be performed because it increases the radiation dose without providing any additional diagnostic information. CT can demonstrate fluid collections with rim enhancement consistent with subperiosteal abscesses (see Fig. 8.17) and bone erosion of osteomyelitis as seen with Pott puffy tumor (extracranial subperiosteal abscess from frontal sinusitis) (see Fig. 8.20).[42,43]

MRI is indicated to further assess known or suspected intracranial extension of disease and should include imaging of the brain, sinuses, and orbits. MRI protocols for the brain should include diffusion and contrast-enhanced sequences and should evaluate for venous thrombosis. MRI protocols for the paranasal sinuses and orbits should include high-resolution axial and coronal images before and after administration of gadolinium. MRI is more sensitive than CT in the assessment of leptomeningeal enhancement, small extraaxial fluid collections, and parenchymal abnormalities such as cerebritis and cerebral abscess (see e-Fig. 8.19E–G). MRI also can detect early stages of osteomyelitis by demonstrating bone marrow edema with associated contrast enhancement. Diffusion-weighted imaging will show restricted diffusion of fluid collections with purulent contents (see Fig. 8.11).

Subperiosteal abscesses appear hypointense on T1-weighted imaging and hyperintense on T2-weighted imaging with peripheral contrast enhancement. Signs of cavernous sinus thrombosis include enlargement or heterogeneous enhancement of the cavernous sinus with associated enlargement or thrombosis of the superior ophthalmic vein (Fig. 8.21). Subdural and epidural empyemas appear as T1-hypointense and T2-hyperintense fluid collections with adjacent dural enhancement and central decreased diffusivity as a result of the presence of purulent material (see e-Figs. 8.19B through D). Cerebritis appears as a poorly defined area of T2 prolongation without ring enhancement, whereas a cerebral abscess will present as a ring-enhancing lesion with central decreased diffusivity and perilesional edema (see e-Figs. 8.19E and F).

***Treatment.*** Treatment includes combinations of systemic intravenous antibiotics and surgical interventions such as drainage of the sinuses, functional endoscopic sinus surgery, and craniotomy. Because of the high incidence of seizures associated with intracranial abscess, prophylactic anticonvulsant therapy is recommended.[40]

## Sinonasal Disease in Cystic Fibrosis

CF is caused by a genetic defect in the long arm of chromosome 7, which affects the protein that regulates transmembrane passage of chloride and causes dysfunction of multiple organs and systems.[44] High concentrations of chloride, mucus thickness, and reduction of mucociliary clearance predisposes to inflammation and chronic infection of the respiratory tract. Nearly all persons with CF present clinically with nasal obstruction and chronic rhinosinusitis.[45] The most common colonizing organisms in order of frequency are *Pseudomonas aeruginosa*, *S. aureus*, and *Streptococcus viridans*.[46]

***Imaging.*** CT is the imaging modality of choice for evaluating sinus disease in patients with CF and will nearly always show abnormalities. Findings include mucosal thickening and sinonasal polyposis. The incidence of nasal polyposis in children with CF varies between 10% and 86%.[47–49] High-attenuation material often is present in the sinus cavities, consistent with inspissated secretions (Fig. 8.22). However, superimposed fungal infection has a similar appearance and cannot be excluded by imaging. Bony sclerosis and thickening of the sinuses can be seen in older patients. Frontal sinus hypoplasia or aplasia is a common finding and may be a result of chronic obstruction. The severity of the imaging findings does not necessarily correlate with the severity of symptoms.[45]

***Treatment.*** Medical and surgical treatment depends on symptoms and the overall condition of the patient, including pulmonary status and infection frequency. Not all patients will require surgery.[50] Imaging findings of CF cannot be differentiated from other causes of chronic sinusitis such as allergic sinusitis with polyposis or fungal allergic sinusitis.

## Allergic Sinusitis

It is estimated that allergic rhinosinusitis affects about 10% of the population. In the United States, the most common form is seasonal pollinosis, resulting from an immunoglobulin E reagin–antibody reaction (type I immunologic disorder), which manifests clinically with sneezing, nasal obstruction, and rhinorrhea. This condition can result in hypertrophic, thickened, and redundant

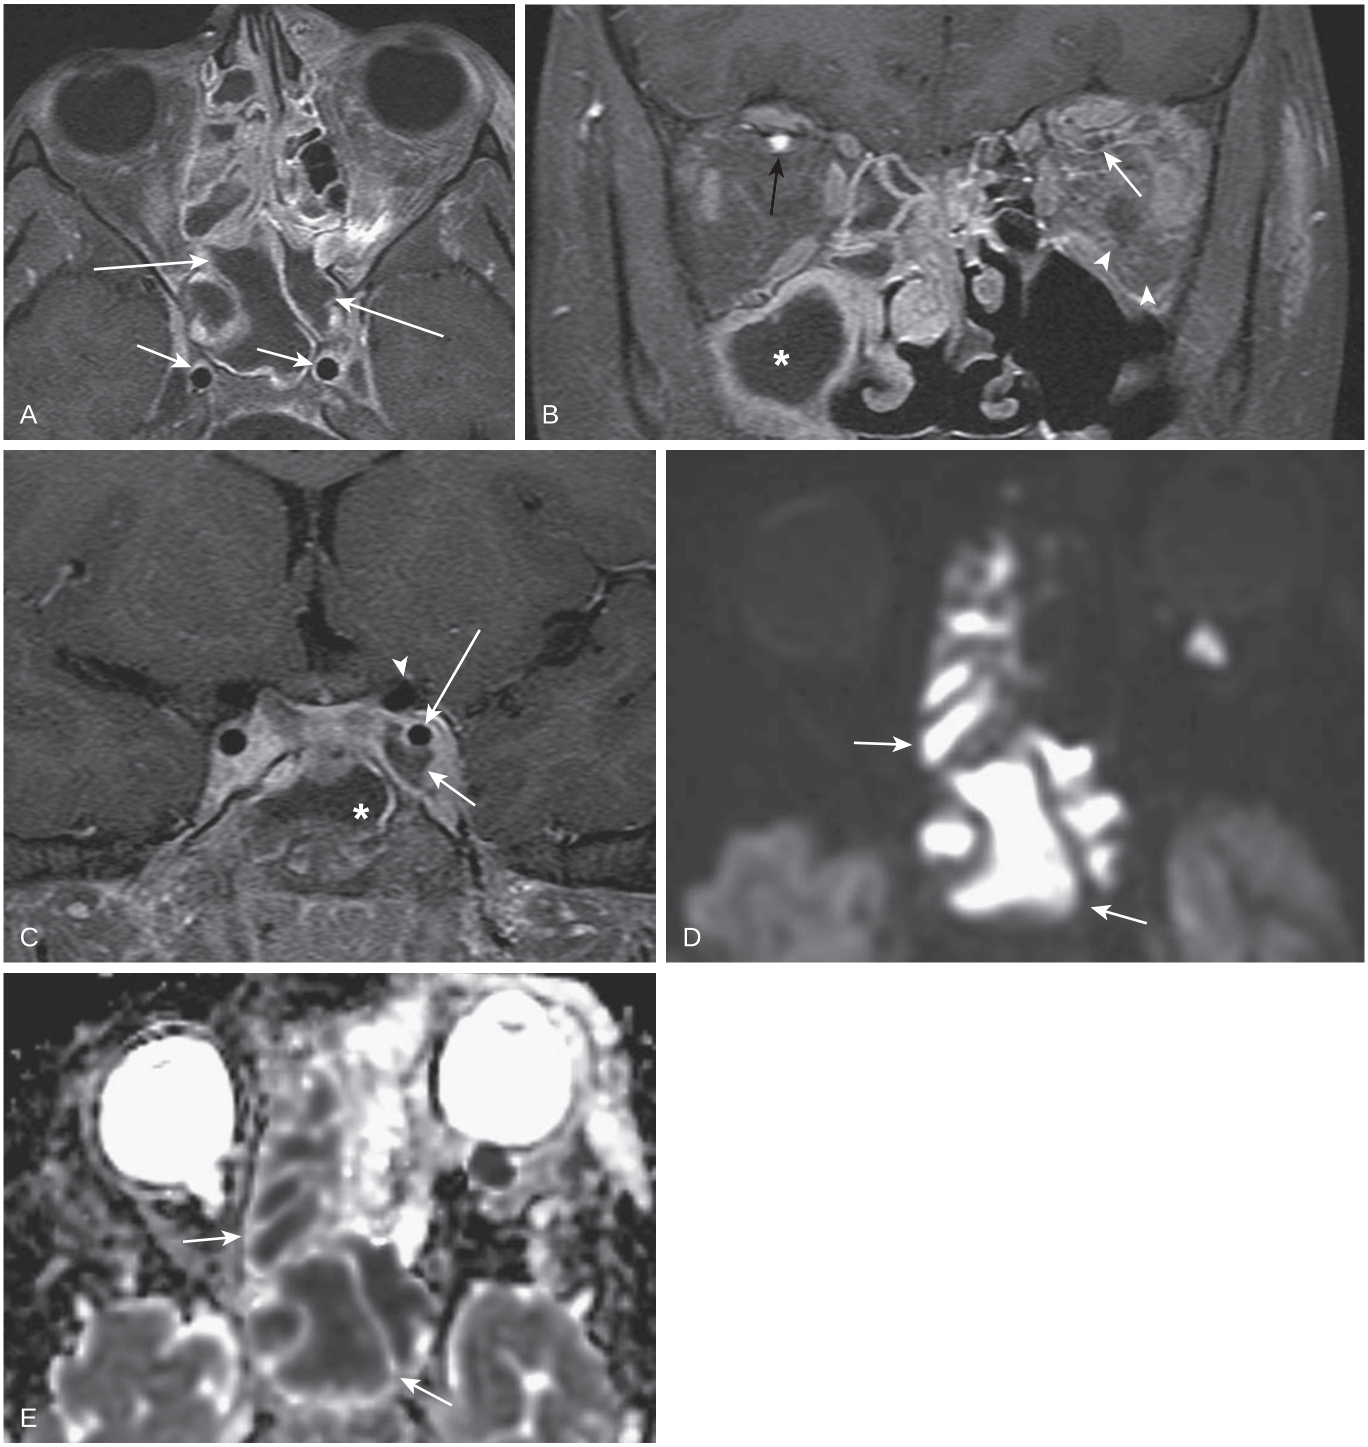

**Figure 8.21. Sinusitis with a left periorbital abscess and cavernous sinus thrombosis in a 10-year-old boy.** (A) Axial contrast-enhanced fat-saturated T1-weighted MR image shows hypointense fluid within the ethmoid and sphenoid sinuses with circumferential mucosal enhancement *(long arrows)* and normal flow voids of the cavernous internal carotid artery (ICA) segments *(short arrows)*. (B) Coronal fat-saturated T1-weighted MR image shows a thrombus in the left superior ophthalmic vein *(white arrow),* normal enhancement of the right superior ophthalmic vein *(black arrow),* and inflammatory changes in the retro-orbital fat *(arrowheads)*. The right maxillary sinus is fluid-filled *(asterisk)*. (C) Coronal fat-saturated T1-weighted MR image shows a thrombus in the left cavernous sinus *(bottom arrow)* and normal flow void of the left ICA cavernous segment *(long arrow)* and left ICA supraclinoid segment *(arrowhead)*. A fluid-filled sphenoid sinus is shown *(asterisk)*. Corresponding restricted diffusion on diffusion-weighted imaging (D) and apparent diffusion coefficient maps (E) are consistent with purulent material *(arrows)*.

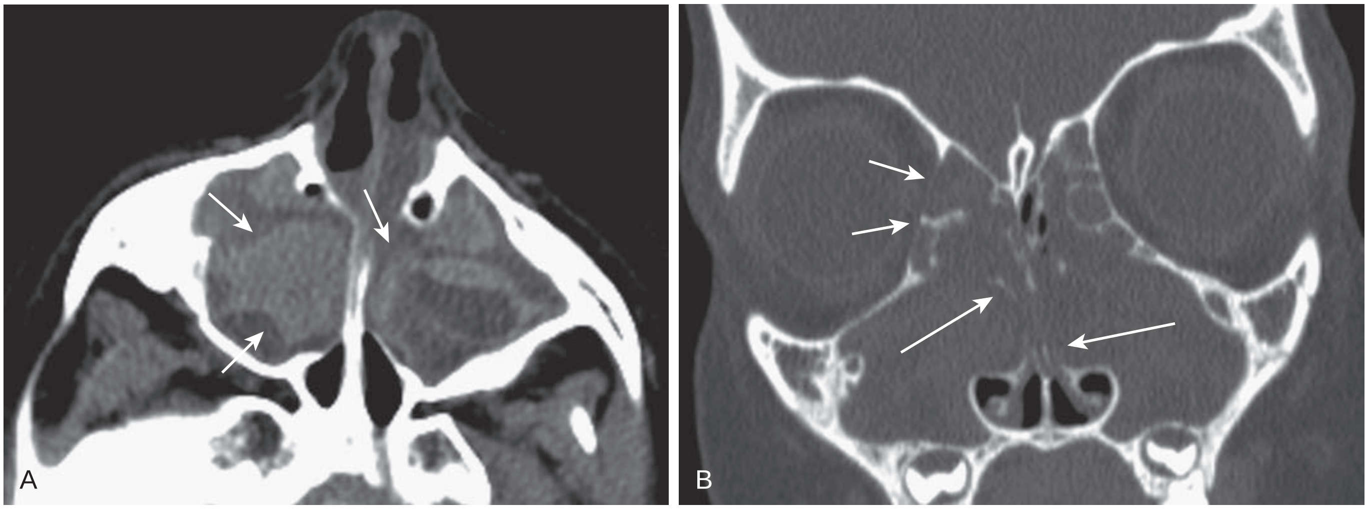

**Figure 8.22. Cystic fibrosis in an 8-year-old child.** (A) Axial CT image shows high attenuation secretions in the maxillary sinuses *(arrows)*. (B) Coronal CT image shows polyps causing expansion of the sinuses *(short arrows)* and nasal cavity with demineralization of septations *(long arrows)*.

mucosa, which is prone to bacterial infection. Allergic sinusitis often coexists with chronic asthma, and 30% of patients will present with polyps. Conversely, up to 80% of patients with polyps have asthma.[51,52] The association of allergic asthma, allergy to aspirin, and aggressive polyposis is known as Samter triad (e-Fig. 8.23). Polyps in this condition can be destructive and invade the anterior cranial fossa.[5]

## Fungal Rhinosinusitis Disorders

Fungal infections can cause both acute and chronic rhinosinusitis. These infections have been classified into four clinicopathologic types that can present as either tissue-invasive disorders (acute invasive fulminant disease and chronic invasive infection) or noninvasive disorders (noninvasive mycotic colonization ["fungus ball" or mycetoma] and allergic fungal [mycotic] sinusitis).[53] All of these entities are rare in children.

Acute invasive fulminant disease occurs in immunosuppressed patients and clinically presents as pale mucosa that can progress to gangrene. Spread through neuronal routes can cause vascular invasion with intracranial spread and parenchymal infarcts. Mucormycosis is a disease caused by several types of fungi and can have an acute and fulminant course. In patients with diabetes, mucormycosis can present more as a chronic tissue-invasive infection and frequently causes periorbital invasion (orbital apex syndrome).[53]

A fungal ball or "mycetoma" consists of fungal hyphae compressed into a thick exudate within a sinus lumen.[53] It is a benign fungal colonization and may occur in patients with previous sinus surgery, oral-sinus fistula, a history of chemotherapy or radiotherapy for cancer, or in those without any known predisposing factor.

Allergic fungal rhinosinusitis should be considered in all adults with chronic sinusitis, but it is rarely seen in young children. Clinical presentation may include a history of allergic sinusitis, chronic rhinosinusitis, nasal polyps, allergic asthma, and immunosuppression, and it can present with proptosis from an inflammatory mass.[38,54] The diagnosis is primarily histopathologic. At surgery, a characteristic inspissated sinonasal inflammatory exudate called allergic mucin is encountered and must be positive for fungal hyphae on fungal staining or cultures. No evidence for mucosal fungal invasion should be present.[54]

***Imaging.*** Radiographically, fungal disease is difficult, if not impossible, to distinguish from bacterial infection. Radiographic signs include sinonasal polyposis with a heterogenous soft tissue inflammatory mass with remodeling or destruction of bone and increased densities in the sinuses, which can represent calcifications. Allergic mucin is largely responsible for the sinus CT hyperattenuation.[54] MRI findings can suggest fungal infection because, in contrast to the high signal intensity on T2-weighted images seen with acute bacterial disease, the presence of calcium, air, or ferromagnetic elements in the fungus causes decreased signal intensity on T1-weighted and T2-weighted images. However, inspissated secretions as seen in patients with CF can have a similar appearance.

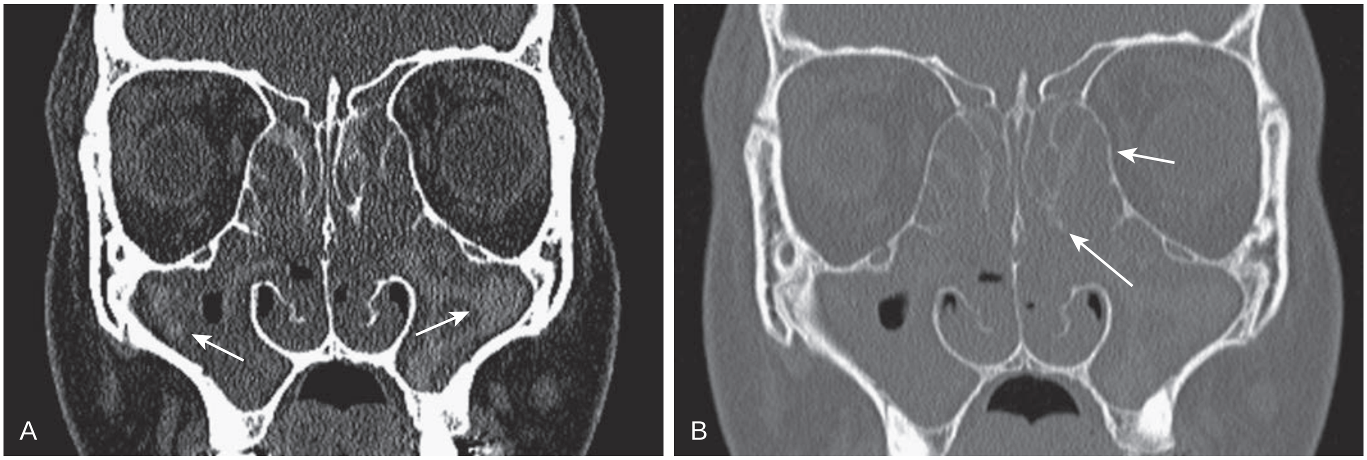
# INFLAMMATORY SINONASAL MASSES

## Cysts, Polyps, and Mucoceles

Cysts and polyps are frequent complications of inflammatory rhinosinusitis. A mucous retention cyst results from the obstruction of a submucosal mucinous gland, and the cyst wall is the duct epithelium. These cysts can occur in any sinus but are more frequent in the inferior aspect of the maxillary sinuses. A serous retention cyst results from the accumulation of serous fluid in the submucosal layer of the sinus mucosal lining.[5] These cysts are not inflammatory lesions and appear as dome-shaped, well-defined, homogeneous, nonenhancing structures on CT; they are hypointense on T1-weighted MR images and hyperintense on T2-weighted images (Fig. 8.24A). Cysts also can be found incidentally in 10% to 30% of patients.[55]

Polyps, in contrast, are a manifestation of an allergic or inflammatory process, or both. When they are associated with an allergy, polyps tend to be multiple. These lesions can become large and cause bony distortion with expansion and erosion. Polyps can be difficult to distinguish from mucous retention cysts in some cases and malignancies in others. Polyps have a high T2-weighted MR signal, in contrast to most neoplasms, which helps in the diagnosis.

An antrochoanal polyp (ACP) is a solitary maxillary sinus polyp that fills the sinus, expands the sinus ostium, and prolapses through it into the posterior choana, presenting as a nasal or nasopharyngeal polyp (Figs. 8.24B and C). Rarely, sphenochoanal and ethmochoanal polyps can also occur. In the general population, these polyps represent 4% to 6% of all nasal polyps; however, in children the incidence increases to 28% to 33%.[56] ACPs differ from inflammatory polyps; they tend to be fibrotic with minimal inflammation and are composed of a cystic portion filling the maxillary sinus and a solid dumbbell-shaped portion that emerges into the nasal cavity through the maxillary infundibulum or through an accessory



**e-Figure 8.23. Allergic sinusitis (Samter triad) in a 15-year-old boy.** (A) Coronal CT image with soft tissue window shows high attenuation inspissated secretions in the maxillary sinuses *(arrows)*. (B) Coronal CT image with bone window shows expanded sinuses and nasal cavity as a result of extensive polyposis with demineralized osseous structures *(arrows)*.

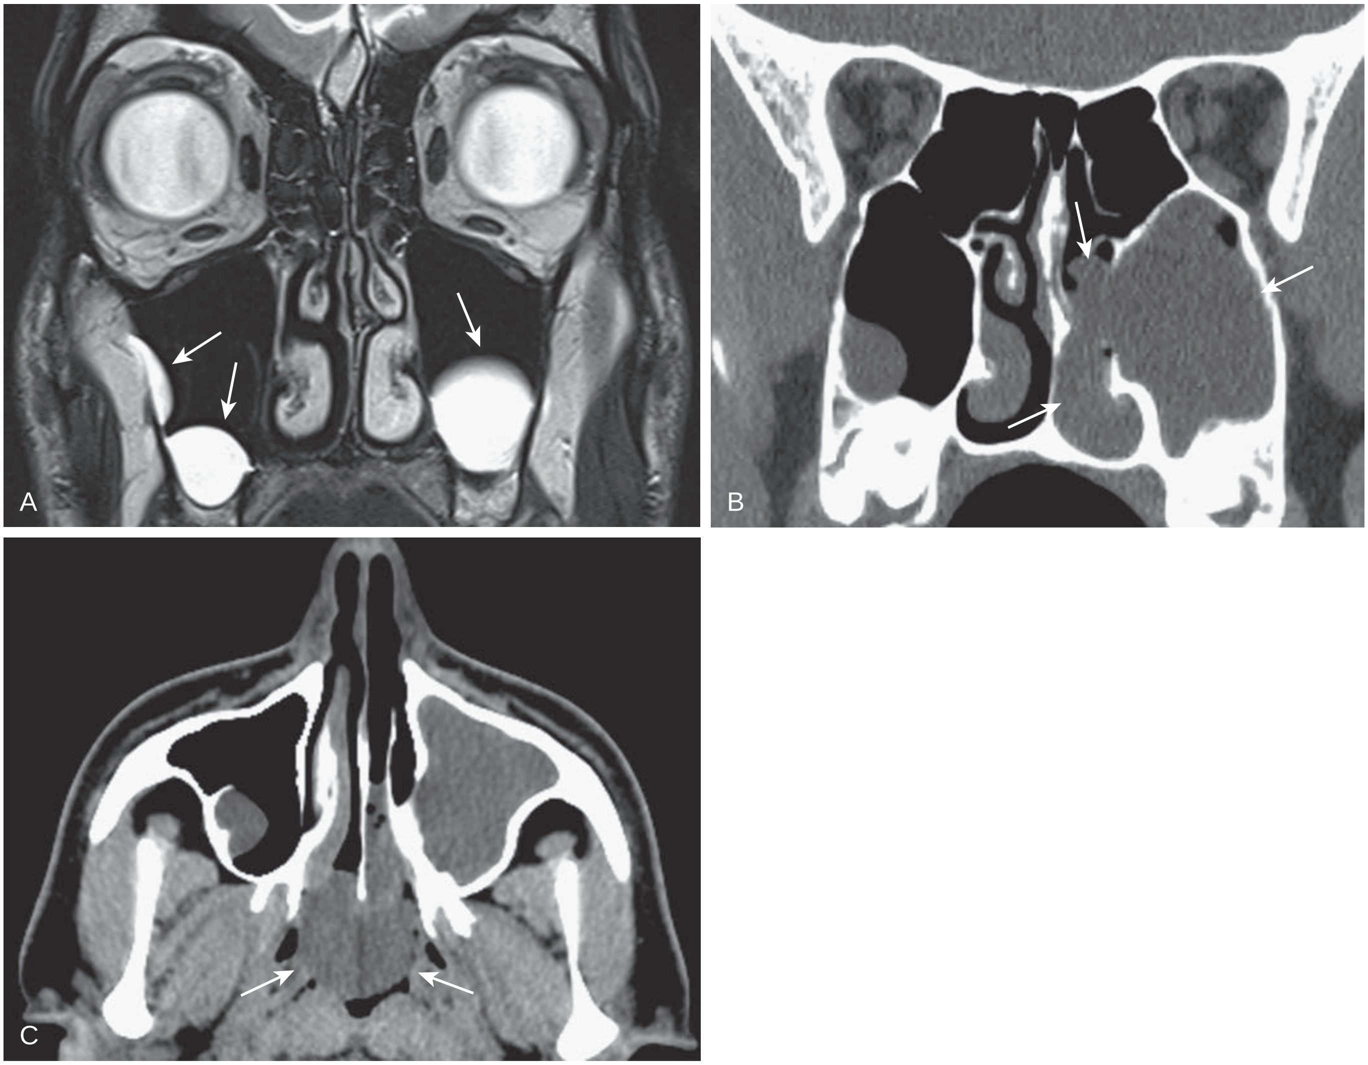


**Figure 8.24. Sinus polyps and retention cysts.** (A) Coronal T2-weighted MR image in a 17-year-old boy shows multiple hyperintense maxillary retention cysts *(arrows)*. (B) Axial coronal CT image in a 16-year-old boy shows a large antrochoanal polyp that fills in the left maxillary antrum extending through the ostium to the nasal cavity *(arrows)*. (C) Coronal CT image shows posterior extension of the polyp to the nasal choana, crossing the midline to the right *(arrows)*.

ostium of the maxillary sinus. These polyps are usually unilateral solitary lesions; however, bilateral ACPs can be seen in 20% to 25% of cases. The clinical presentation is nasal obstruction and discharge, mouth breathing, snoring, and sleep apnea.

On CT, most ACPs have mucoid attenuation and show mucosal surface contrast enhancement without central enhancement. ACPs can appear denser when inspissated secretions are present. On MRI, ACPs are usually hyperintense on T2-weighted images because of their high water content.

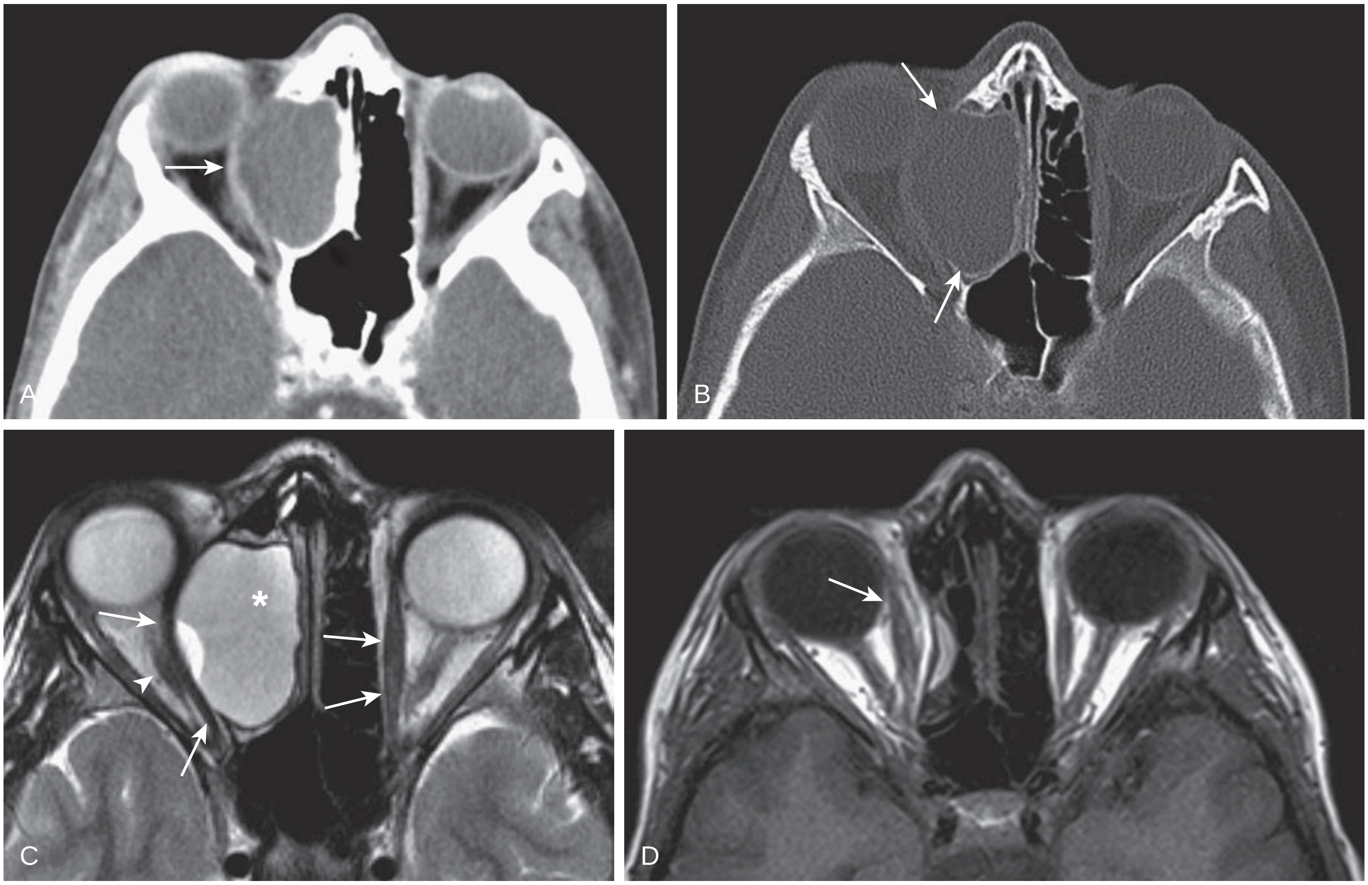
Mucoceles, which are most common in the frontal (60%) and ethmoid (30%) sinuses and result from obstruction or sequestration of a portion of the sinus, are cystic lesions lined with respiratory epithelium and filled with mucoid secretions.[57] Mucoceles are rare in the sphenoid[58] and maxillary sinuses. The association of mucoceles and CF is frequent.[59] Clinical symptoms result from the mass effect of the lesion and depend on location; these symptoms may include proptosis, headache, cranial nerve impingement, or nasal obstruction (e-Fig. 8.25).

On CT, mucoceles are low-density, nonenhancing masses that can expand the sinus. Thin rim enhancement can occur; however, if enhancement is thick or nodular, infection should be considered. Calcification in the wall suggests remote infection. The signal varies on MRI, depending on the relative concentrations of water, protein, and mucus.

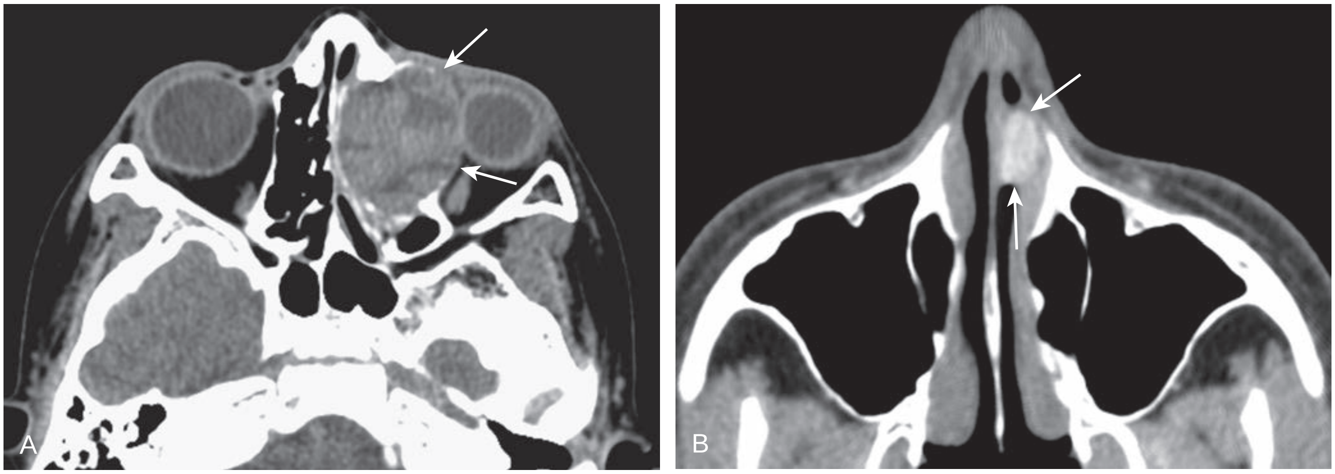
If the bony wall of the portion of the sinus bordering the brain is disrupted and the rim of the sinus enhances, it is likely that the mucocele is adherent to thickened dura that may lead to complications such as empyema, meningitis, and abscess. A mucocele within the sphenoid sinus before enhancement may mimic the appearance of a pituitary adenoma or chordoma. After administration of IV contrast material, however, these entities should be differentiated easily.

## Neoplasms of the Sinonasal Cavity

Benign neoplasms and tumor-like conditions of the sinonasal cavity in children include fibro-osseous lesions (e.g., fibrous dysplasia and ossifying fibroma), bony tumors (e.g., giant cell tumor and aneurysmal bone cyst) (e-Fig. 8.26A), juvenile nasopharyngeal angiofibroma (Fig. 8.27), nasal pleomorphic adenoma, odontogenic cysts or tumors, and vascular tumors such as hemangiomas and nasal pyogenic granuloma.



**e-Figure 8.25. Ethmoidal mucocele in a 13-year-old.** (A) Axial contrast-enhanced CT image shows a well-circumscribed, nonenhancing, hypodense, expansile mass centered in the right ethmoid sinus with significant effect of the mass on the right orbit, causing proptosis and lateral deviation of the medial rectus muscle *(arrow)*. (B) Axial CT image shows bone remodeling and septal destruction *(arrows)*. (C) Axial T2-weighted MR image shows a cystic, hyperintense, expansile lesion *(asterisk)* and lateral displacement of the right medial rectus muscle compared with the left *(arrows)*. The optic nerve is laterally displaced *(arrowhead)*. (D) After endoscopic marsupialization, resolution of the ethmoidal expansion and proptosis is seen. Note the normal position of the medial rectus muscle *(arrow)*.



**e-Figure 8.26. Benign nasosinal neoplasms.** (A) Aneurysmal bone cyst in a 7-year-old child. Axial contrast-enhanced computed tomography image shows a left intranasal expansile lesion with intrinsic fluid-fluid levels and effect of the mass on the orbit *(arrows)*. (B) Nasal pyogenic granuloma in a 13-year-old boy. Axial contrast-enhanced CT image shows a well-circumscribed, avidly enhancing oval mass in the anterior left nasal cavity *(arrows)*.

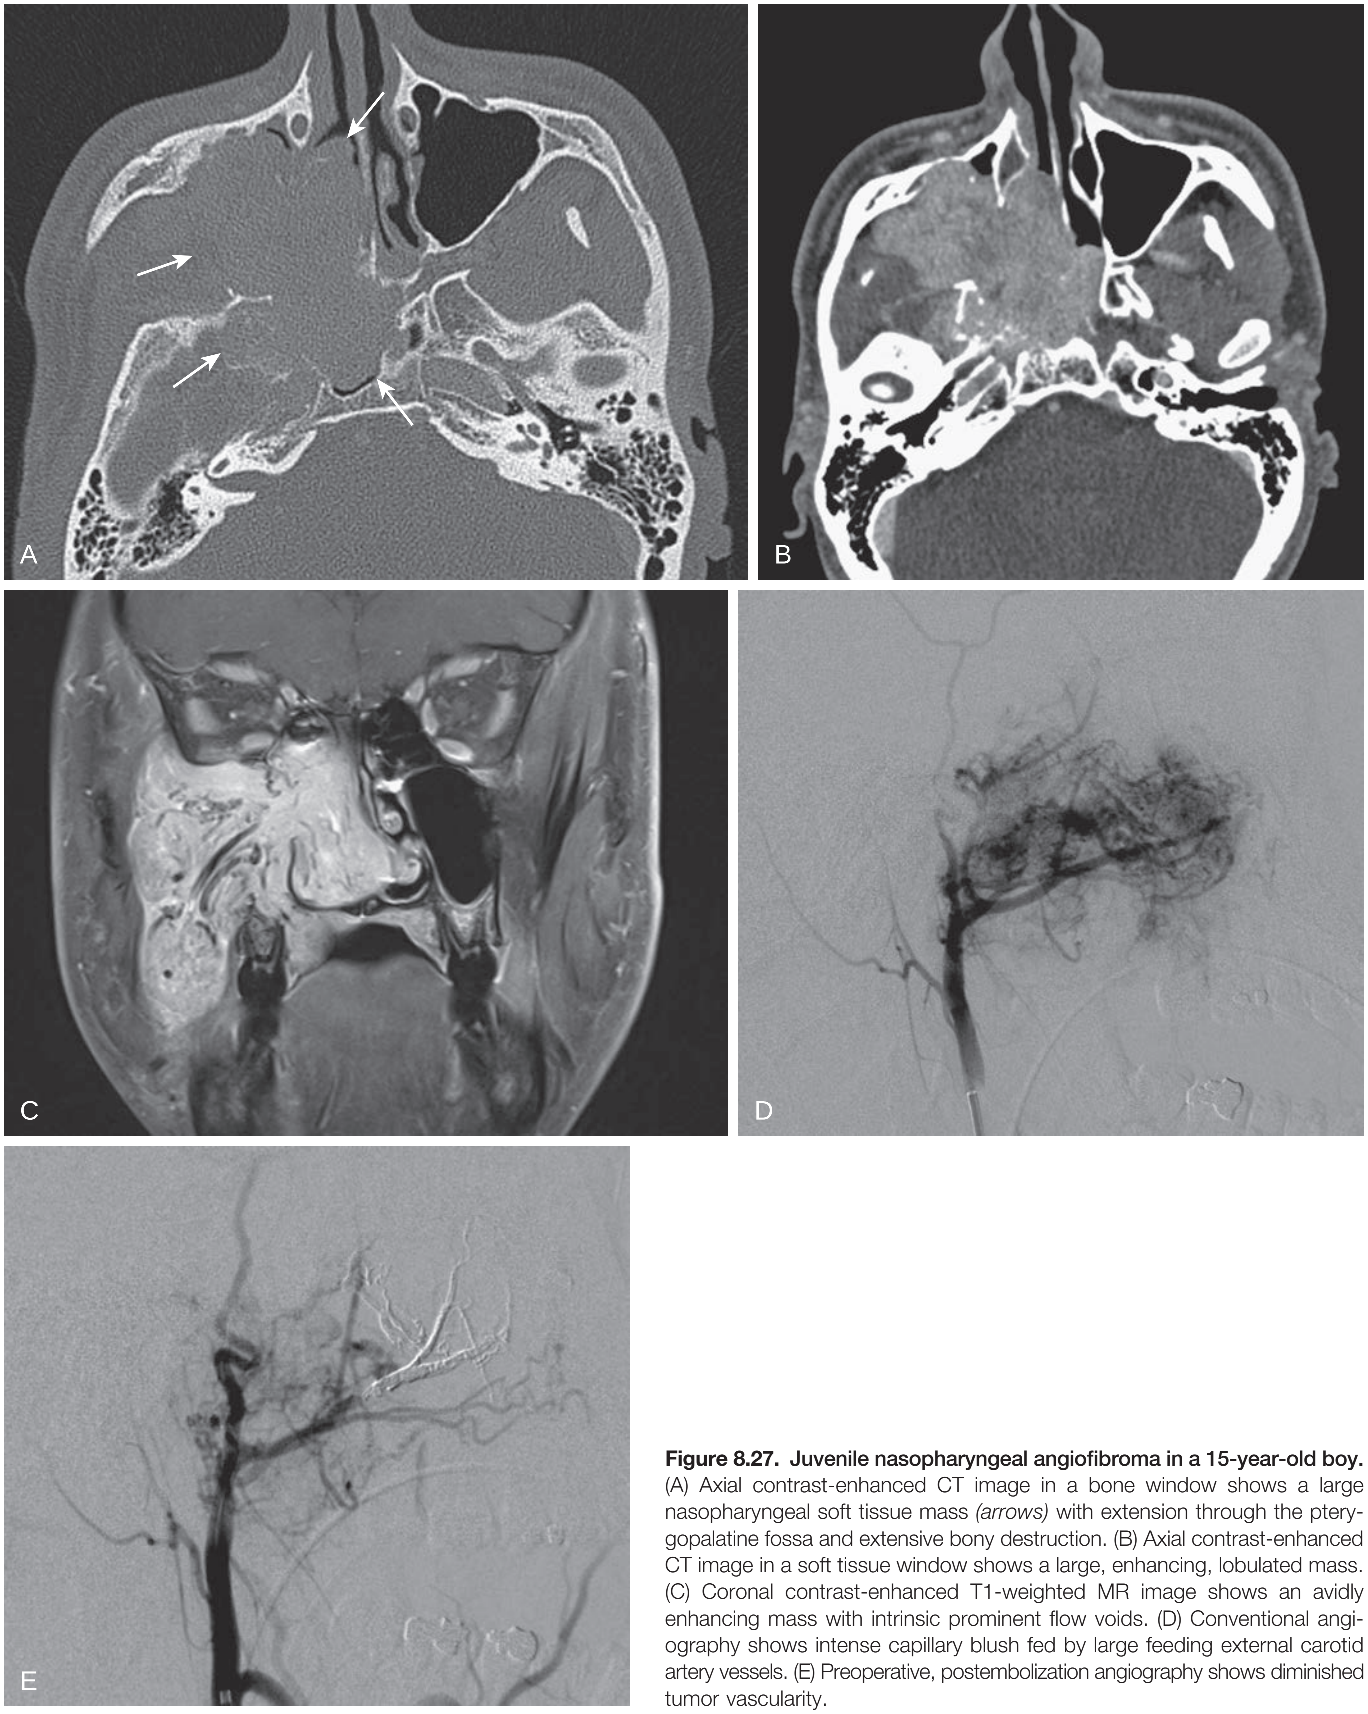


**Figure 8.27. Juvenile nasopharyngeal angiofibroma in a 15-year-old boy.** (A) Axial contrast-enhanced CT image in a bone window shows a large nasopharyngeal soft tissue mass *(arrows)* with extension through the pterygopalatine fossa and extensive bony destruction. (B) Axial contrast-enhanced CT image in a soft tissue window shows a large, enhancing, lobulated mass. (C) Coronal contrast-enhanced T1-weighted MR image shows an avidly enhancing mass with intrinsic prominent flow voids. (D) Conventional angiography shows intense capillary blush fed by large feeding external carotid artery vessels. (E) Preoperative, postembolization angiography shows diminished tumor vascularity.

Hemangiomas are benign vascular tumors that can occur in the face and neck and may also present as a nasal mass. Infantile hemangioma is the most common tumor in infancy and presents on imaging as a well-defined, lobular hypervascular soft tissue mass, with hypointense signal on T1-weighted images and bright signal on T2-weighted images.

Pyogenic granuloma, also known as lobular capillary hemangioma, is a benign vascular tumor of capillary proliferation that can arise from the skin, or from oral or nasal mucosa. The etiology remains unclear; trauma and hormonal changes may play a role, however, it can also present spontaneously without a clear cause. Nasal pyogenic granuloma is rare and can arise from the anterior nasal septum, turbinates, or roof of the nasal cavity. In children, there is a slight male predilection. Clinical presentation is with epistaxis, nasal obstruction, rhinorrhea, and pain. On nonenhanced CT, it appears as a well-circumscribed, hypoattenuating, 1 to 2 cm homogeneous soft tissue mass, without calcification, and can cause bone remodeling. On contrast-enhanced CT, there is intense diffuse enhancement (e-Fig. 8.26B). On MR imaging, it is isointense to cerebral gray matter on T1-weighted imaging and heterogeneously hyperintense on T2-weighted imaging, with marked contrast enhancement and a nonenhancing hypointense rim. The preferred treatment for nasal pyogenic granuloma is surgical excision.

Malignant neoplasms of the sinonasal cavity in children include rhabdomyosarcoma (e-Fig. 8.28), leukemia (e-Figs. 8.29A and B), lymphoma (e-Fig. 8.29C), nasopharyngeal carcinoma (e-Fig. 8.30), metastatic disease (neuroblastoma), and rarely esthesioneuroblastoma.

## FRACTURES OF FACIAL BONES

Nasal fractures, which typically result from direct frontal impact, occur most often in the lower third of the nasal bone. Lateral blows cause more complex fractures and often are associated with other facial fractures. Associated dislocation of the septal cartilage and fracture of the nasal spine also can be seen.

Radiographs may evaluate simple fractures, but CT is the preferred method to evaluate more complex fractures and for preoperative planning.[60] Ultrasound has proven to be a reliable diagnostic tool for the evaluation of nasal fractures, especially in low-grade nasal fractures.[61,62]

After nasal trauma, nasal examination by anterior rhinoscopy is mandatory to exclude septal hematoma. Early diagnosis and treatment, consisting of incision and drainage, are critical to avoid complications such as abscess formation, septal necrosis and perforation, and "saddle-nose" deformity. A septal hematoma most often appears on CT as an isodense to hypodense collection centered in the nasal septum but may also be heterogeneous.

### KEY POINTS

- Maxillary and ethmoid sinuses are present at birth. Sphenoid sinuses develop after fatty marrow transformation of the sphenoid bone. Frontal sinuses appear between 6 and 12 years of age.
- Plain radiographs are extremely limited in the evaluation of the paranasal sinuses and are not indicated in children younger than 2 years.
- With all imaging, a high incidence of mucosal thickening is seen in asymptomatic individuals.
- CT is indicated in patients with complicated acute sinusitis and is the gold standard study that guides management of recurrent or chronic sinusitis and serves as a road map for functional endoscopic sinus surgery.
- MRI is the imaging modality of choice in evaluating intracranial complications of sinusitis.
- CT and MRI are complementary in assessing and mapping neoplasms.

# Embryology, Anatomy, Normal Findings, and Imaging Techniques

Korgün Koral

## EMBRYOLOGY

A detailed study of the development of the ear is beyond the scope of this chapter; only the key embryologic events and their timing are discussed here. It is important to appreciate that the inner ear is derived from the neuroectoderm, whereas the middle ear and the external ear develop from the branchial apparatus, explaining why the abnormalities of the inner ear are generally isolated from the abnormalities of the middle ear/external ear and vice versa. It is also important to remember that the pharyngeal clefts give rise to the ectodermal structures, pouches give rise to the endodermal structures, and intervening arches give rise to the mesodermal structures.

### External Ear

The external auditory meatus (canal) is derived from the first pharyngeal cleft. At the beginning of the third month, the epithelial cells at the bottom of the meatus proliferate and form the meatal plug. The meatal plug dissolves in the seventh month and the epithelial lining of the floor of the meatus participates in the formation of the definitive tympanic membrane. The lateral part of the tympanic membrane arises from the ectoderm, and the medial part of it from the endoderm. There is an intermediate layer of connective tissue in between, called fibrous stratum, derived from the mesoderm.

The pinna (auricle) develops from six mesenchymal proliferations, called hillocks, which are located at the dorsal ends of the first and second pharyngeal arches. They surround the first pharyngeal cleft (future external auditory meatus). These hillocks gradually fuse and form the definitive auricle.[1]

### Middle Ear

The tympanic cavity is derived from the endoderm and develops from the first pharyngeal pouch. This pouch grows laterally until it comes in contact with the floor of the first pharyngeal cleft. The lateral part of the pouch gives rise to the primitive tympanic cavity. The medial part of the pouch is smaller and forms the eustachian tube. The malleus and incus are derived from the cartilage of the first pharyngeal arch, whereas the stapes is derived from the second pharyngeal arch. The ossicles remain embedded in the mesenchyme until the eighth month, when the surrounding tissue dissolves. The tympanic cavity expands dorsally to form the mastoid antrum in late fetal life. Pneumatization of the mastoid process continues after birth.[1]

### Inner Ear

The otic placodes become visible on each side of rhombencephalon on the 22nd day of gestation; they are the first indications of developing ears. The otic placodes invaginate rapidly and form the otic (auditory) vesicles. From the ventral components of the otic placodes, the cochlea and the saccule develop. From the dorsal components of the otic placodes, the utricle, the semicircular canals, and the endolymphatic duct arise. These epithelial structures are collectively named the membranous labyrinth.

Between 6 and 8 weeks of gestation, the cochlear duct, arising from the saccule, penetrates the surrounding mesenchyme and completes the 2½ turns. The ductus reuniens is the thin, residual connection between the cochlea and saccule. At the 10th week, the cartilage surrounding the cochlear duct undergoes vacuolization and two perilymphatic spaces are formed: the scala tympani and the scala vestibuli. The cochlear duct (scala media) is separated from the scala vestibuli by the vestibular membrane and from the scala tympani by the basilar membrane. The lateral wall of the cochlear duct remains attached to the surrounding cartilage by the spiral ligament. Medially, the cochlear duct is attached to the modiolus, which is the axis of the bony cochlea. At the sixth week, semicircular canals appear as outpouchings of the utricular (posterior) component of the otic vesicle.[1]

## ANATOMY AND NORMAL FINDINGS

Learning the anatomy of the temporal bone may appear intimidating initially; however, there are tremendous returns for the relatively small investment of study time. That is because the normal imaging anatomy of the temporal bone is exquisitely displayed on computed tomography (CT) and magnetic resonance imaging (MRI), leaving relatively few gray zones where interpretation is difficult. An exhaustive review of the temporal bone anatomy is beyond the scope of this chapter. What follows is a simple guide for those not previously exposed to temporal bone imaging.

The temporal bone consists of tympanic, squamous, petrous, and mastoid parts, and a styloid process.[2] It may be easier to divide the temporal bone into compartments when studying its anatomy or when reviewing imaging studies. Here, these compartments are presented from lateral to medial.

### Pinna and External Auditory Canal

Abnormalities of the pinna usually coexist with the abnormalities of the external auditory canal (EAC) and middle ear. Mayer et al.[3] reported that ossicular abnormalities were present in 98% of the temporal bones with microtia and EAC abnormality. It may be difficult to detect subtle abnormalities of the pinna, but it is generally possible to identify gross malformations on a temporal bone CT.

The EAC is oval in shape in cross section. Its walls (anterior and posterior; superior and inferior) run parallel throughout the course of the EAC. The EAC consists of two segments: the membranous (fibrocartilaginous) segment makes up the lateral one third of the EAC, and the medial bony segment forms the remainder.[4]

The tympanic membrane separates the EAC from the middle ear cavity and is attached to the tympanic annulus, which is a circumferential bony prominence at the medial-most aspect of the bony EAC. Superiorly, the tympanic membrane attaches

## Abstract:

Understanding the temporal bone anatomy is key to perform clinically relevant examinations and interpretations of the pediatric temporal bone. Having a basic knowledge of the embryology is very useful to conceptualize the congenital malformations of the temporal bone. In this chapter, an introduction to temporal bone embryology and imaging anatomy is provided along with some technical considerations of temporal bone imaging.

to the scutum (Fig. 9.1), which is an important bony landmark in the diagnosis of cholesteatoma. If not thickened, one needs to use wide window settings on CT to visualize the tympanic membrane.

## Middle Ear Cavity (Cleft)

The middle ear cavity is the normally aerated space, via the eustachian tube, medial to the tympanic membrane. It is arbitrarily divided into three compartments: epitympanum (attic), mesotympanum, and hypotympanum. If lines are drawn parallel to the superior and inferior walls of the bony segment of the EAC in the coronal plane, the part of the middle ear cavity above the upper line is the epitympanum (attic) and is the largest portion and houses most of the ossicular chain. The mesotympanum lies between the two lines. The hypotympanum is below the lower line and is normally nonexistent or very small in children (Fig. 9.2).

### Ossicles

The malleus, incus, and stapes form the ossicular chain, which is responsible for amplification (around 30%) and transmission of the sound waves from the tympanic membrane to the oval window on the vestibule.[5]

The manubrium (handle) and the lateral process of the malleus are embedded in the tympanic membrane. The tympanic membrane has two parts, divided by the lateral process of the malleus: a smaller pars flaccida superiorly, and a larger pars tensa inferiorly.[6] Cranial to the manubrium is the neck of the malleus to which the tendon of the tensor tympani muscle attaches. The tensor tympani muscle is a Meckel cartilage (derived from the first branchial arch) structure and is innervated by the only branch of the trigeminal nerve that has motor fibers: V3 (mandibular branch). The head of the malleus forms the “ice cream” of the familiar “ice cream cone” appearance and articulates with the body of the incus (Fig. 9.3). The malleoincudal joint is a diarthrodial (synovial) articulation, as is the incudostapedial joint (see Figs. 9.3 and 9.4). The incus is the largest of the three middle ear ossicles. Its body articulates with the head of the malleus and forms the “cone” on axial images. The short process of the incus (better seen on axial images) extends from the body dorsally and resides in the fossa incudus to which it is secured by ligaments that are invisible on CT. The long process of the incus extends inferiorly from the body. The lenticular process of the incus joins the long process forming a nearly 90-degree angle. The long and lenticular processes of the incus are very delicate and more prone to erosion from infection and/or inflammation than other parts of the ossicular chain. The lenticular process is cup shaped medially and articulates with the head (capitulum) of the stapes. The head of the stapes is connected to the crura (anterior and posterior), which subsequently join the footplate of the stapes. The opening between the crura of the stapes is called the obturator foramen and is where the stapedial artery resides in fetal life. The stapes footplate

articulates with the oval window forming the syndesmotic (fibrous) stapediovestibular joint.[5]

## Recesses and Ridges of the Middle Ear Cavity

The sinus tympani is the medial and posterior recess of the middle ear cavity. It can occasionally be deep, making the visualization of the soft tissue lesions within it difficult at surgery. Lateral to the sinus tympani is a triangular bony prominence: the pyramidal eminence. The stapedius muscle (innervated by the facial nerve) may occasionally be imaged on CT arising from the pyramidal eminence and extending to the stapes. Lateral to the pyramidal eminence is the facial recess.

The Prussak space is important because soft tissue lesions within it may be hidden from the view of the clinical examiner (see Fig. 9.1). The Prussak space is medial to the scutum and lateral to the malleolar head. The superior malleolar ligament (which is not seen on CT) forms the cranial border of the Prussak space.

The anterior epitympanic recess (see Figs. 9.3 and 9.4) is contiguous with the middle ear cavity through an incomplete septum, termed the *cog*, whose integrity may be lost due to infection or inflammation.[5]

## Mastoid Air Cells

The interconnected, air-filled mastoid air cells communicate with a mastoid antrum, which in turn communicates with the middle ear cavity (see Figs. 9.3 and 9.4). The connection between the middle ear cavity and mastoid antrum is called the aditus ad antrum (opening to antrum). The mastoid air cells are separated by innumerable thin septa. The Koerner septum is the bony thickening that runs obliquely through the mastoid air cells and is an important surgical landmark. The roof of the middle ear cavity is called the tegmen tympani (see Fig. 9.1).

## Facial and Vestibulocochlear Nerves and Internal Auditory Canal

The facial nerve has motor, parasympathetic, and special sensory (taste) fibers. Its nuclei are in the dorsal pons. The motor fibers of the facial nerve swing posterior to the nuclei of the abducens nerve, generating the swellings of the facial colliculi. It is important to remember that the facial nerve has a rather long intraaxial segment extending from the nuclei through the nerve exit zone at the surface of the lateral pons. The cisternal and canalicular segments of the facial nerve are evaluated on high-resolution T2-weighted MRI of the temporal bone. The cisternal segment, the longest segment of the facial nerve, can routinely be identified on high-resolution MRI. The facial nerve enters the internal auditory canal (IAC) through the porus acusticus and is named the canalicular segment thereafter. In the IAC, the facial nerve lies in the anterior-superior quadrant. The lateral-most aspect of the IAC is termed the *fundus*, which is divided by the crista falciformis (see Fig. 9.1) into superior and inferior compartments. The superior compartment is further divided into anterior and posterior parts by a vertical, variably calcified/ossified arachnoid membrane, called the Bill's bar. The cochlear nerve occupies the anterior-inferior quadrant and the vestibular nerve (superior and inferior branches) is seen in the posterior quadrants[7] (Figs. 9.5 and 9.6).

The facial nerve enters the labyrinthine canal where it occupies approximately 95% of its volume. The labyrinthine segment of the facial nerve is particularly susceptible to ischemia because its bony confines do not leave room for swelling during inflammation. The labyrinthine segment synapses at the geniculate ganglion from which the parasympathetic greater superficial petrosal nerve (GSPN) arises. The GSPN recruits some sympathetic fibers and becomes the vidian nerve and provides the parasympathetic innervation of the lacrimal gland. Distal to the geniculate ganglion, the facial nerve makes a dorsal turn and becomes the tympanic segment. The distal labyrinthine segment, geniculate ganglion, and proximal tympanic segment make up the anterior genu. The tympanic segment of the facial nerve lies at the medial wall of the tympanic cavity and immediately inferior to the lateral semicircular canal. The tympanic segment has a thin, inconsistent bony covering and lies just lateral to the oval window. The posterior genu is a nearly 90-degree bend where the tympanic segment meets the mastoid (or descending) segment (see Fig. 9.4). The mastoid segment exits the temporal bone through the stylomastoid foramen. Just proximal to the stylomastoid foramen, the chorda tympani arises from the mastoid segment, extends into the middle ear cavity in its own canal, and traverses the middle ear cavity within the tympanic membrane, between the manubrium of the malleus and incus. The chorda tympani contains the taste sensation fibers from the anterior

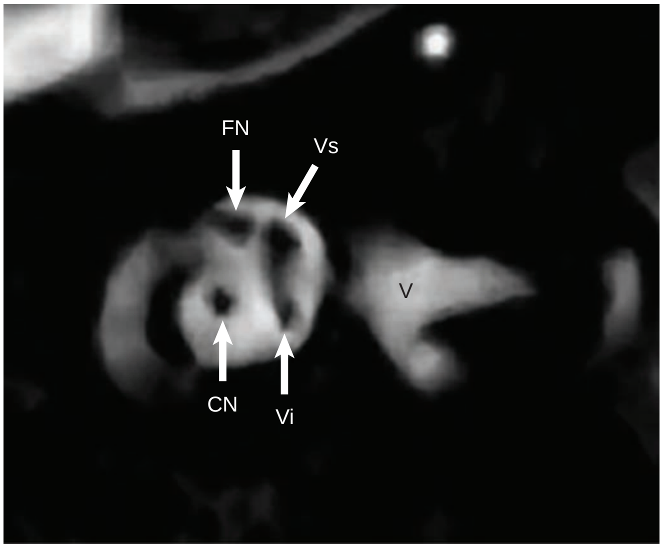

**Figure 9.6.** Oblique sagittal balanced fast field echo MRI through the fundus of the internal auditory canal shows the facial nerve *(FN),* cochlear nerve *(CN),* and superior *(Vs)* and inferior *(Vi)* branches of the vestibular nerves.

two-thirds of the tongue, as well as the parasympathetic fibers to the submandibular and sublingual glands.[2] After exiting the temporal bone, the facial nerve traverses the parotid gland (but does not innervate it) and innervates the facial musculature. The parotid gland is divided by the facial nerve into deep and superficial lobes.

The cochlear nerve is equal in size or slightly larger than the facial nerve, as seen on oblique-sagittal T2-weighted MRI. It enters the cochlea through the cochlear aperture, which can be appreciated on both CT and MRI. Stenosis or atresia of the cochlear aperture is usually associated with deficiency or absence of the cochlear nerve.

### Oval Window/Round Window

The stapes footplate resides on the oval window (see Fig. 9.4). It can easily be appreciated on both the axial and coronal CT images. Abnormalities of the oval window include atresia and stenosis, which are usually associated with abnormalities of ossicles and external ear. The round window is easier to appreciate on coronal images as a fluid-air interface at the inferior aspect of the vestibule.

### Jugular Bulb/Carotid Canal

The right jugular bulb is generally the dominant one. The term *high-riding* is used when the jugular bulb and basal turn of the cochlea are seen on the same axial image. Without bony dehiscence or protrusion of the internal jugular vein into the posterior tympanic cavity, a high-riding jugular bulb is insignificant. The carotid canal should be identified in all temporal bone examinations. The aberrant internal carotid artery running in the tympanic cavity is a very rare but important anomaly.

### Vestibular Aqueduct/Cochlear Aqueduct

The vestibular aqueduct (seen on CT) is the bony housing of the endolymphatic duct and sac (seen on MRI, usually when enlarged) (see Fig. 9.3). The vestibular aqueduct is considered enlarged when it measures greater than 1.0 mm at its midpoint.[8]

Although its enlargement is commonly associated with sensorineural hearing loss (SNHL), this observation does not alter the management if the patient is otherwise a good cochlear implantation candidate.

### Foramen Ovale/Foramen Spinosum

Identification of the foramen spinosum posterolateral to the foramen ovale is important because when it is absent, in about one-third of the cases it is associated with a persistent stapedial artery. The obturator foramen of the stapes should be inspected thoroughly for a soft tissue density when the foramen spinosum is not visualized.

### Temporomandibular Joint and Mandibular Head/Condyle

All temporal bone CT examinations should evaluate the temporomandibular joint because dysplasia is commonly associated with abnormalities of the auricle and ossicles, particularly aural atresia.

## Inner Ear

MRI is the modality of choice in the assessment of the inner ear, but attention should be paid to the bony labyrinth on temporal bone CT examinations because many of the inner ear abnormalities can be seen. The cochlea lies anterior to the IAC and is made up of basal, middle, and apical turns. The basal and middle turns are complete 360-degree turns, whereas the apical turn covers 180 degrees, hence the 2½ turns. On MRI the line representing the osseous spiral lamina is consistently seen throughout the cochlear lumen. The modiolus is the bony axis of the cochlea and has a "star" or "crown" shape and can be seen atop the cochlear aperture (see Figs. 9.4 and 9.5). The vestibule has a delicate, nearly cylindrical shape (see Figs. 9.3 and 9.5). The semicircular canals (superior, posterior, and lateral) are at right angles to each other and connect to the vestibule. Although one expects six openings in the inner surface of the vestibule (two for each semicircular canal), there are five openings because the posterior limb of the superior semicircular canal and the superior limb of the posterior semicircular canal unite to form the common crus, which has its own opening to the vestibule. The lateral semicircular canal is slightly larger than the other two semicircular canals.

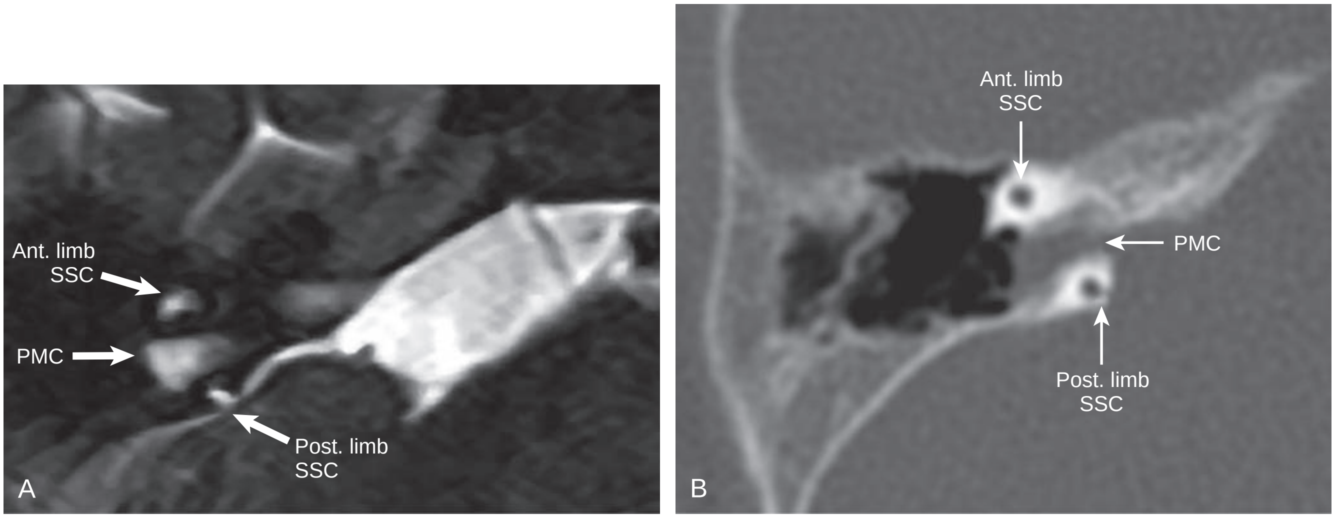
### Petromastoid (Subarcuate) Canal

The petromastoid canal (PMC) is almost always visualized on temporal bone CT. It lies underneath the arch of the superior semicircular canal and is closer to its posterior limb. Its size decreases with age. The PMC houses the vascular supply to the tympanic segment of the facial nerve, middle ear cavity, and regional mastoid air cells. It appears as a T2-weighted hyperintense structure that is relatively wider laterally in infants (e-Fig. 9.7).[9]

## IMAGING TECHNIQUES

CT is reserved for conductive hearing loss whereas MRI is used in the evaluation of SNHL. A low-dose technique is employed in volumetric CT acquisition. At our institution the imaging parameters include a kVp of 90 and an mA of 80, resulting in a dose length product of approximately 90 mGy.cm. The lenses should be outside the field of the primary beam. Coronal (and if necessary oblique-sagittal) reformations are generated. The slice thickness is on the order of 0.5 to 0.6 mm.

For high-resolution MRI, three-dimensional acquisition (e.g., T2-weighted or a steady state sequence) of the membranous labyrinth is performed in the axial plane. The reconstructed images yield an effective slice thickness of 0.75 mm. Oblique-sagittal images of the cerebellopontine angles and IACs are acquired. It is prudent to complement the temporal bone MRI with a brain MRI to exclude central causes of hearing loss.



**e-Figure 9.7.** Axial balanced fast field echo MRI (A) and axial CT (B) images cranial to the internal auditory canal in a 6-month-old boy show the petromastoid canal *(PMC)*. Anterior *(Ant. limb SSC)* and posterior *(Post. limb SSC)* limbs of the semircircular canal.

## KEY POINTS

- The developmental abnormalities of the external ear and middle ear generally coexist and are separate from the abnormalities of the inner ear, because the external ear and middle ear are derived from the pharyngeal apparatus whereas the inner ear arises from the neuroectoderm.
- In general, CT is reserved for the evaluation of conductive hearing loss (e.g., aural atresia, cholesteatoma) whereas MRI is used in the workup of sensorineural hearing loss (primarily in the evaluation of cochlear implantation candidacy).
- The lenses should be kept outside the primary beam during CT acquisition.

# Congenital and Neonatal Abnormalities

*Timothy N. Booth*

The discussion of congenital and neonatal temporal bone abnormalities in this chapter is approached from lateral to medial. External canal atresia and associated middle and inner ear anomalies are discussed initially. Isolated middle ear anomalies with associated branchial arch malformations are then addressed, along with associated anomalous development of the middle ear windows. A classification and description of inner ear malformations is discussed along with potential surgical outcomes. Finally, vascular anomalies involving the temporal bone are briefly discussed.

## EXTERNAL AUDITORY CANAL ATRESIA

***Clinical Presentation and Etiologies.*** The external and middle ear both are derived from the branchial apparatus, in contrast to the inner ear, which is of neuroectodermal origin. As a result, dysplasia of the external auditory canal (EAC) is commonly associated with a malformed auricle and anomalies of the middle ear and the mandible. These children usually present with microtia and conductive hearing loss (CHL). Mild stenosis of the EAC with normal or mildly malformed pinna may also occur.[1] Inner ear anomalies occur in 20% of children with aural atresia and are more likely to involve the vestibular apparatus (usually without profound sensorineural hearing loss ([SNHL]).[2] Atresia of the EAC is more common than inner ear anomalies with an incidence of 1 in 10,000 to 20,000 at birth. It is bilateral in one-third of cases, and appears to be more common in the United States than elsewhere.[3]

***Imaging.*** A spectrum of involvement is seen, with only mild bony stenosis of the EAC present in some children. Canal atresia may be membranous or bony. The severity of middle ear anomalies correlates with the extent of external malformation. Preoperative CT plays an integral role in determining potential candidates for hearing restorative surgery and should be performed shortly before intended surgery.[4] If SNHL is present, magnetic resonance imaging (MRI) may offer additional information that may affect treatment.

Ossicular anomalies are often associated with EAC atresia. The handle of the malleus is commonly fused to the atretic plate (e-Fig. 10.1). The malleus may be fused to the incus, with severe dysplasia usually present. The incudostapedial joint can be involved as well and is demonstrated on axial and coronal images. Patent oval and round windows are essential in achieving a good surgical outcome with oval window atresia seen with syndromic associations (Fig. 10.2). The stapes can be dysplastic, malpositioned, or absent. Significant abnormalities of the stapes often necessitate removal and placement of a total ossicular prosthesis. The size of the middle ear cavity is significant, and the degree of mastoid pneumatization also may affect the surgical approach.[5,6] Rarely, a boomerang-shaped ossicular mass has been reported in more severe cases of EAC atresia with both medial and lateral fixation points (e-Fig. 10.3).[7] Mild stenosis of the EAC with no associated microtia may be seen in children presenting with CHL with computed tomography (CT) showing fusion of the manubrium to the anterior tympanic annulus[1] (e-Fig. 10.4).

Determining the position of the facial nerve position is critical. The most common anomaly involves anterior displacement of the descending segment of the facial nerve, with the stylomastoid foramen lying just posterior to the temporal mandibular joint. The posterior genu usually is more anteriorly positioned immediately posterior to the level of the oval window[8] (Fig. 10.5). Less commonly, the tympanic segment may be positioned into the oval window or more inferiorly over the cochlear promontory. Atresia or stenosis of the oval window is usually associated with this anomalous facial nerve position. The facial nerve can be hypoplastic and difficult to visualize[9] (Box 10.1).

Syndromic EAC atresia usually is associated with more severe middle ear anomalies and a higher incidence of inner ear anomalies. Multiple genetic associations have been found[10,11] (e-Fig. 10.6), (Table 10.1).

***Treatment.*** Grading systems have been developed to assess the probability of surgical success. These systems take into account such findings as middle ear volume, ossicular anomalies, and the status of the oval window.[3,12] Transmastoid and anterior surgical approaches are used, with formation of a new tympanic membrane, mobilization of the ossicles, and possibly placement of an ossicular prosthesis. Active middle ear implants have recently been introduced as a potential treatment with a simplified grading system proposed.[13] The presence of a cholesteatoma also is a potential issue in both the imaging evaluation and surgical management of these patients.

## ISOLATED MIDDLE EAR ANOMALIES

***Clinical Presentation and Etiologies.*** Minor ear anomalies are associated with a normal EAC and are much less common. Minor ear anomalies usually present with a nonprogressive CHL, and a child with unexplained CHL should undergo CT evaluation to search for possible etiology.[14] Ossicular abnormalities may be unilateral or bilateral, with unilateral ossicular abnormalities usually sporadic and isolated. Bilateral anomalies may be associated with autosomal-dominant inheritance, and syndromic associations include Goldenhar and Treacher Collins syndrome. Round window atresia is caused by a deficiency in the development of cartilage during ossification of the otic capsule and typically is associated with CHL. Oval window atresia is likely caused by anomalous development of the second branchial arch and classically is associated with a mixed sensorineural and CHL. Oval window atresia can be seen with the CHARGE association (*C*oloboma of the eye, *H*eart defect, *A*tresia of choanae, *R*etarded growth and development, *G*enital anomalies, and *E*ar defect with deafness).

***Imaging.*** High-resolution CT using both axial and reconstructed coronal planes is the imaging modality of choice in evaluating patients with isolated middle ear anomalies. Anomalies of the stapes include aplasia, partial absence, columnar deformity, fusion of the head to the promontory, and footplate fixation. The incus can be aplastic; it can be fused to the lateral semicircular canal or scutum; it can have a malformed long process; it may be absent; or it may be fixed at the incudostapedial joint (e-Fig. 10.7). Similar anomalies involve the malleus; rarely, a bony bar fixes the malleus to the anterior lateral epitympanic wall[15,16] (Fig. 10.8). These anomalies have been classified into five classes on the basis of their surgical success rate and include (from better to worse):

Class 1: Normal stapes with abnormal incus or malleus
Class 2: Mobile stapes footplate
Class 3: Stapes footplate fixation only
Class 4: Stapes footplate fixation with other anomaly
Class 5: No stapes footplate[17,18]

Congenital stapes deformity or fixation may be associated with a perilymphatic fistula.[19]

## Abstract:

The temporal bone is a complex anatomical region that has varied embryologic origins. This chapter will focus on congenital abnormalities and discuss clinical presentation, appropriate imaging, as well as surgical implications. Normal variants that may mimic disease and affect surgical approach will be reviewed. The reader should have a thorough understanding of congenital pathology and variants that involve the temporal bone and regional structures.

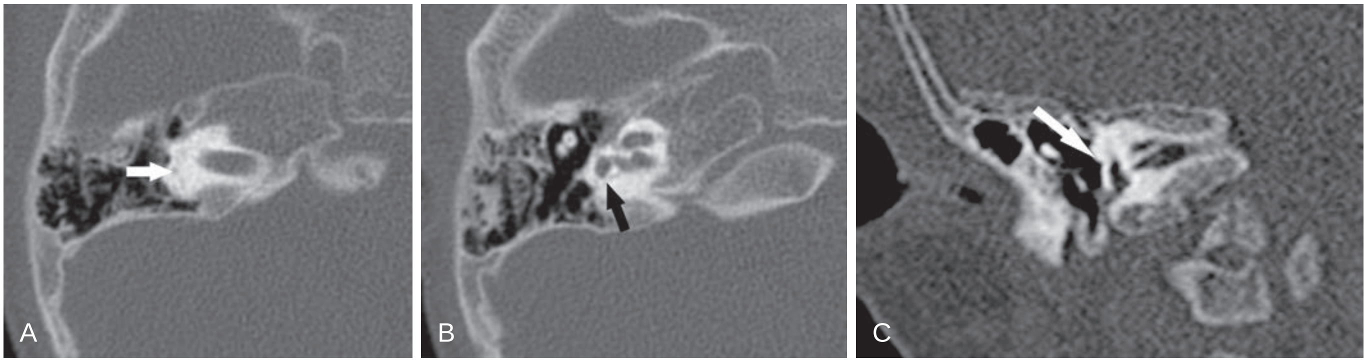
Round window atresia is not associated with malposition of the facial nerve or ossicular abnormalities, but malposition has been reported in association with oval window atresia.[20,21] A normal EAC is present in isolated atresia of the oval window. The absent oval window often is associated with malposition of the tympanic segment of the facial nerve into or inferior to the atretic oval window. The stapes is malformed and oriented toward the tympanic facial nerve rather than the oval window. The long and lenticular portions of the incus are abnormal. Anomalous development of the second branchial arch is likely the cause, with the facial nerve, incus, and a portion of the stapes arising from this arch[22,23] (Fig. 10.9).

The CHARGE association usually presents with mixed hearing loss and has typical imaging features; oval window atresia is present in nearly all cases (e-Fig. 10.10). Anomalies of the incus and stapes are found along with fixation of the malleus to the anterior tympanic wall. The inner ear is malformed in all cases, and the cochlea is hypoplastic. Vestibular findings include a small vestibule and absent semicircular canals. The facial nerve often is difficult to identify in these patients and may be small and malpositioned.[24,25] A hypoplastic clivus and absent olfactory bulbs are additional findings that may be seen with MRI, which is recommended as these patients commonly have cochlear nerve deficiency.[26,27]



**e-Figure 10.10. A 9-year-old with CHARGE syndrome and oval window atresia.** A and B, Axial high-resolution computed tomography (CT) images demonstrate a very hypoplastic vestibule and absent semicircular canals *(arrows)*. C, A coronal CT image shows absence of the oval window *(arrow)*.

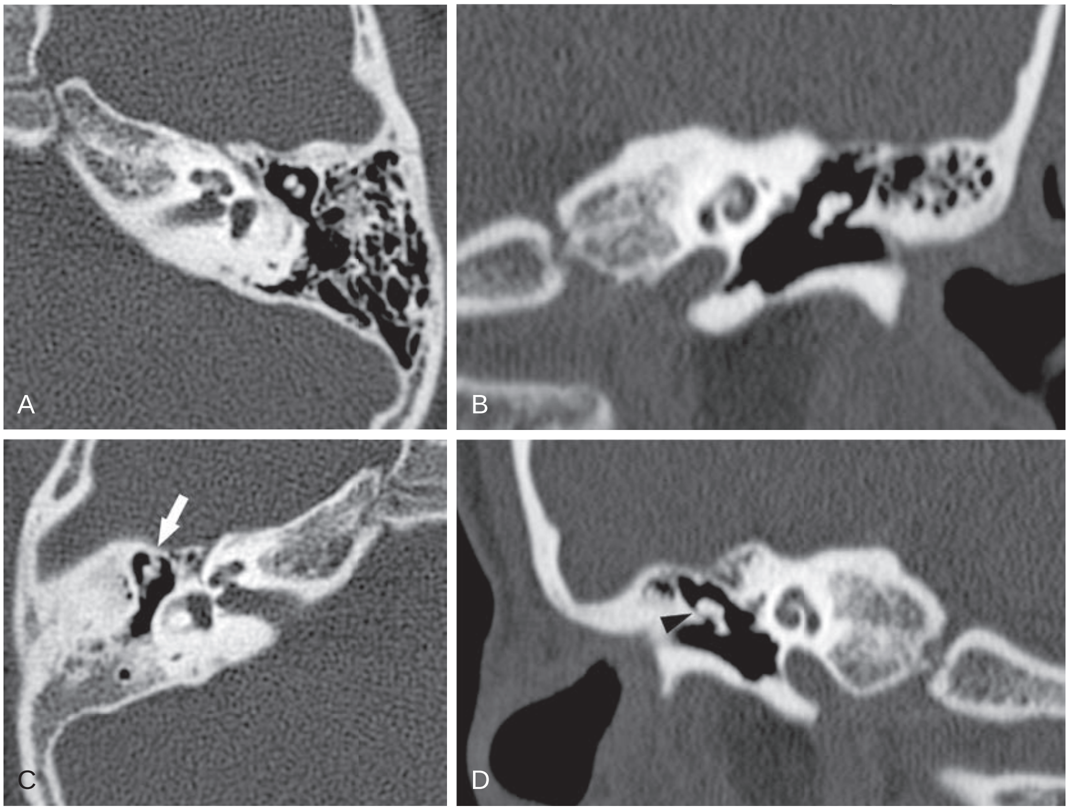


**Figure 10.8. A 10-year-old boy with right-sided conductive hearing loss.** A and B, Axial and coronal high-resolution computed tomography through the normal left middle ear. C and D, Corresponding axial and coronal computed tomography images of the right middle ear shows incomplete separation of the malleolar head from the tegmen *(arrow)* and narrowing of Prussak space *(arrowhead)*. Ossicular fixation was confirmed surgically.

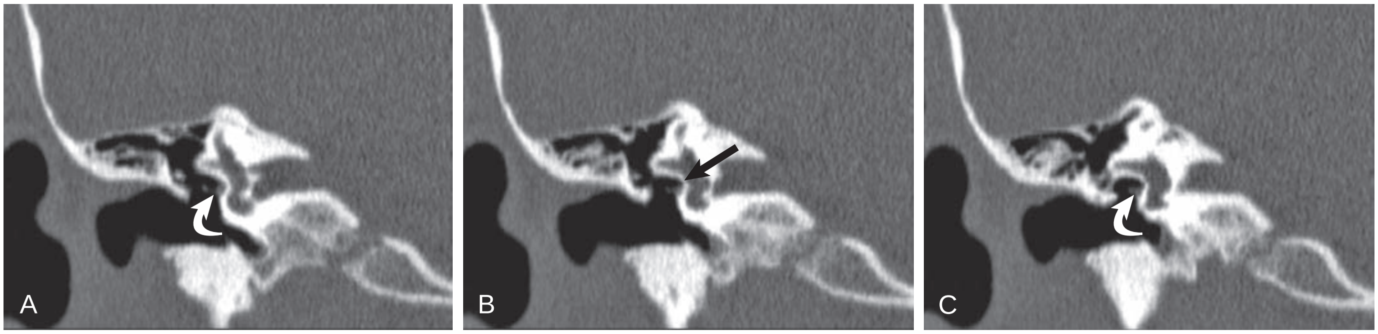

**Figure 10.9. Oval window atresia.** Seven-year-old with mixed hearing loss and a 60-dB threshold. (A–C) Coronal high-resolution CT images from anterior to posterior. The oval window is atretic *(arrow),* with displacement of the facial nerve within and slightly below the structure *(curved arrows)*. The stapes was not visualized, and the lenticular process of the incus appears adherent to the displaced facial nerve.

***Treatment.*** Ossicular chain reconstruction is the mainstay of treatment. Accurate preoperative assessment is essential to plan the appropriate procedure. The status of the oval window is important because atresia imparts a poor surgical prognosis. Determining the facial nerve position is essential.

## INNER EAR ANOMALIES

***Clinical Presentation and Etiologies.*** Study of the genetic defects associated with congenital SNHL is increasing. Nonsyndromic congenital SNHL is not associated with additional medical anomalies and constitutes 70% of cases. Genetic mutations found in persons with nonsyndromic congenital hearing loss are most commonly autosomal recessive, with approximately 50% of nonsyndromic recessive SNHL caused by a mutation in the *GJB2* gene.[28] In this subset of patients with *GJB2* mutation, CT usually demonstrates no or subtle abnormalities with no patient having an enlarged vestibular aqueduct in a recent series.[29]

Children with enlarged endolymphatic ducts have mutations of the *SLC26A4 (PDS)* gene in up to 82% of the hereditary cases and 30% of the sporadic cases.[30] Auditory neuropathy/dyssynchrony may be associated with mutations in the *OTOF* gene, as well as associated brain anomalies. These patients typically have a poor response to hearing aids and may benefit from earlier cochlear implantation.[31,32] The future classification of congenital hearing loss is likely to be based on a combined genetic and morphologic evaluation.

Syndromic congenital SNHL accounts for 30% of cases, with Pendred (enlarged vestibular aqueduct, thyroid dysfunction), Usher, Waardenburg, and branchio-oto-renal syndromes representing a large percentage of the associated syndromes. Characteristic imaging findings may suggest the diagnosis in some patients[28] (Table 10.2) (e-Fig. 10.11). A wide spectrum of syndromes is associated with congenital anomalies of the ear, which include inner ear malformations.[9,33]

Congenital SNHL can be difficult to diagnose clinically in sporadic cases, and perinatal insults can be responsible. Congenital cytomegalovirus infection, hypoxia, ototoxic drugs, kernicterus, and, rarely, tumors should be considered and may be suggested by MRI[34] (Fig. 10.12).

***Imaging.*** Inner ear imaging evaluation for congenital SNHL may be accomplished with high-resolution CT and/or high resolution fluid sensitive MRI. Cochlear and vestibular anomalies, intracranial abnormalities, and deficiency of the cochlear nerve often are found in children with congenital SNHL.[35] MRI is preferred because it provides improved evaluation of the membranous labyrinth and endolymphatic sac, and direct visualization of the cochlear nerve; it also permits a better evaluation of intracranial structures compared with CT.

The wide spectrum of congenital inner ear anomalies previously were all grouped together as "Mondini dysplasia." These anomalies were reclassified into five types, based on the stage of arrested development and appearance of the cochlea.[36] More recently, a revised classification by Sennaroglu has been proposed to better describe the anomalies of the cochlea found in children with SNHL. The sequence of anomalies corresponds to the timing of the potential insult to the developing inner ear, with the more severe anomalies occurring earlier in gestation[37]:

1. Complete labyrinthine aplasia (Michel malformation): All labyrinthine structures are absent (Fig. 10.13).
2. Cochlear aplasia: The cochlea is completely absent and the cochlear promontory is absent on coronal high resolution CT. A normal or malformed vestibule and semicircular canals may be present (e-Fig. 10.14).
3. Common cavity: A single cystic cavity represents the cochlea and vestibule without further differentiation (e-Fig. 10.15). Formed semicircular canals may be present.
4. Incomplete partition type I: The modiolus and cribriform area are absent, resulting in a cystic appearance. The vestibule is abnormally enlarged and cystic but remains a separate structure.
5. Cochlear hypoplasia: The cochlea shows further differentiation with the presence of a small cochlea, with a height less than 4 mm and fewer than two and a half turns (e-Fig. 10.16). A spectrum of severity is present, ranging from a

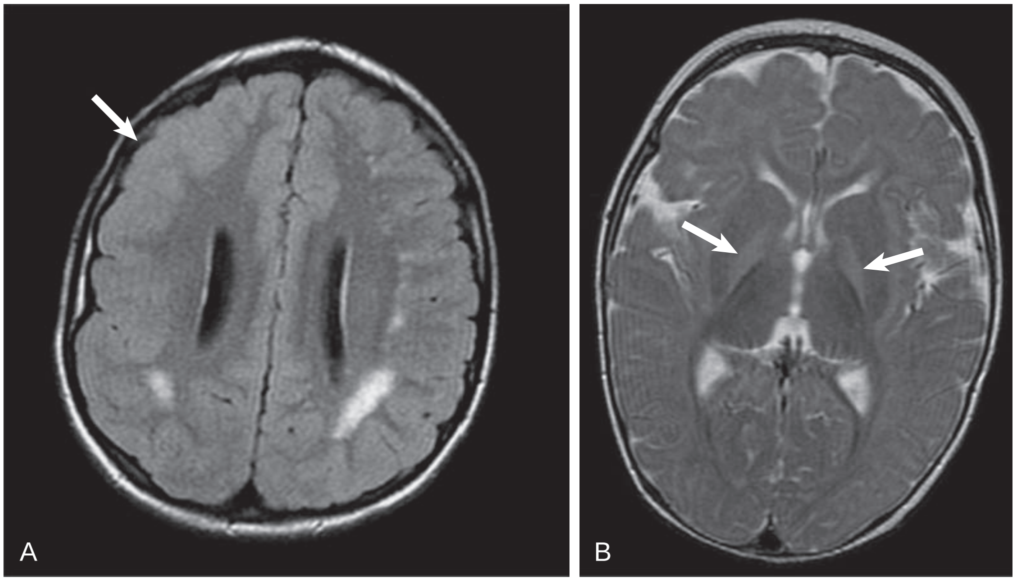

**Figure 10.12. Congenital sensorineural hearing loss.** (A) Axial fluid attenuated inversion recovery MR image shows abnormal increased signal within the supratentorial white matter. Cortical dysplasia is present within the right frontal region *(arrow)*. The findings are consistent with congenital cytomegalovirus infection. (B) Axial T2-weighted MR image through the basal ganglia in a different child with sensorineural hearing loss and a history of prematurity shows an increased T2-weighted signal in the globus pallidus bilaterally *(arrows),* consistent with kernicterus.

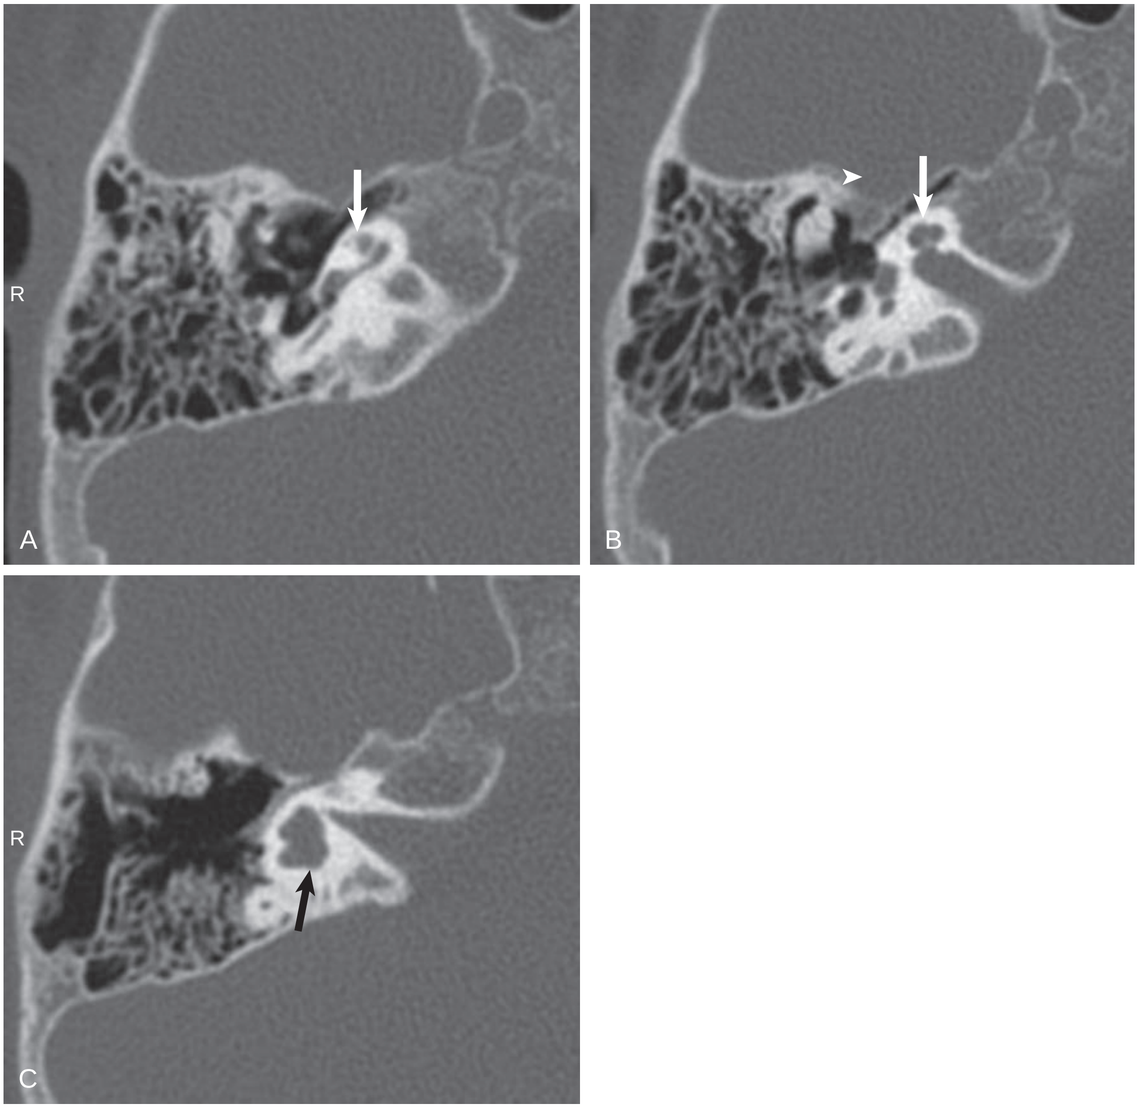
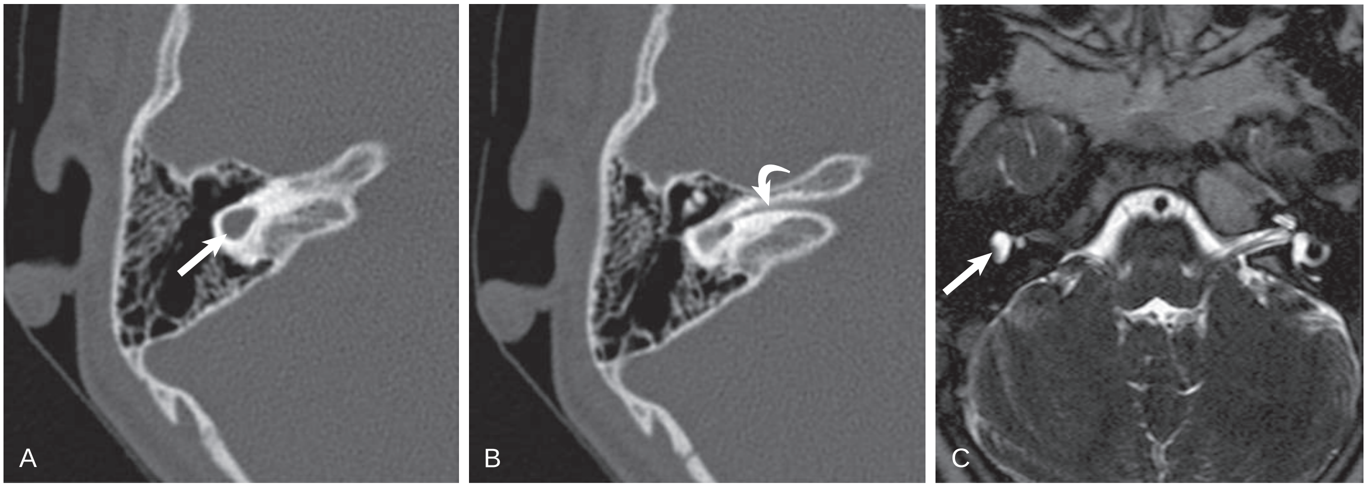
**TABLE 10.2** Syndromes Associated With and Characteristic of Inner Cochlear Anomalies

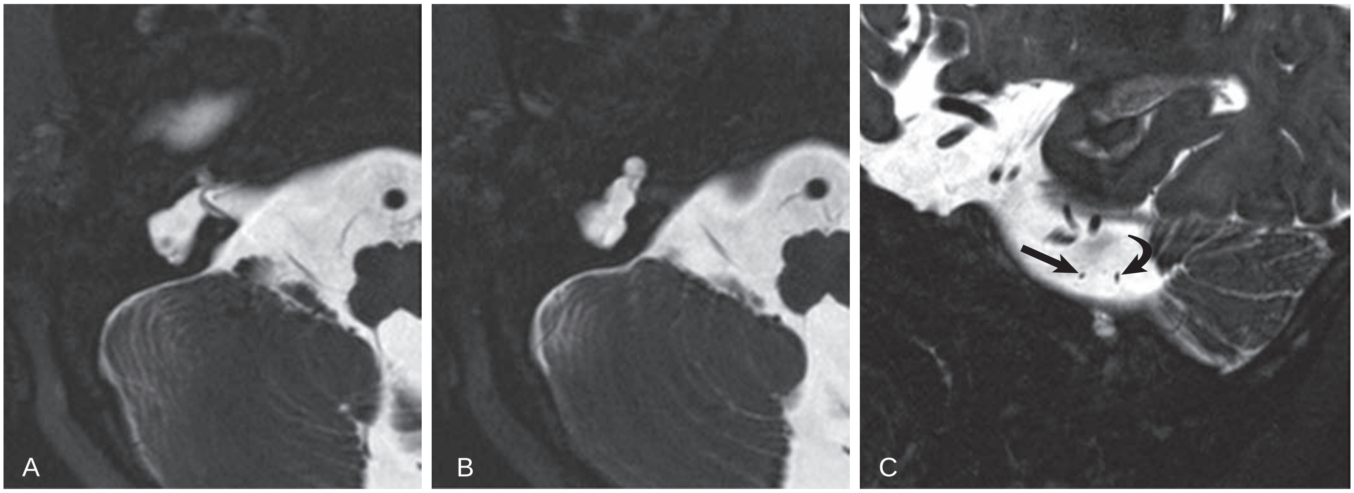
| Syndrome | Cochlea | Other Findings | Gene |
|---|---|---|---|
| Branchio-oto-renal/branchio-otic | Hypoplastic apical turn with "unwound" appearance. | Facial nerve canal medial to cochlea, funnel IAC, patulous Eustachian tube | *EYA1*, *SIX1*, *SIX5* |
| X-linked mixed hearing loss (incomplete partition type III) | Incomplete partition type III. "Corkscrew" appearance of cochlea, absent modiolus | Enlarged facial nerve canal and IAC, associated with gusher | *POU3F4* |
| Pendred syndrome | Incomplete partition type II. "Baseball cap" cochlea with absent lateral notch. Deficient modiolus | Dilated endolymphatic sac/vestibular aqueduct. Dilated vestible | SLC26A4 (PDS) |



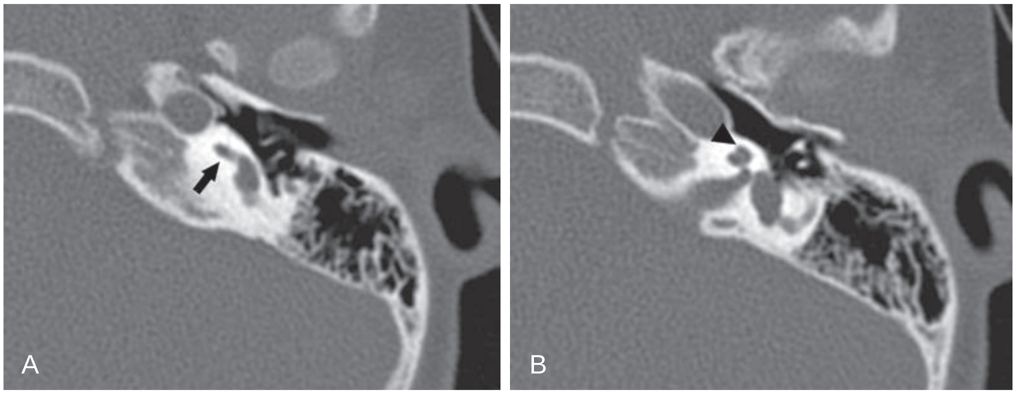
**e-Figure 10.11. Pre-auricular pits and hearing loss in a 5-year-old.** (A–C) Axial high-resolution CT images from inferior to superior. (A and B) There is an "unwound" cochlea with hypoplastic apical and middle turns *(arrows)*. The head of the malleus is also fixed to the anterior superior wall of the middle ear *(arrowhead)*. (C) A dysmorphic vestibule is present *(arrow)*.



**e-Figure 10.14. Cochlear aplasia.** (A and B) Axial high-resolution CT images in a 6-year-old with profound bilateral SNHL show a single fluid cavity *(straight arrow),* which represents a dysplastic vestibule. The cochlea is absent and the internal auditory canal is small *(curved arrow)*. (C) Axial three-dimensional T2-weighted MR image of a different patient demonstrates cochlear aplasia *(arrow)* on the right with a hypoplastic internal auditory canal and absence of the cochlear nerve *(not shown)*.



**e-Figure 10.15. Common cavity malformation.** (A and B) Axial 3D T2-weighted MR images in a 1-year-old with profound hearing loss show a large fluid-filled cavity replacing the cochlea and vestibule. The semicircular canals are absent. (C) Oblique sagittal 3D T2-weighted MR image through the cerebellopontine angle demonstrates a facial nerve *(straight arrow)* and a diminutive vestibulocochlear nerve *(curved arrow)*. The cochlear nerve was absent in the more lateral internal auditory canal *(not shown)*.



**e-Figure 10.16. A 4-year-old with bilateral sensorineural hearing loss.** A and B, Axial high-resolution computed tomography images show a hypoplastic cochlea with a small basal turn *(arrow)* and rudimentary apical turns *(arrowhead)*.

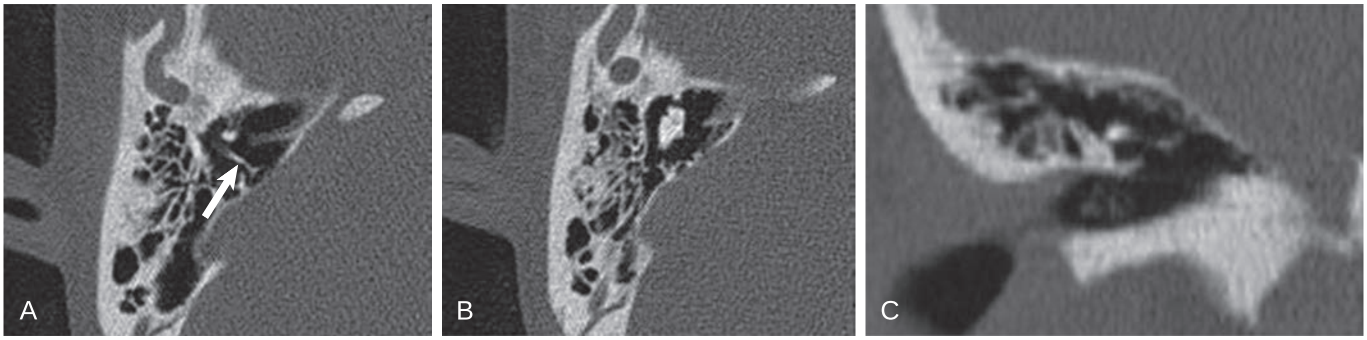


**Figure 10.13. Complete labyrinthine aplasia (Michel malformation).** (A and B) Axial high-resolution CT images and (C) coronal reformatted image of a child with profound hearing loss show complete absence of the membranous labyrinth. Imaging findings are consistent with an early embryologic insult and resultant aplasia (Michel deformity). The ossicles are abnormally oriented *(arrow)*. *(Images courtesy of Nafi Aygun, MD, Johns Hopkins, Baltimore, MD.)*

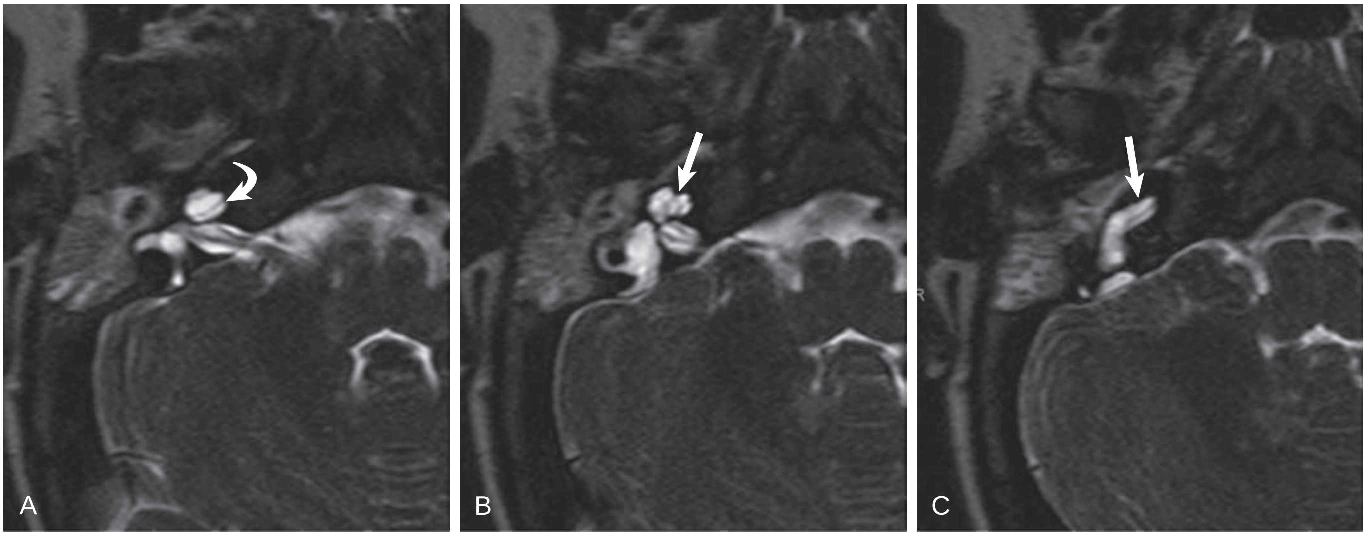

**Figure 10.17. Incomplete partition type II (classic Mondini deformity).** (A–C) Axial 3D T2-weighted MR images in a 9-month-old with bilateral SNHL show a mildly dysplastic basal turn with coalescent apical and middle turns *(straight arrows)*. The intrascalar septum is deficient and scalar asymmetry is present *(curved arrow)*. A dilated endolymphatic duct and enlarged vestibule also are noted. The constellation of findings is typical for incomplete partition type II (Mondini deformity).

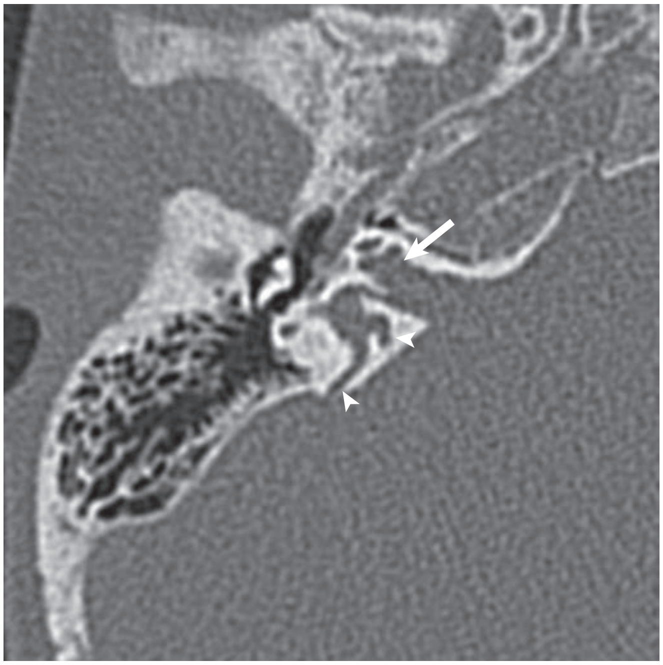
small cochlear bud to a well-formed basal turn and small apical and middle turns.

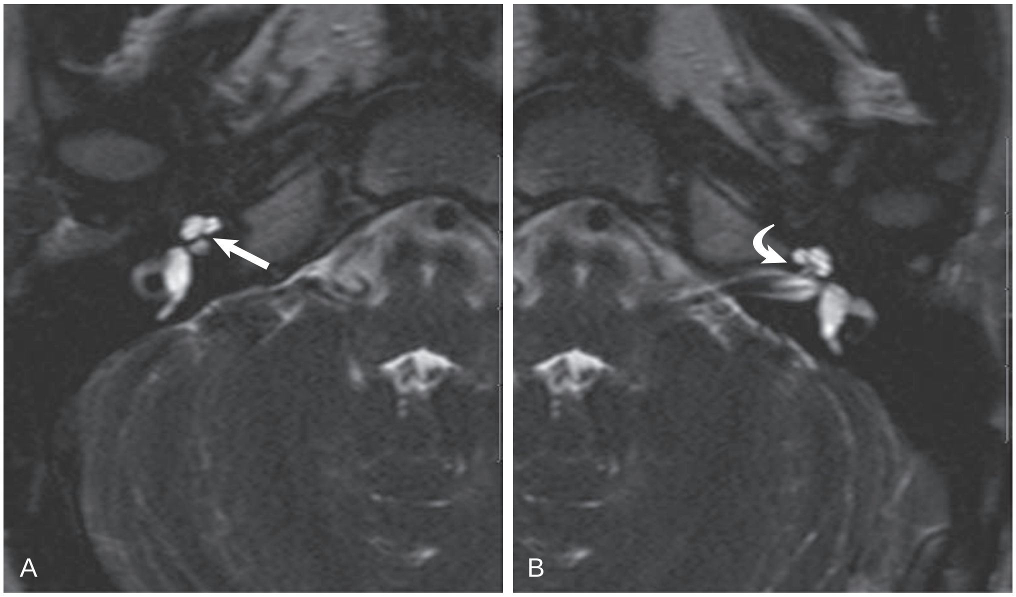
6. Incomplete partition type II (classic Mondini deformity): A normal basal turn of the cochlea is present. The middle and apical structures become a single cystic structure with an incomplete or absent interscalar septum and scalar asymmetry. A dilated vestibule and enlarged vestibular aqueduct/endolymphatic duct often are associated (Fig. 10.17). Numerous syndromes may have an associated Mondini defect, including DiGeorge, Waardenburg, Alagille, Klippel–Feil, Wildervanck, and Pendred syndromes, and chromosomal trisomies.[38]
7. Incomplete partition type III (X-linked mixed hearing loss): There is deficient bone between basal turn of cochlea and internal auditory canal (IAC) as well as the modiolus (corkscrew appearance). The labyrinthine facial, vestibular, and singular canals are enlarged. The patient is at risk for a cerebrospinal fluid (CSF) gusher during surgery (e-Fig. 10.18).[39] A mutation involving *POU3F4* has been suggested as a cause.[40]

It has been suggested that cochlear hypoplasia may be further subcategorized into cochlear bud, basal turn cochlea, and hypoplastic cochlea.[41] MRI has allowed for improved visualization and categorization of the milder forms of cochlear malformation. Modiolar deficiency often is found in children undergoing evaluation for SNHL, with the cochlear modiolus appearing flattened and with a diminished number of bony projections extending into the cochlea (e-Fig. 10.19). In normal ears, the scala vestibuli (anterior) is approximately equal in size to the scala tympani (posterior). Scalar asymmetry is present when the anterior chamber is larger and can be present in children with SNHL (see Fig. 10.17).[42]

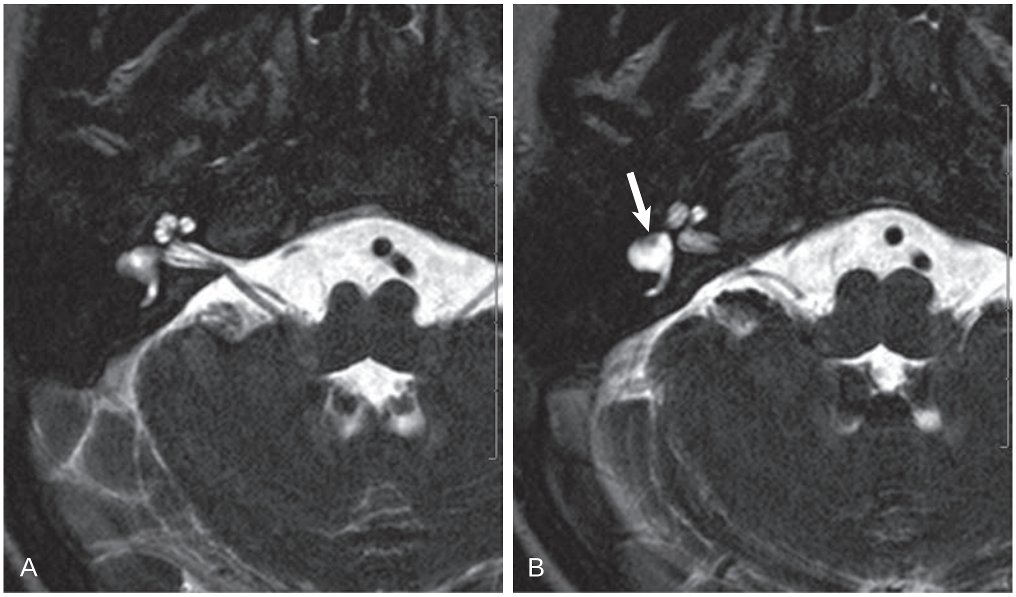
Anomalies of the vestibule usually are associated with other inner ear abnormalities and are seldom isolated. The semicircular canals may be partially or completely assimilated into the vestibule. The diameter of the vestibule should normally be equal to the diameter of the bony plug between the vestibule and lateral semicircular canal.[42] The bony island should be 3 mm or larger[43] (e-Fig. 10.20). Although the abnormal vestibule is usually dilated, it can be small. If the vestibule is small, the oval window is frequently stenotic or atretic, and the facial nerve is often malpositioned.



**e-Figure 10.18. Incomplete partition type III (X-linked mixed hearing loss).** Axial high-resolution CT image in an 11-year-old male with bilateral mixed hearing loss demonstrates an absent modiolus and widened cochlear aperture *(arrow)*. The singular canal and malpositioned vestibular aqueduct are enlarged *(arrowheads)*.



**e-Figure 10.19. Profound right sensorineural hearing loss in a 6-year-old.** Axial 3D T2-weighted MR images show a flattened deficient modiolus *(arrow)* on the right (A) and the normal left for comparison (B, *curved arrow*). The internal auditory canal was small on the right with absence of the right cochlear nerve *(not shown)*.



**e-Figure 10.20. Bilateral sensorineural hearing loss in a 3-year-old.** (A and B) Axial 3D T2-weighted MR images show incorporation of the lateral semicircular canal into the vestibule with absence of the normal bony plug or island *(arrow)*. The cochlea is normal.

This constellation of findings are found in the CHARGE association, along with absent semicircular canals.[24] Absent semicircular canals with a large or deformed vestibule can be seen in Waardenburg syndrome associated with *SOX10* mutations. Isolated absence of the posterior semicircular canal is seen in this syndrome and also in Alagille syndrome (e-Fig. 10.21).[44] A small vestibular bone island has been documented in Down syndrome patients along with small IACs and cochlear nerve canals with borderline association of SNHL.[45]

Enlargement of the vestibular aqueduct often is reported as the most common inner ear anomaly to be demonstrated by imaging; however, using 3D fluid-sensitive MRI sequences, milder forms of cochlear dysplasia may be more common.[35] An enlarged vestibular aqueduct is associated with progressive SNHL, complete hearing loss after trauma, as well as CHL due to a third window phenomenon.[46] The aqueduct is enlarged when the midaperture diameter is 1.0 mm or greater and is best demonstrated on axial CT.[43] CT, as compared with MRI, may have a greater yield for enlarged vestibular aqueduct.[47] Although, MRI can directly demonstrate a dilated endolymphatic duct as well as the sac. Dilatation of the sac may be seen as an isolated abnormality in children with SNHL. MRI has demonstrated that a large percentage of these cases have associated anomalies of the membranous labyrinth (84%), which include modiolar deficiencies, scalar asymmetry, an enlarged vestibule, and an enlarged lateral semicircular canal[42] (Box 10.2) (e-Fig. 10.22).

Embryologically, the endolymphatic duct and sac form at the same time as partitioning of the cochlea occurs, which may explain the common association of cochlear dysplasia. Most cases of large vestibular aqueduct are sporadic, but it also has been reported in persons with Pendred syndrome, distal renal tubular acidosis, CHARGE association, and branchio-oto-renal syndrome.[48,49] The presence of heterogeneous signal within the sac on steady-state T2-weighted MR images may correlate with high protein levels, indicating the presence of Pendred syndrome and possibly the development of goiter.[50]

**BOX 10.2** Associations of an Enlarged Endolymphatic Duct

- Modiolar deficiency
- Scalar asymmetry
- An enlarged vestibule and lateral semicircular canal
- Dehiscent semicircular canals
- SLC26A4 (PDS) gene mutation
- Incomplete partition type II (Mondini deformity)

The size and contents of the IAC should be evaluated on MRI in all patients. The IACs are usually symmetric; however, considerable variability is found in shape, size, and orientation. The IAC may be absent or hypoplastic with severe IAC narrowing associated with deficiency or absence of the cochlear nerve. A duplicated IAC represents the facial nerve canal and a hypoplastic IAC with the presence of a deficient or absent cochlear nerve.[51] A duplicated IAC has been reported to be associated with pontine tegmental cap dysplasia and other entities[52] (e-Fig. 10.23).

It is important to note that the size of the IAC correlates with the presence or absence of the cochlear nerve; however, a normal-sized cochlear nerve can be associated with a small IAC, and a deficient or absent cochlear nerve can be seen with a normal IAC.[35] The osseous channel for the cochlear nerve (cochlear aperture) is well demonstrated on CT, with a small or absent channel representing an indirect sign of cochlear nerve deficiency or absence[53] (e-Fig. 10.24). A cutoff value of 1.5 mm has been suggested for the size of the cochlear nerve canal, with a value of equal or lower size suggesting deficiency of the cochlear nerve.[54]

The size and presence of the cochlear nerve is best assessed with direct oblique sagittal MR images through the IAC. The cochlear nerve should be greater or equal in size to the adjacent facial nerve (Fig. 10.25). If the IAC is stenotic and the cochlear nerve is not well seen, the vestibulocochlear nerve complex can be found in the cerebellopontine cistern, with the vestibulocochlear nerve complex normally greater than two times the size of the adjacent facial nerve.[55,56] The IAC may be enlarged in neurofibromatosis type 1 as a result of dural ectasia or in association of translabyrinthine fistulae in children who have severe malformations of the inner ear.[57] PHACES syndrome (*P*osterior fossa malformations, *H*emangiomas, *A*rterial anomalies, *C*ardiac defects, *E*ye abnormalities, *S*ternal cleft) may be associated with a large IAC, possibly relating to an involuted infantile hemangioma.[58]

***Treatment.*** Hearing aids and cochlear implantation are the most common interventions in a child with SNHL. CT and MRI are

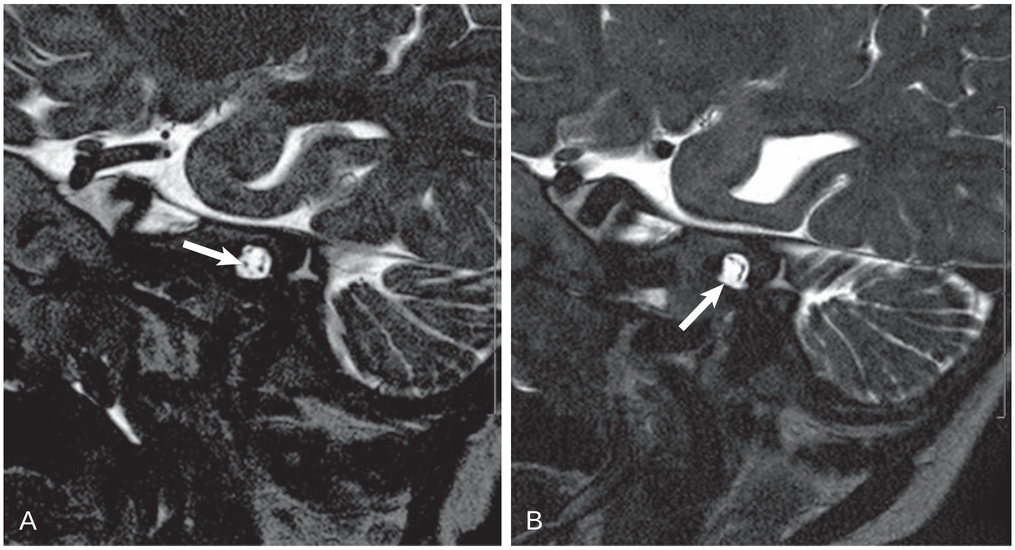


**Figure 10.25. Cochlear nerve aplasia.** One-year-old with profound right sensorineural hearing loss. (A) Left and (B) right oblique sagittal 3D T2-weighted MR images show absence of the right cochlear nerve and a normal left cochlear nerve *(arrows)*.

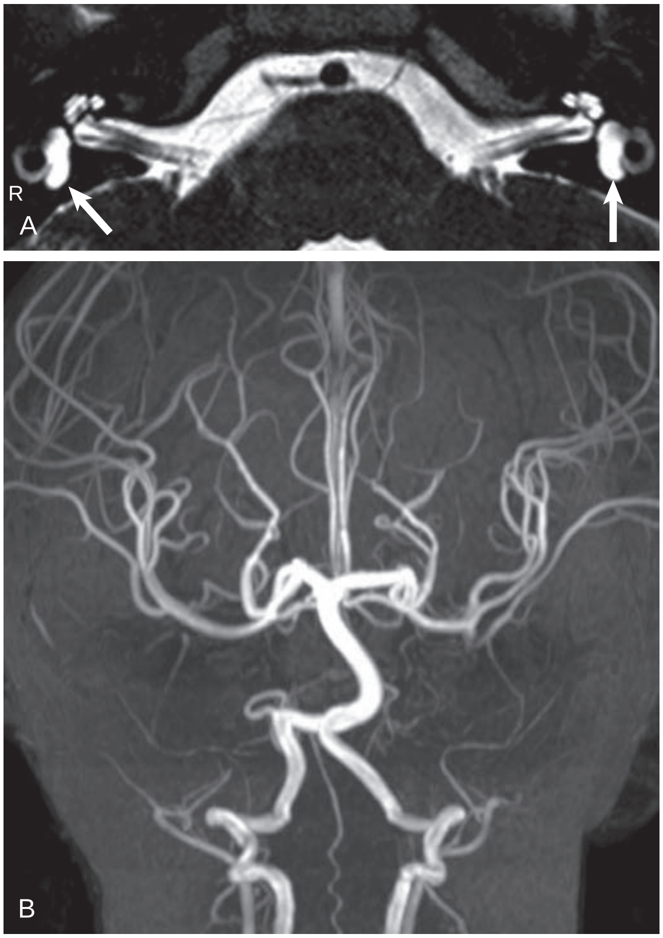
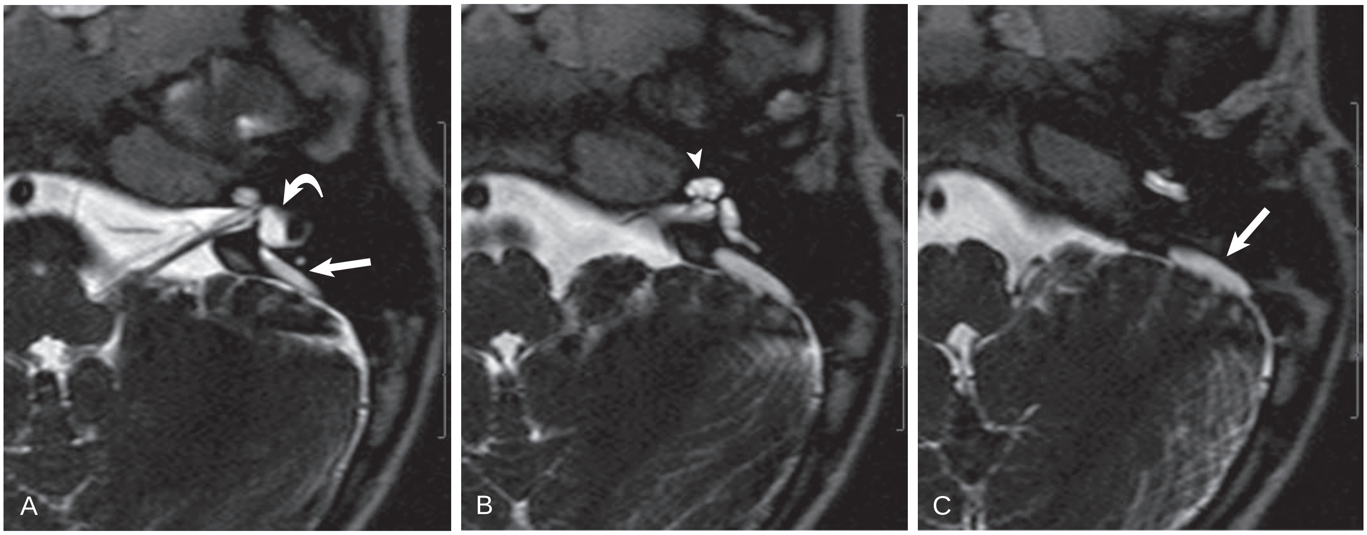
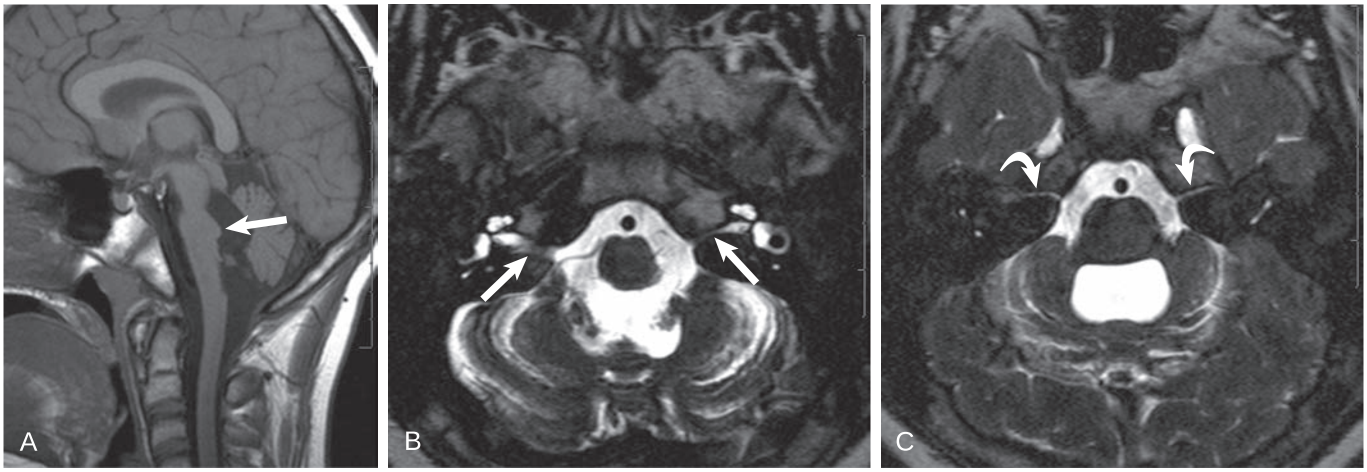


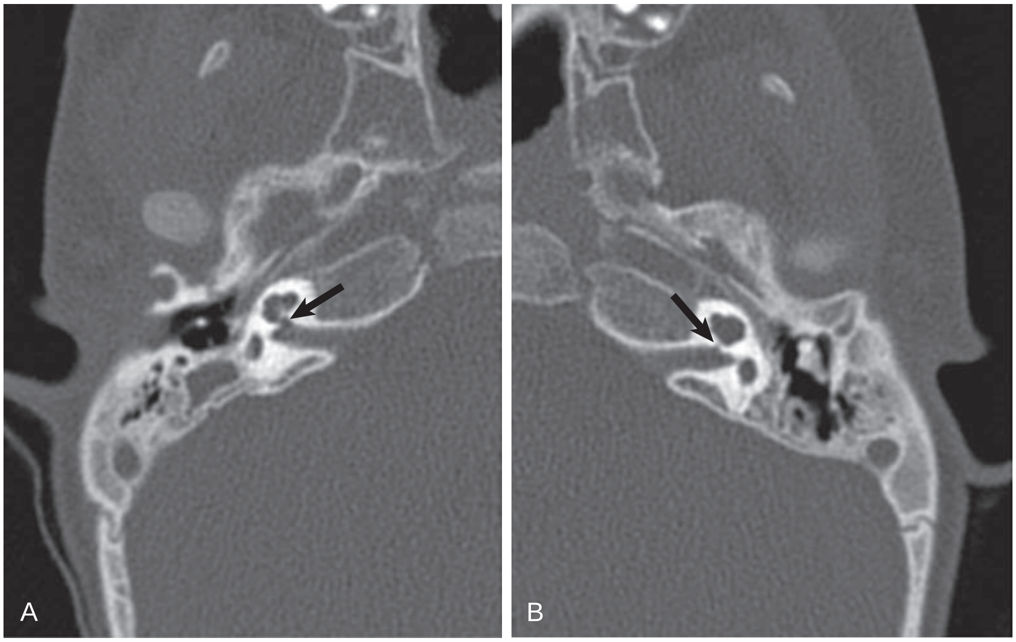
**e-Figure 10.21. Chronic cholestasis and Alagille syndrome in a 4-year-old.** (A) Axial 3D T2-weighted MR image show absent posterior semicircular canals with a rudimentary pouch projecting from the posterior vestibule *(arrows)*. (B) MR arteriogram demonstrates congenital absence of the internal carotid arteries with large vertebral and basilar arteries present.



**e-Figure 10.22. Progressive bilateral sensorineural hearing loss in a 5-year-old.** (A–C) Axial 3D T2-weighted MR images demonstrate an enlarged endolymphatic duct and sac *(straight arrows)*. The cochlea is malformed (incomplete partition type II) *(arrowhead)* with a deficient modiolus. The vestibule is abnormally enlarged as well *(curved arrow)*.



**e-Figure 10.23. Pontine tegmental cap dysplasia in a 14-year-old.** Bilateral sensorineural hearing loss and corneal ulcers (fifth cranial nerve) were present clinically. (A) Midline sagittal T1-weighted MR image shows a markedly dysmorphic brainstem with a typical dorsal protrusion *(arrow)*. (B and C) Axial 3D T2-weighted MR images demonstrate small native internal auditory canals *(straight arrows)* and accessory canals for both facial nerves *(curved arrows)*.



**e-Figure 10.24. Bilateral sensorineural hearing loss in a 2-year-old.** (A and B) Axial high-resolution CT images show a normal cochlear nerve canal on the right and absence of the cochlear nerve on the left *(arrows)*. MRI demonstrated a normal nerve on the right and an absent nerve on the left *(not shown)*. The internal auditory canals are symmetric in size. The left cochlea is malformed (B) with only a cystic fluid collection present (incomplete partition type I).

able to classify the severity of inner ear malformations encountered. MRI is better able to evaluate the intracranial contents and directly visualize the cochlear nerve, which allows the otolaryngologist to better assess the potential success of implantation and potentially directs the side to be implanted. After implantation, CT becomes the mainstay in the evaluation of complications and implant position.

## CEREBROSPINAL FLUID FISTULA, GUSHER, AND RECURRENT MENINGITIS

***Clinical Presentation and Etiologies.*** Recurrent meningitis, perilymphatic fistula, or gusher may be caused by anomalies associated with modiolar deficiency and absent lamina cribrosa, which may be found in severe inner ear anomalies, incomplete partition type I, and X-linked mixed hearing loss. There is a resultant abnormal communication between the subarachnoid space and middle ear. Congenital perilymphatic fistula is a cause of unexplained asymmetric SNHL in children, recurrent meningitis, vertigo, as well as a gusher during stapes surgery. The most common site of a fistula is in the region of the stapes footplate, resulting from malformation of the stapes. Fistulas may occur via a dilated cochlear aqueduct or more commonly via a deficient lamina cribrosa.[57]

***Imaging.*** CT findings include deficient modiolus, lamina cribrosa, and fluid or soft tissue protruding though the oval window. This bulging oval window is well demonstrated on MRI (e-Fig. 10.26). Less commonly, the labyrinthine facial nerve canal may be enlarged, and the IAC has an undulating contour.[59] This anatomy may result in perilymphatic fistula and a gusher during stapedial footplate manipulation or cochlear implantation.[60]

***Treatment.*** Knowledge of the potential perilymphatic fistula is important preoperatively and can obviate the need for a second surgery. A preemptive packing procedure can prevent the development of a significant leak during manipulation of the oval and or round window.

## VASCULAR ABNORMALITIES

***Clinical Presentation and Etiologies.*** Vascular abnormalities often are encountered in the temporal bone. The anomalies can be asymptomatic or result in CHL and may alter potential surgery. A child with a glomus tumor or hemangioma may present with a vascular, bluish mass within the middle ear cavity (Box 10.3).

***Imaging.*** Arterial: The internal carotid artery (ICA) may be congenitally absent on either one or both sides. The entity can be confirmed by documenting absence of the associated carotid canal on CT.

With an aberrant ICA, the cervical portion of the ICA may regress during embryogenesis and is replaced by an anastomosis of the enlarged inferior tympanic and caroticotympanic arteries. The aberrant ICA enters the tympanic cavity, posterior to the course of the normal ICA, through an enlarged tympanic canaliculus. It joins the horizontal carotid canal through a dehiscence in the carotid plate. This abnormality may be unilateral or bilateral. Clinical presentations include tinnitus, vertigo, hearing loss, and ear pain. An aberrant ICA also can be associated with a persistent stapedial artery (e-Fig. 10.27).

The stapedial artery usually regresses during the third month of gestation. The persistent stapedial artery is a rare anomaly that may be unilateral or bilateral and may occur with or without an aberrant ICA. The anomalous artery originates at the genu of the ICA. The artery courses superiorly over the cochlear promontory and through the crura of the stapes into the tympanic segment of the facial nerve canal. The CT appearance includes enlargement of the tympanic segment of the facial nerve and absence of foramen spinosum[61,62] (Fig. 10.28). It is important to know that the foramen spinosum can be absent in 3% of the normal population.[63]

Venous: Variants of the jugular bulb include agenesis, atresia, stenosis, diverticulum, protrusion, and high location. Agenesis of the jugular bulb is extremely rare. Associated agenesis of the sigmoid bulb may be present, with redirection of flow via transmastoid channels into regional scalp veins. Associated dilated venous collaterals should be described because they may affect potential surgery. Jugular atresia and stenosis may be isolated or associated with other disorders such as achondroplasia, Crouzon syndrome, and CHARGE association. MR or CT venography may be used to assess for venous obstruction in these patients[64] (e-Fig. 10.29).

A high jugular bulb is the most common variant, characterized by elevation of the roof of the jugular bulb above the inferior tympanic ring or floor of the IAC. It usually is unilateral but may be bilateral in up to 12% of cases. It is well demonstrated by CT or jugular venography.

Protrusion of the jugular bulb through a dehiscence of the floor of the middle ear into the hypotympanum is a common vascular anomaly of the temporal bone (e-Fig. 10.30). Clinically, the bluish mass behind the tympanic membrane may be mistaken for a vascular mass in the middle ear. Symptoms include hearing loss, usually CHL due to obstruction of the oval window or contact with the ossicles, pulsatile tinnitus, and headaches. The enhancing soft tissue mass in the middle ear and the bony defect above the jugular bulb in the floor of the hypotympanum are demonstrated on CT.[65]

A jugular diverticulum emanates from a jugular bulb that rises superomedially in the petrous pyramid. In contrast to a protruding bulb, it is more medially and posteriorly located in the petrous bone and does not invade the middle ear. The diagnosis is made only by imaging because it is not visible clinically.

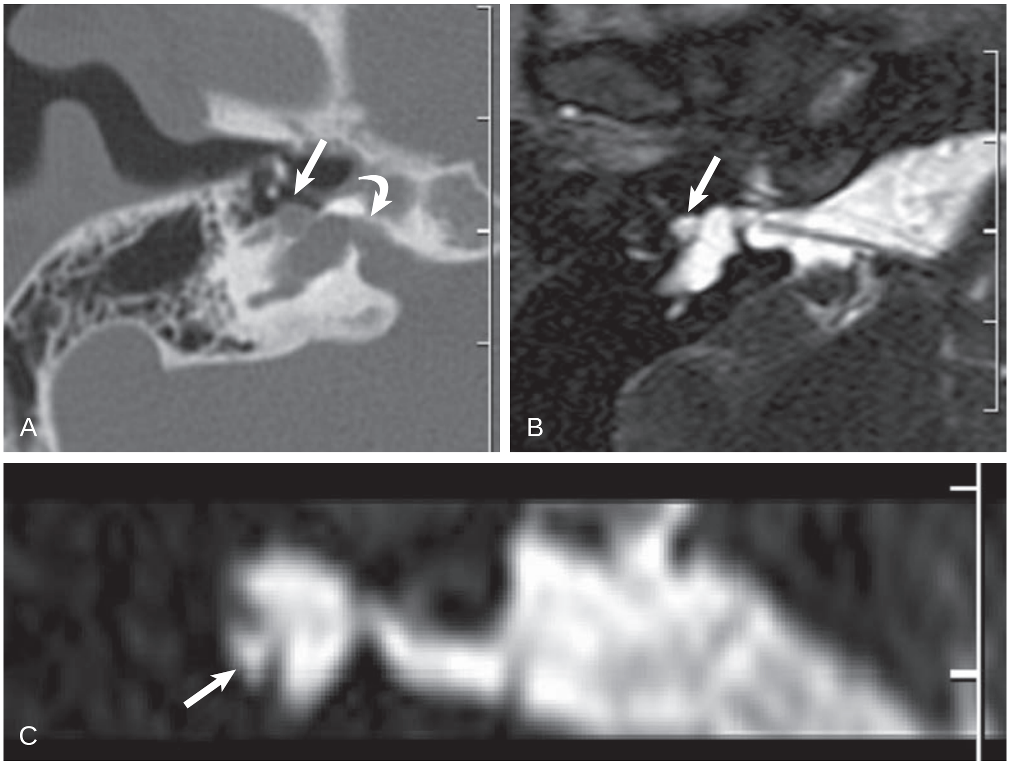
***Treatment.*** These lesion abnormalities need to be recognized and qualify them as "don't touch" lesions, with surgery usually being avoided. The presence of a jugular diverticulum may affect surgery involving the IAC and should be commented on in the imaging report.[47,61]

### **BOX 10.3** Vascular Abnormalities of the Middle Ear

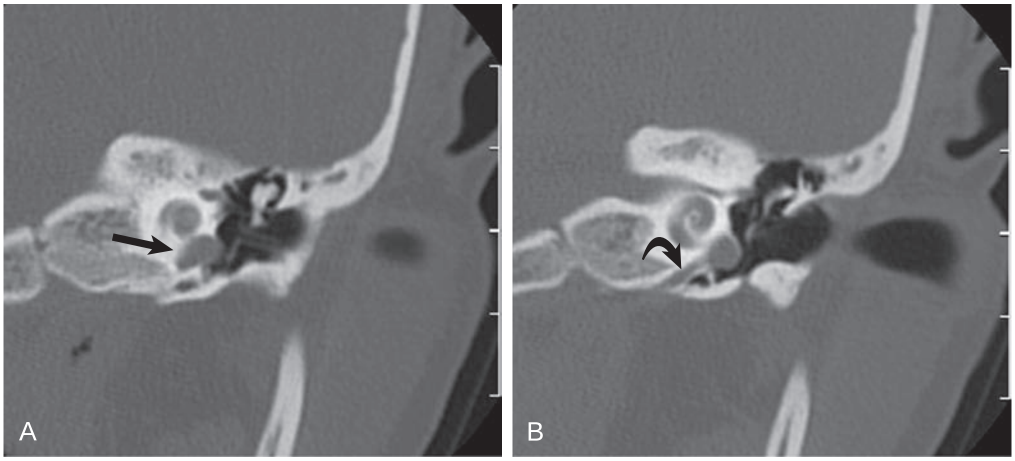
- Agenesis ICA
- Aberrant ICA
- Persistent stapedial artery
- Dehiscent-protruding jugular bulb
- Jugular bulb diverticulum
- Venous agenesis—obstruction

### KEY POINTS

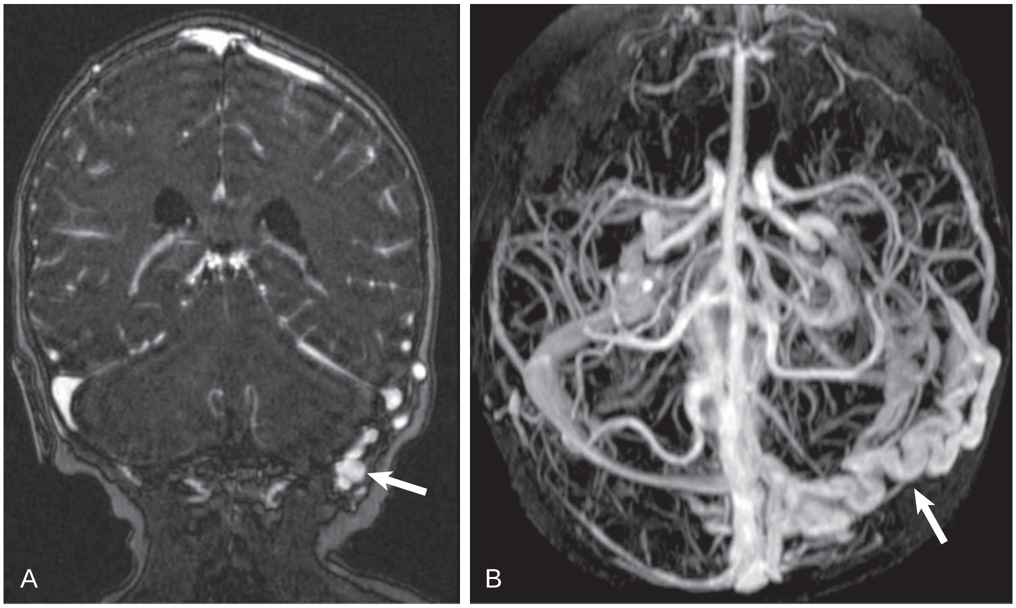
- Facial nerve position in EAC atresia is critical.
- Round window atresia usually is associated with CHL.
- Isolated oval window atresia is a second branchial arch anomaly associated with mixed hearing loss. A malformed incus and stapes often is associated with mixed hearing loss, along with a malpositioned facial nerve.
- Imaging findings in persons with CHARGE association include ossicular fixation, a small vestibule, absent semicircular canals, and oval window atresia.
- The cochlear nerve canal should be greater or equal to 1.5 mm.
- Deficiency of the lamina cribrosa or cochlear modiolus can predispose to recurrent meningitis and a CSF gusher during surgery.



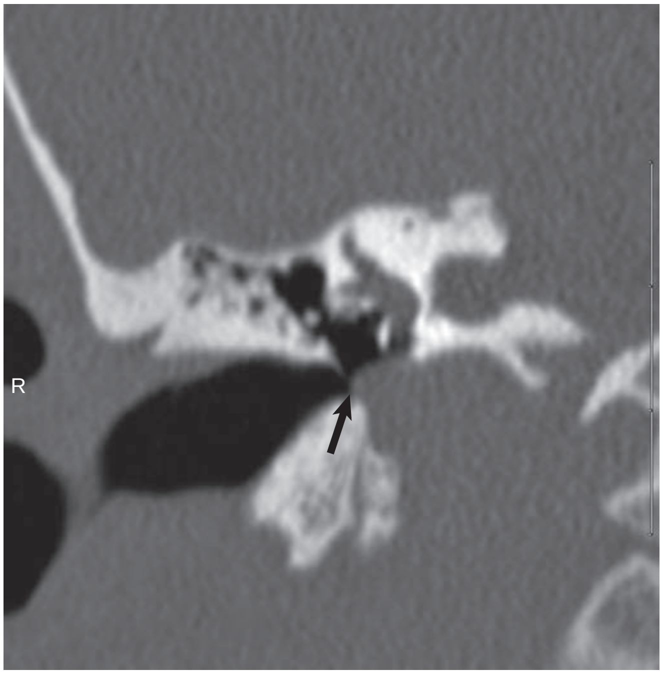
**e-Figure 10.26. Profound hearing loss and recurrent meningitis in an 11-year-old.** (A) Axial CT image shows fluid bulging through the oval window *(straight arrow)* and a deficient lamina cribrosa *(curved arrow)*. (B and C) Axial and coronal reformatted 3D T2-weighted MR images show fluid protruding through the oval window *(arrows)*.



**e-Figure 10.27. Aberrant internal carotid artery.** (A and B) Coronal high-resolution CT images show a vascular structure protruding into the middle ear cavity lateral to the cochlea *(straight arrow)*. The aberrant internal carotid artery enters the temporal bone via the inferior tympanic canaliculus *(curved arrow)*.



**e-Figure 10.29. Crouzon syndrome and hearing loss.** (A and B) Coronal source and maximum-intensity projection images from a gadolinium-enhanced MR venogram show stenosis of the jugular bulb with extensive extracranial collateral formation *(arrows)*.



**e-Figure 10.30. High-riding protruding jugular bulb in a child with a clinically suspected middle ear mass.** A coronal reconstructed computed tomography image shows the jugular bulb extending into the middle ear cavity and compromising the round window *(arrow)*.

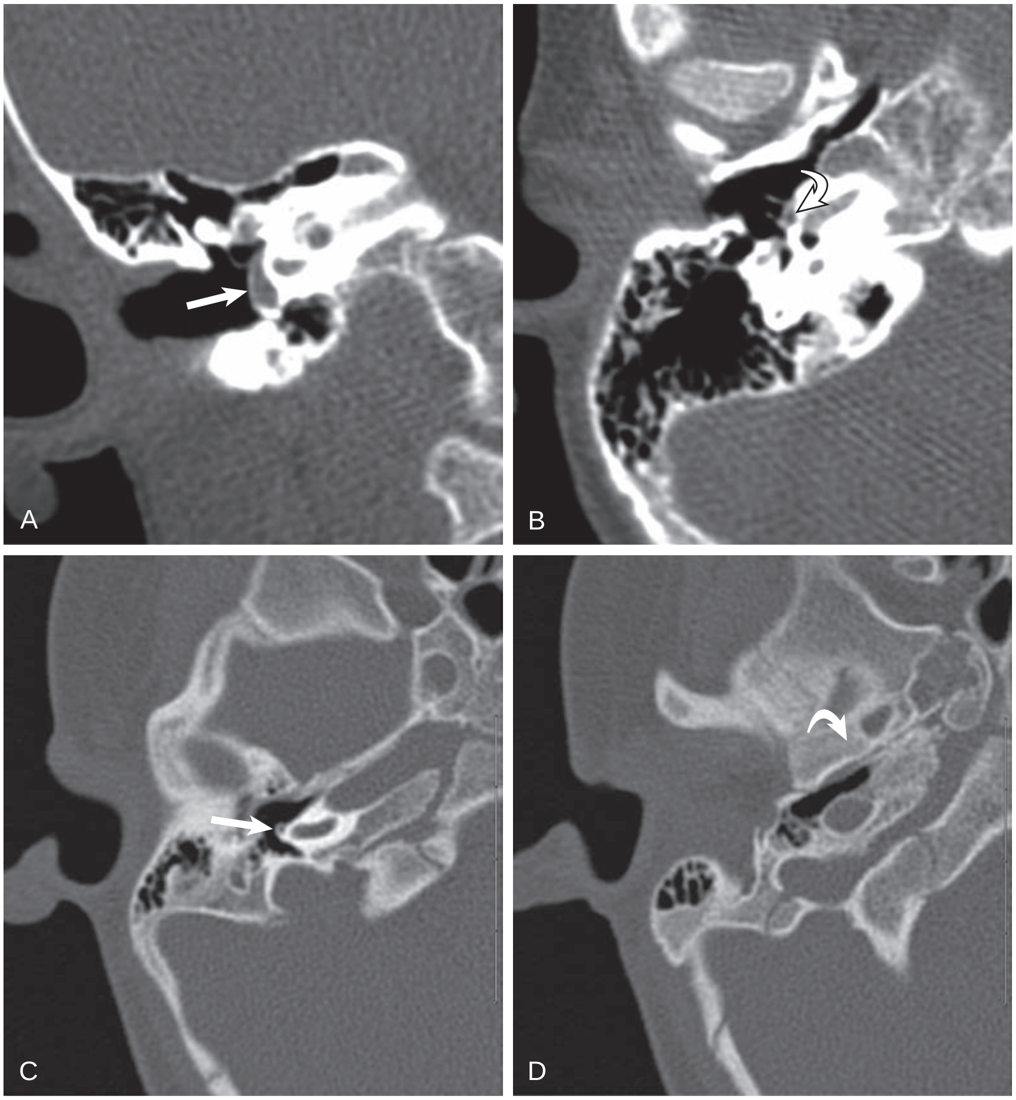


**Figure 10.28. Persistent stapedial artery.** (A) Coronal and (B) axial high-resolution CT images show a vascular structure ascending vertically along the cochlear promontory *(straight arrow)* through the stapedial crura *(curved arrow)*. (C and D) Axial CT images in a different patient demonstrating a bony covered vessel on the cochlear promontory *(straight arrow)* and absence of the foramen spinosum *(curved arrow)*.

# 11

# Infection and Inflammation

Timothy N. Booth

Infectious and inflammatory disorders commonly involving the temporal bone; external, middle, and inner ear; and the facial nerve are discussed in this chapter.

The auricle, the cartilaginous canal, and the external auditory canal (EAC) comprise the external ear, with the tympanic membrane representing the division between the external and middle ear.

The middle ear is predominately composed of the tympanic cavity and its contents. The Eustachian tube connects the middle ear to the nasopharynx and can be a path for the spread of infection. All air spaces are lined with mucosa, which makes them susceptible to the spread of infection and inflammation. The membranous and bony labyrinths make up the inner ear, with potential communication with the subarachnoid space.

## EXTERNAL EAR

### External Otitis

***Clinical Presentation and Etiologies.*** Children present with variable degrees of pain, as well as secretions that can be serous early and progress to frank purulence. External otitis is associated with swimming and can be caused by a number of pathogens, including fungi. Otomycosis is more common in the postsurgical ear and presents in a similar fashion to a bacterial infection.[1]

***Imaging.*** The diagnosis of otitis externa should be made clinically; however, the diagnosis can be made in the evaluation of periauricular inflammation with parotiditis and an infected type 1 branchial cleft cyst also being a consideration.[2] Soft tissue swelling centered within the EAC, is demonstrated on computed tomography (CT) (e-Fig. 11.1). The condition is termed *malignant* or *necrotizing otitis externa* when there is more extensive involvement of regional soft tissues and bone.[3] Langerhans cell histiocytosis can infiltrate the soft tissue of the external canal but is more often associated with extensive bony destruction commonly associated with middle ear and mastoid involvement. Involvement of the petrous apex is encountered more frequently with rhabdomyosarcoma.[4]

***Treatment.*** Usual treatment comprises appropriate antibiotics and antifungal treatment in the postoperative ear. Surgical intervention is typically not necessary.

### Malignant (Necrotizing) Otitis Externa

***Clinical Presentation and Etiologies.*** Usually, the presentation is acute, with associated systemic symptoms of fever and leukocytosis. *Pseudomonas aeruginosa* is the most common cause. Diabetes is a common predisposing condition; however, any condition resulting in immunodeficiency can predispose.[5–7]

***Imaging.*** CT shows extensive inflammation within the EAC and can demonstrate bony destruction. Magnetic resonance imaging (MRI) with gadolinium demonstrates osteomyelitis, with increased signal on fat-suppressed T2-weighted images and abnormal enhancement in the regional bone. MRI is useful in confirming central skull base involvement, especially in the presence of multiple cranial nerve palsies, and in evaluating for intracranial complications.[7] It is important to consider prior surgical history as a transcanal approach can result in irregularity and bony defects in the absence of infection.[8]

Single photon emission CT (SPECT) technetium-99m bone scan is an effective way to confirm or exclude bone involvement in a patient whose condition evokes high clinical suspicion and can be positive in the absence of osseous destruction on CT.[9] In adults, radionuclide antigranulocytic studies have shown promise in diagnosis and follow-up as well.[10]

***Treatment.*** Several weeks of intravenous antibiotics are required. CT helps assess the extent of inflammation and surrounding bony involvement and is used to stratify patients into nonsevere and severe groups, with the latter offered early surgical intervention and debridement.[11] Children are reported to have better outcomes compared with adults.

### Other Lesions Encountered Within the External Auditory Canal

Acquired cholesteatoma may present as debris or a mass within the EAC (e-Fig. 11.2), as can keratosis obturans.[12] Exostoses of the external canal may result from chronic inflammation caused by prolonged exposure to water. Exostoses tend to be bilateral, broad based, and of bony density. Foreign bodies and osteomas can also occur in the external canal, with osteomas appearing pedunculated and very dense (e-Fig. 11.3).[13]

## MASTOID AND MIDDLE EAR

### Acute Infections

#### Otitis Media

***Clinical Presentation and Etiologies.*** Otitis media is the most common childhood infection treated with antibiotics. The otoscopic findings are critical to the diagnosis. Acute otitis media typically presents with fever, ear pain, and a red tympanic membrane.[14] The initial cause of the infection is likely viral and may not require treatment with antibiotics, but it may be bacterial or represent a secondary bacterial infection. Complications may occur in up to 10%, but conservative practice guidelines have not led to an increased incidence of acute mastoiditis.[15]

***Imaging.*** CT and MRI have little place in the evaluation of uncomplicated acute otitis media. It is important to realize that fluid in the middle ear and mastoid is often found in asymptomatic individuals and may have no significance.

#### Mastoiditis

***Clinical Presentation and Etiologies.*** Acute mastoiditis is the most common complication of acute otitis media and usually presents with high fever and elevated systemic inflammatory markers. Bacterial infections are most commonly caused by *Streptococcus pneumoniae* and group A beta-hemolytic streptococci. Nonbacterial causes include tuberculosis and fungal infections. Disease in the very young or infections that are not responsive to antibiotic therapy should raise the suspicion of an atypical infection or possible Langerhans cell histiocytosis (e-Fig. 11.4).[16] Facial nerve paralysis is uncommon in bacterial mastoiditis, usually is temporary, and the presence may suggest atypical etiologies. Complications of acute mastoiditis are common in children, reported in up to 25% of cases.[17–19]

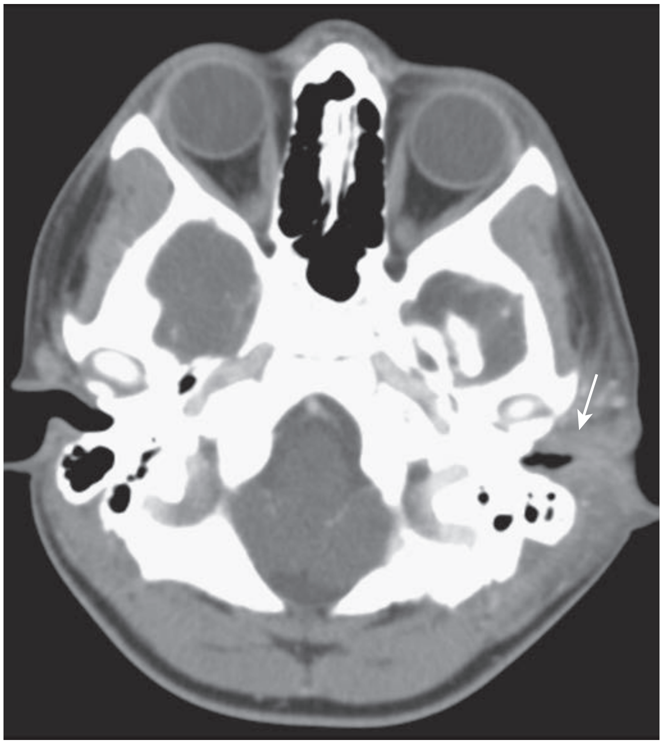
***Imaging.*** Mastoid air fluid levels can be seen in uncomplicated acute mastoiditis; however, the diagnosis remains a clinical diagnosis.

## Abstract:

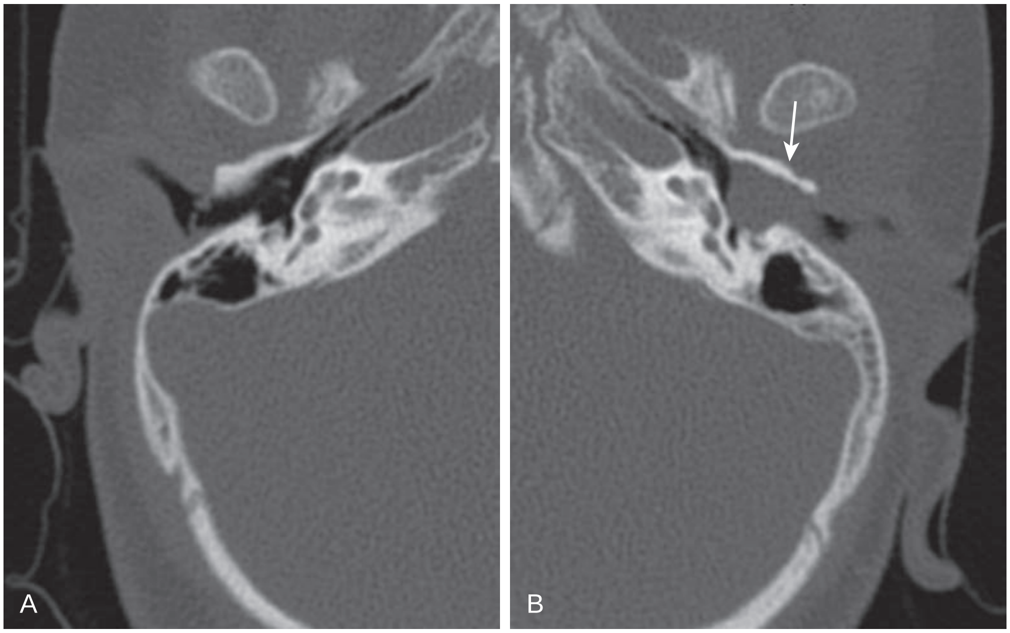
The temporal bone is a complex region, which is susceptible to both infectious and inflammatory conditions. This chapter will review the most common etiologies and discuss clinical presentation, indication for imaging and findings, as well as potential treatment options. The reader should have a thorough understanding of infectious and inflammatory pathologies that involve the temporal bone and regional structures.

## Keywords:

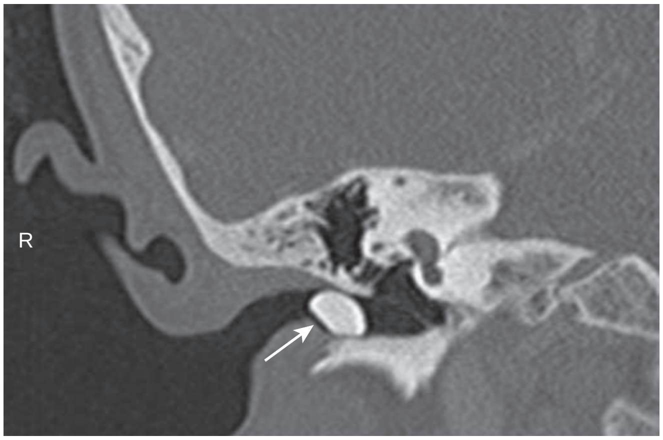
Temporal bone
Infection
Inflammation
mastoiditis
otomastoiditis
cholesteatoma
labyrinthitis



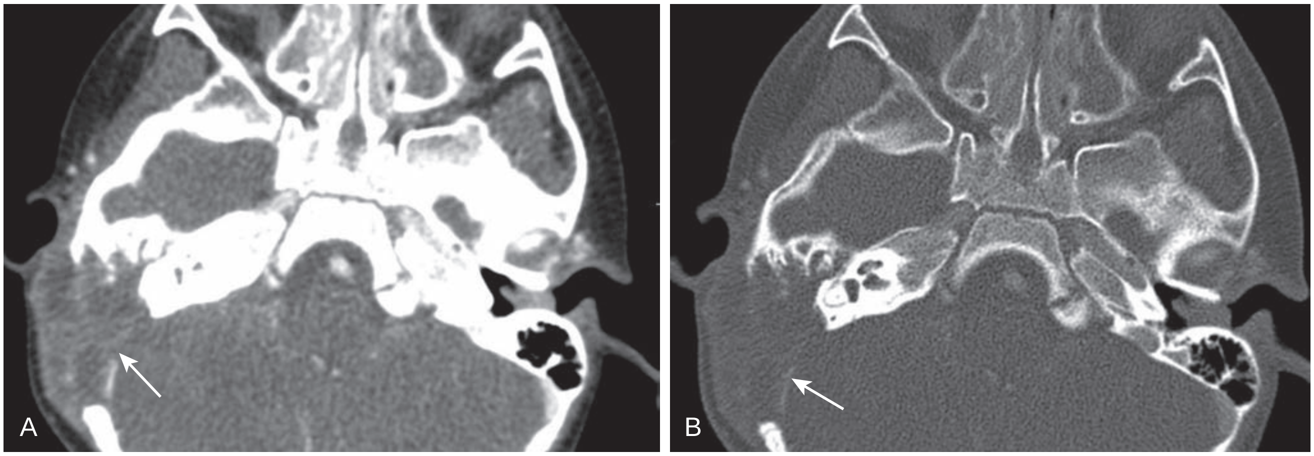
**e-Figure 11.1. Otitis externa in a 13-year-old with ear pain and soft tissue swelling.** Axial postcontrast CT through the level of the external canal shows extensive inflammation surrounding the left external canal *(arrow)* with normal aeration of the adjacent mastoids and a normal parotid gland *(not shown)*.



**e-Figure 11.2. Acquired cholesteatoma in a 5-year-old with otorrhea.** (A) Axial CT image through the normal right external canal. (B) Axial CT image through the left external canal. A large soft tissue mass with erosion of the anterior wall *(arrow)* is present. The tympanic membrane bulges medially with findings representing an external canal cholesteatoma.



**e-Figure 11.3. Foreign body in an 8-year-old with mass in the external canal.** Axial CT image demonstrates a dense mass in the external canal *(arrow)*. Surgery revealed the mass to represent a foreign body rather than an osteoma, but both should be considered.



**e-Figure 11.4. Langerhans cell histiocytosis in a 2-year-old with periauricular soft tissue swelling.** (A and B) Axial CT through mastoids, soft tissue (A) and bone windows (B) show a destructive mass centered within the posterior lateral mastoid region *(arrows)*.

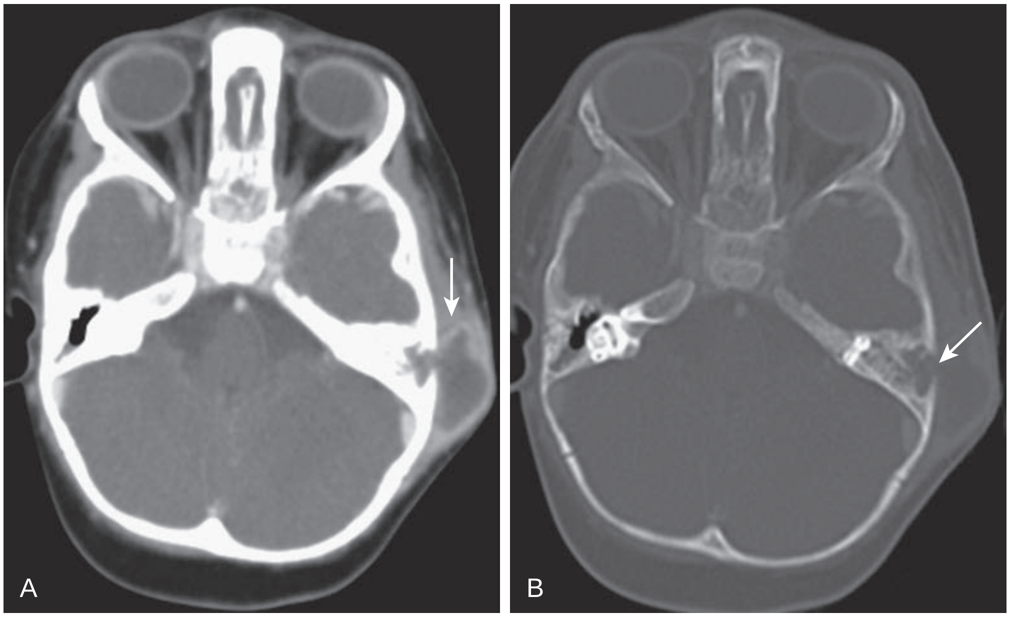


**Figure 11.5. Mastoiditis in a 2-year-old with post auricular swelling.** (A) Axial CT image through the mastoids shows a large subperiosteal abscess *(arrow)*. (B) Axial CT with bone windows demonstrates destruction of the lateral mastoid wall *(arrow)*. No intracranial extension is present with a normally enhancing sigmoid sinus.

Imaging becomes useful in evaluating for possible complications, with CT diagnosing the complications of mastoiditis with a high sensitivity and positive predictive value.[20] MRI and magnetic resonance venography (MRV) are valuable in assessing intracranial involvement and associated dural sinus thrombosis.

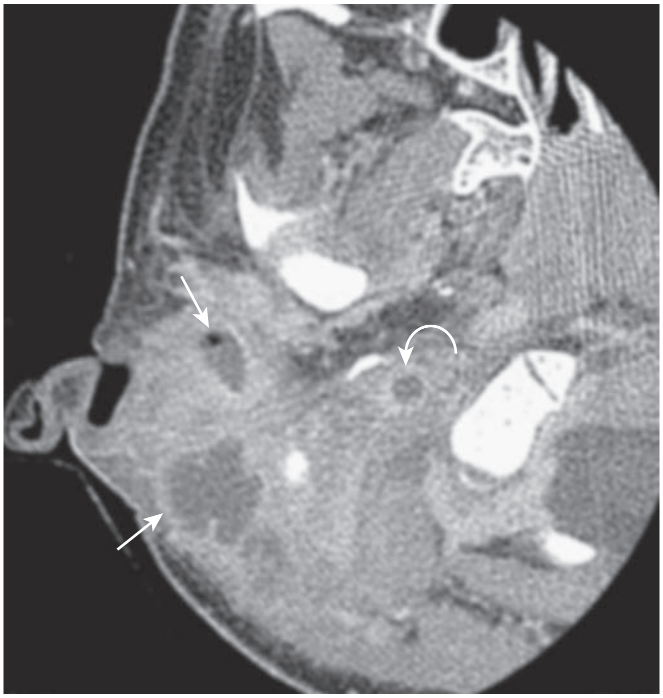
The initial CT finding is decreased definition of the mastoid trabeculae caused by inflammatory hyperemia. With the development of bone destruction, the process is termed coalescent mastoiditis.[21] The subsequent development of a subperiosteal abscess is, by far, the most common complication and typically occurs in the postauricular region where bone is thin, termed the Macewen triangle. CT demonstrates a rim-enhancing fluid collection that is adherent to bone; the underlying bone is usually intact but may show focal destruction (Fig. 11.5). The infection may also progress inferiorly through the mastoid tip, resulting in a Bezold abscess (e-Fig. 11.6) or anterior lateral resulting in a Luc abscess beneath the temporalis muscle.[22] The Eustachian tube allows infection to spread into the retropharyngeal space, and children with mastoiditis may present with a retropharyngeal abscess and rarely Grisel syndrome or tortocolis.[23] MRI findings suggestive of mastoiditis over simple effusion include signal intensity hypointense to cerebrospinal fluid (CSF) on T2-weighted images, restricted diffusion, and intense enhancement (e-Fig. 11.7).[24] Routine MR imaging in all cases of acute mastoiditis is likely not necessary and should be reserved for those patients with suspected intracranial complications.[25]

Mastoid infection may extend to the central skull base though the continuous mucosal spaces, resulting in petrous apicitis and osteomyelitis. Petrous apicitis classically presents as the clinical Gradenigo triad of purulent otorrhea, pain in the distribution of the fifth cranial nerve, and ipsilateral sixth cranial nerve palsy.[26] CT demonstrates bony destruction, commonly subtle in children, and associated epidural empyema. MRI demonstrates a peripherally enhancing fluid collection within the apex, and diffusion-weighted images show restricted diffusion with associated empyema or, less commonly, brain abscess (Fig. 11.8).

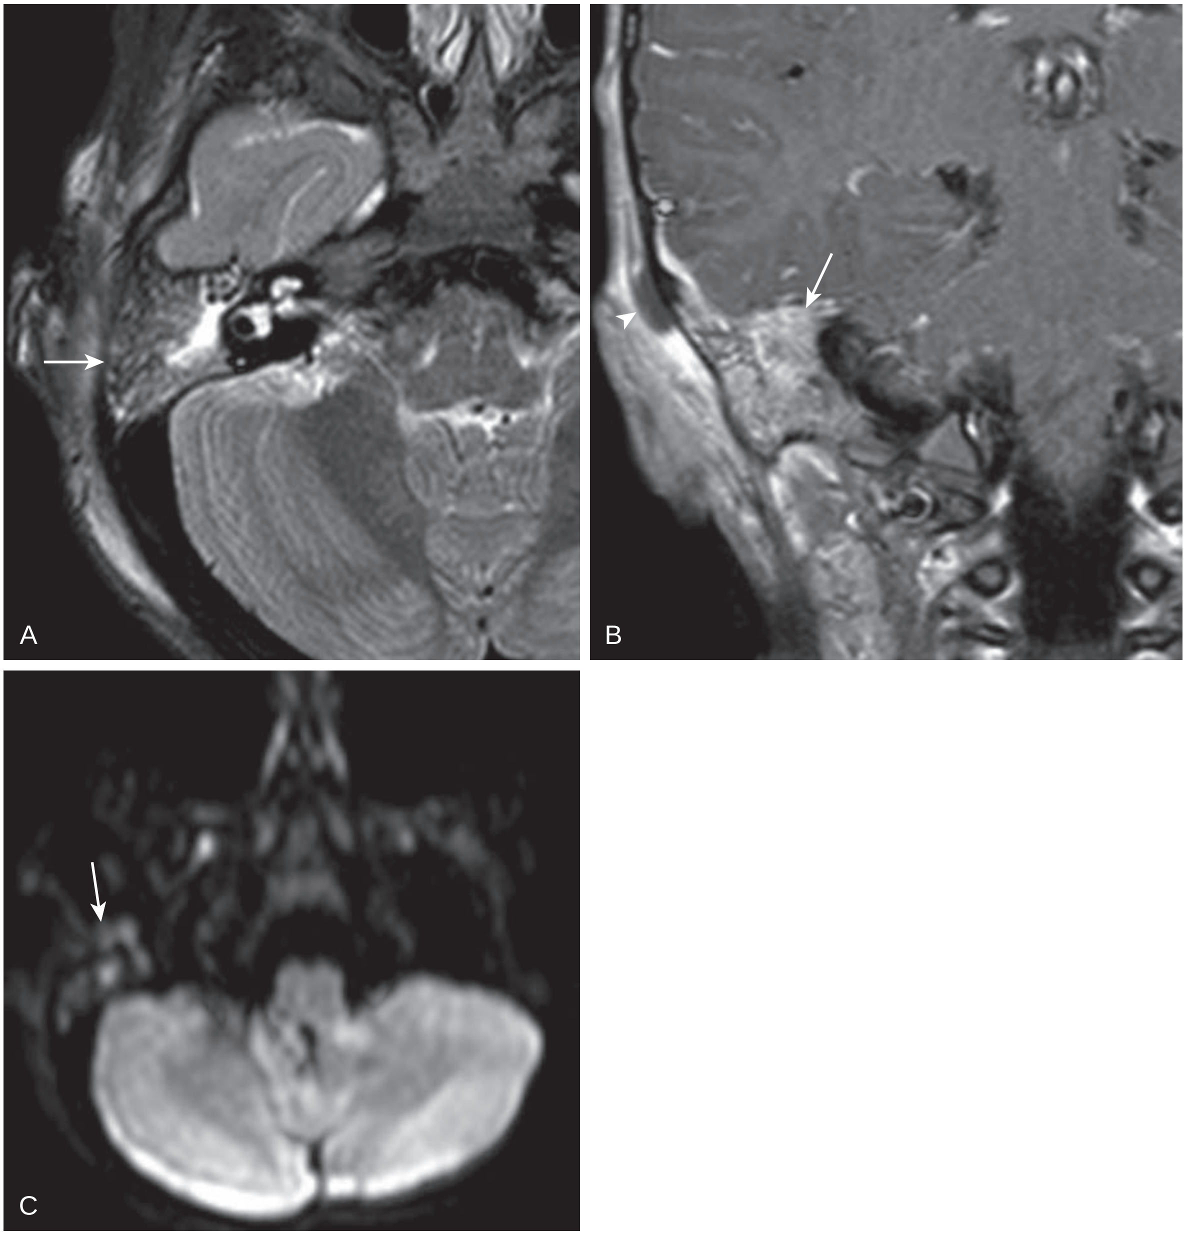
Pathways that allow infectious intracranial extension include bone erosion, thrombophlebitis, and preformed pathways. The oval and round windows, cochlear and vestibular aqueducts, internal auditory canal, dehiscent tegmen, and patent petrosquamosal suture are preformed pathways that allow early or late intracranial extension. These pathways may lead to the development of suppurative labyrinthitis, as shown by abnormal enhancement of the membranous labyrinth (e-Fig. 11.9). Meningitis can occur via these pathways by spread to the subarachnoid space.[21]

Meningitis, epidural empyema, dural sinus thrombosis, and cerebellar or cerebral abscesses are intracranial complications of mastoiditis. Bony erosion commonly involves the relatively thin sigmoid plate (Trautmann triangle) and may result in an epidural empyema or anterior lateral cerebellar abscess. Usually, significant compression of the adjacent sigmoid sinus occurs, and it may be difficult to distinguish between extrinsic mass effect and thrombosis of the sinus. Nodular thickening surrounding the sigmoid sinus on contrast-enhanced CT has been shown to be associated with empyema and the need for surgical intervention, whereas a smooth halo is not usually associated with an epidural abscess (e-Fig. 11.10).[27] Erosion through the tegmen results in a middle cranial fossa epidural empyema and/or temporal lobe abscess (Fig. 11.11). Veins allow organisms to readily traverse both bone and dura, resulting in thrombophlebitis. The sigmoid sinus is the most common to become thrombosed; however, the lateral, petrosal, and cavernous sinuses may be involved, especially with infection of the petrous apex.[21,28,29] Venous sinus thrombosis may lead to venous infarctions or otitic hydrocephalus caused by impaired venous drainage.[30] Gadolinium-enhanced MRV can be helpful in diagnosing dural sinus thrombosis (e-Fig. 11.12). Diffusion-weighted images show increased signal from purulent material, which may be especially helpful in postoperative imaging (Fig. 11.13 and Box 11.1).[28] Mastoid fluid may be the result rather than the cause of venous thrombosis, and additional findings should be sought for a definitive diagnosis of mastoiditis as the cause of dural sinus thrombosis (e-Fig. 11.14).[31]

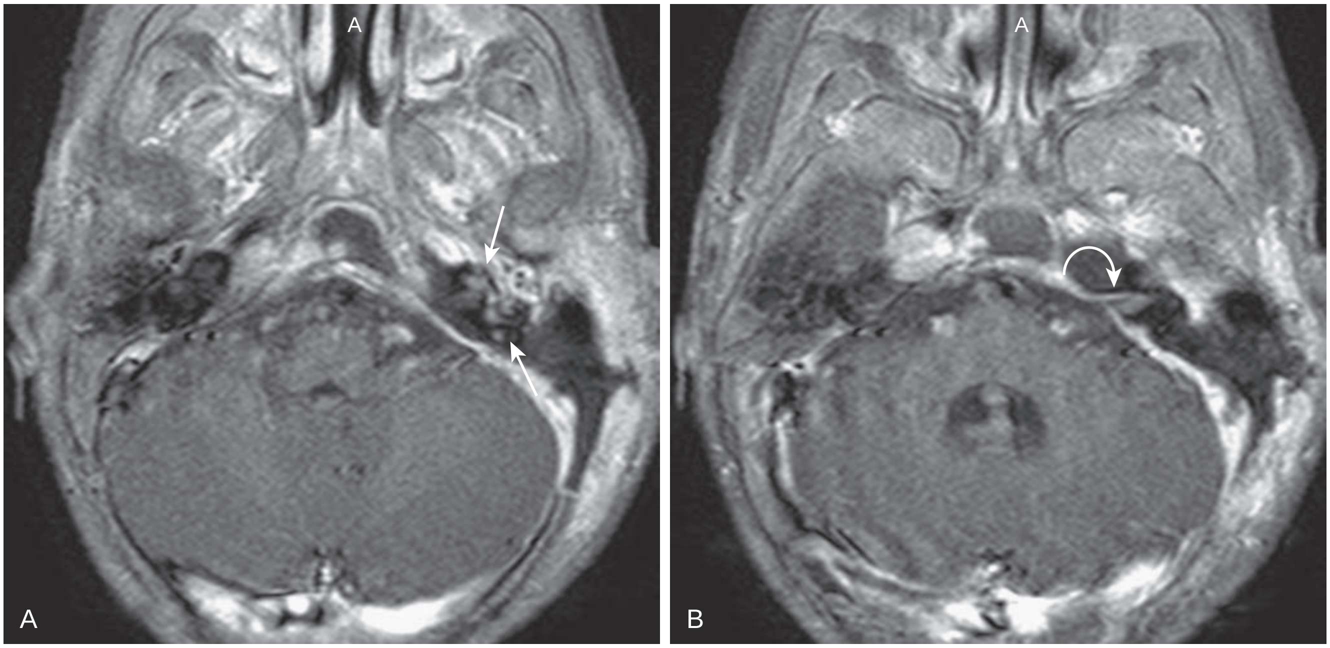
***Treatment.*** Subperiosteal abscess and other complications have traditionally been treated with drainage, cortical mastoidectomy, and ventilation tube.[17,18] However, more conservative surgical management has been recently reported. Antibiotic therapy, followed by retroauricular puncture and grommet insertion, has been proven to be an effective alternative to surgical management of



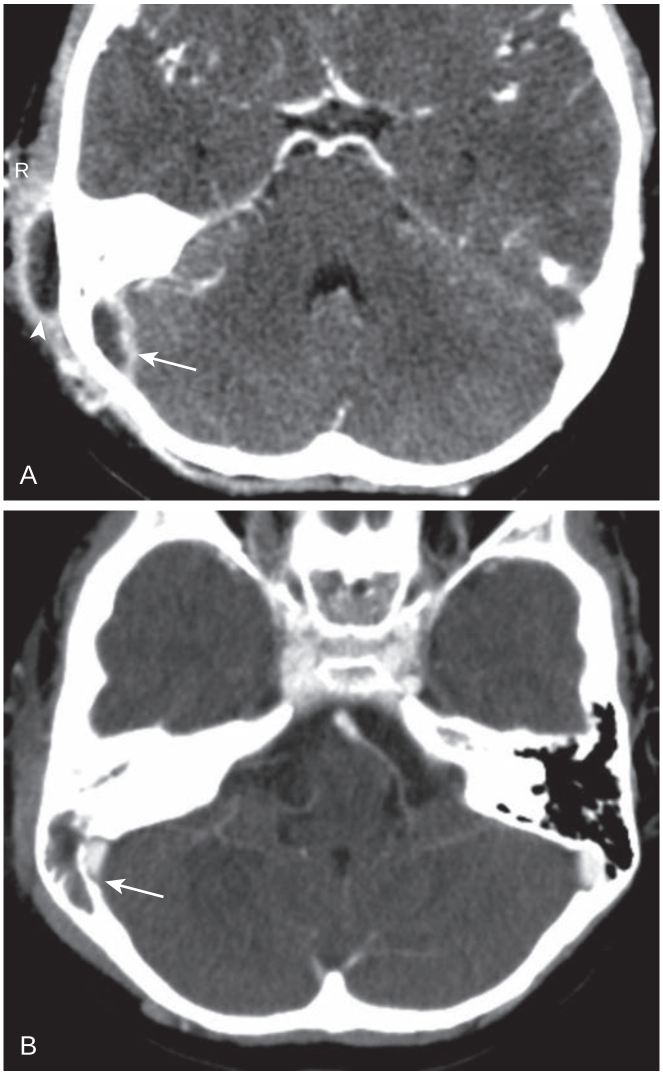
**e-Figure 11.6. Complicated mastoiditis.** Axial postcontrast CT shows a Bezold abscess inferior to the mastoids *(arrows)* with the anterior fluid collection containing air. Thrombosis of the internal jugular vein is also present *(curved arrow)*. *(Case courtesy of L. Gilbert Vezina MD.)*



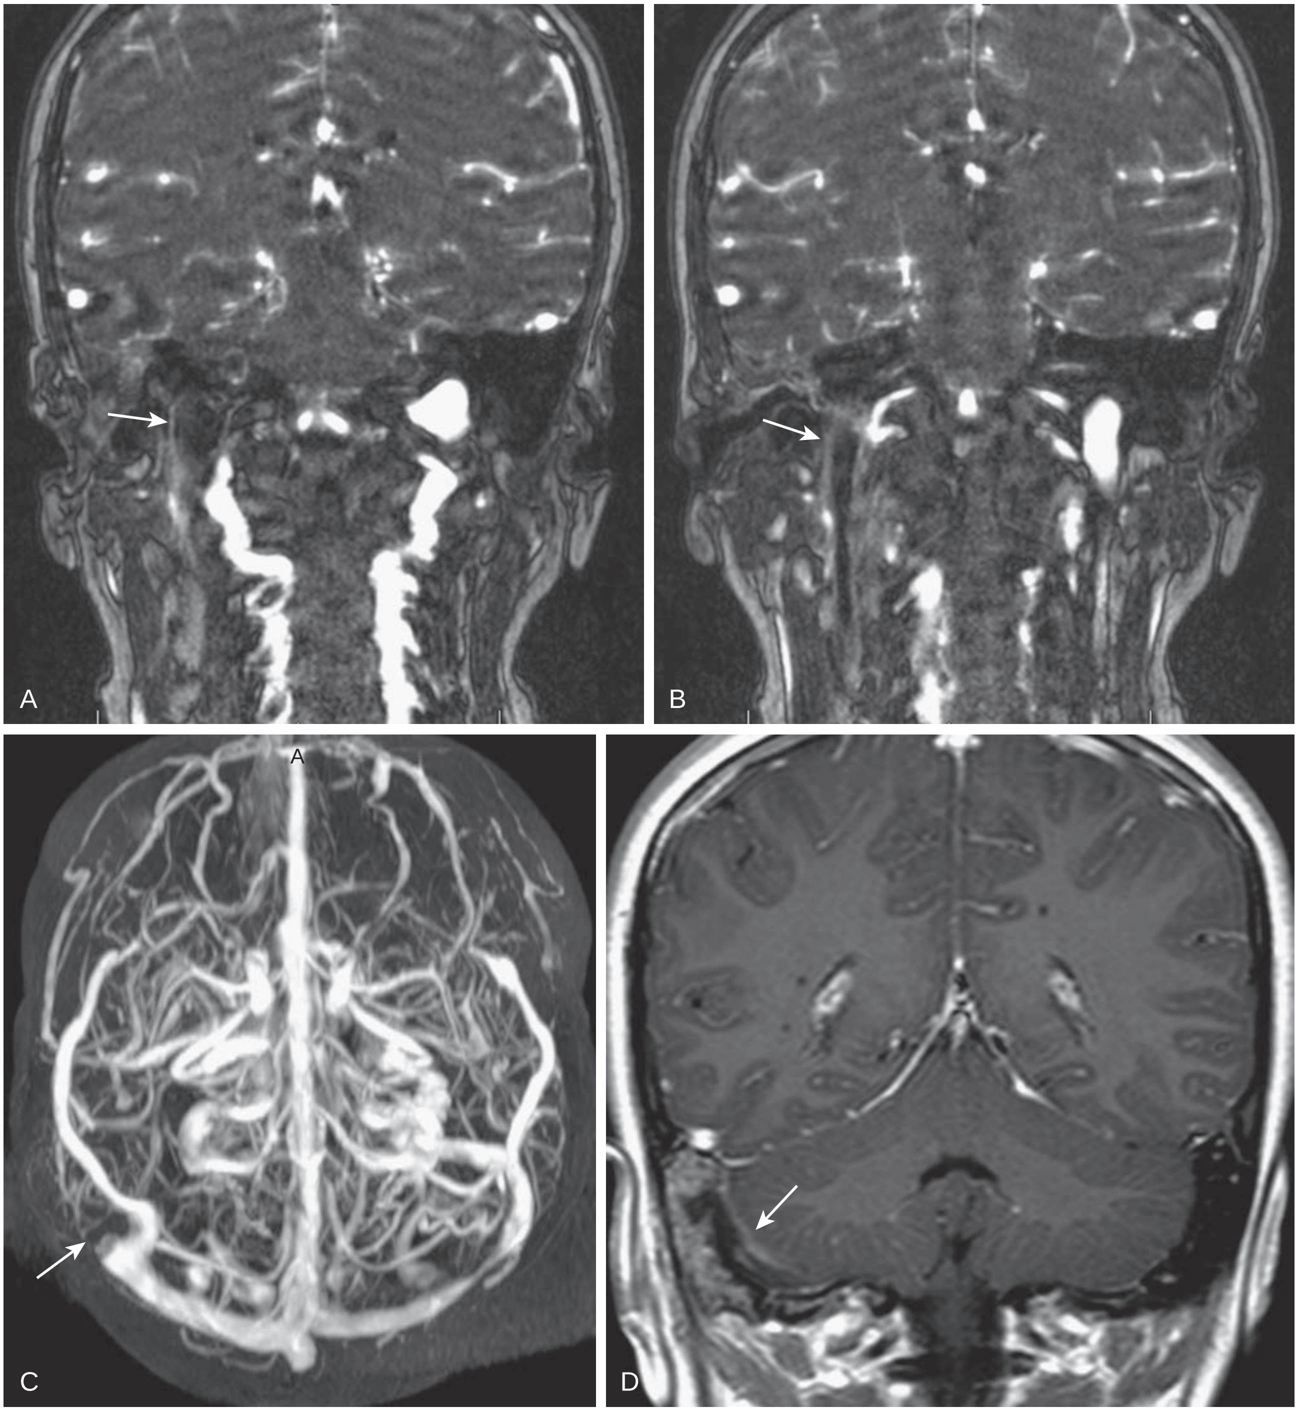
**e-Figure 11.7. Mastoiditis, MRI findings.** (A) Axial T2-weighted MR images show relatively low T2 signal fluid within the right mastoids *(arrow)*. (B) Axial postgadolinium T1-weighted MR images with fat suppression. Extensive enhancement within the right mastoid is present *(arrow),* no enhancement on the left. Dural enhancement is present and a small subperiosteal abscess *(arrowhead)*. (C) Diffusion-weighted MR image shows foci of restricted diffusion *(arrow)*.



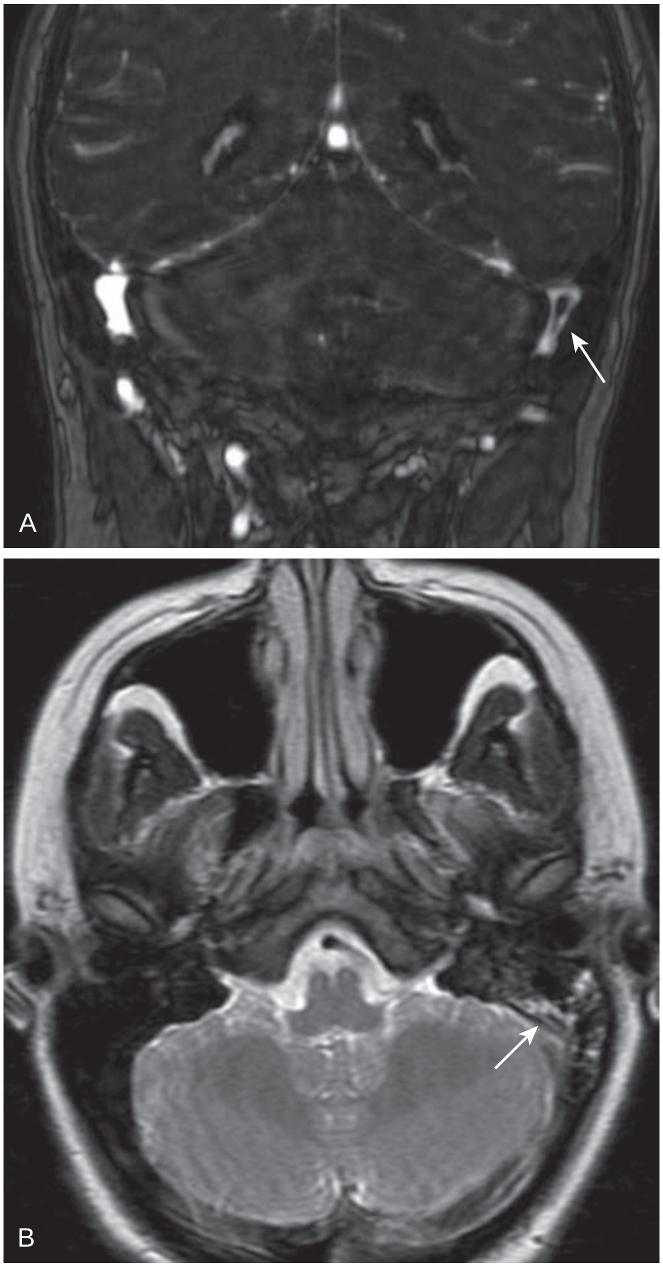
**e-Figure 11.9. Suppurative labyrinthitis in an 18-month-old with mastoiditis.** (A and B) Axial postgadolinium T1-weighted MR images through the membranous labyrinth shows extensive peripheral enhancement throughout the mastoids and extension to the central skull base along with regional dural enhancement. Abnormal enhancement is present within the left internal auditory canal *(curved arrow),* cochlea, and vestibular system *(arrows),* consistent with suppurative labyrinthitis. A left-sided mastoidectomy has been performed.



**e-Figure 11.10. Mastoiditis, “halo” sign on CT.** (A and B) Axial postcontrast CT in different patients. (A) Nodular soft tissue thickening along the lateral aspect of the right sigmoid sinus is present *(arrow)* with an epidural empyema confirmed at surgery. A subperiosteal abscess is present as well *(arrowhead)*. (B) A thin “halo” of soft tissue surrounds the right sigmoid sinus *(arrow)* with the patient treated conservatively. The sigmoid sinus is normally in direct contact with the inner table of the skull.



**e-Figure 11.12. Venous thrombosis in a 9-year-old with mastoiditis.** (A and B) Coronal source images from a gadolinium-enhanced MRV show a central filling defect in the jugular bulb and high internal jugular vein *(arrows),* representing venous thrombosis. (C) Maximum-intensity projection shows abrupt occlusion of the distal transverse sinus on the right *(arrow)*. (D) Coronal postgadolinium T1-weighted MR image demonstrates a small coexisting epidural abscess *(arrow)*.



**e-Figure 11.14. Dural sinus thrombosis and mastoid effusion.** (A) Gadolinium-enhanced MRV shows thrombus in the left sigmoid sinus *(arrow)*. (B) Axial T2-weighted MR image shows an ipsilateral mastoid effusion *(arrow)*. No other evidence of mastoiditis is present clinically or by imaging.

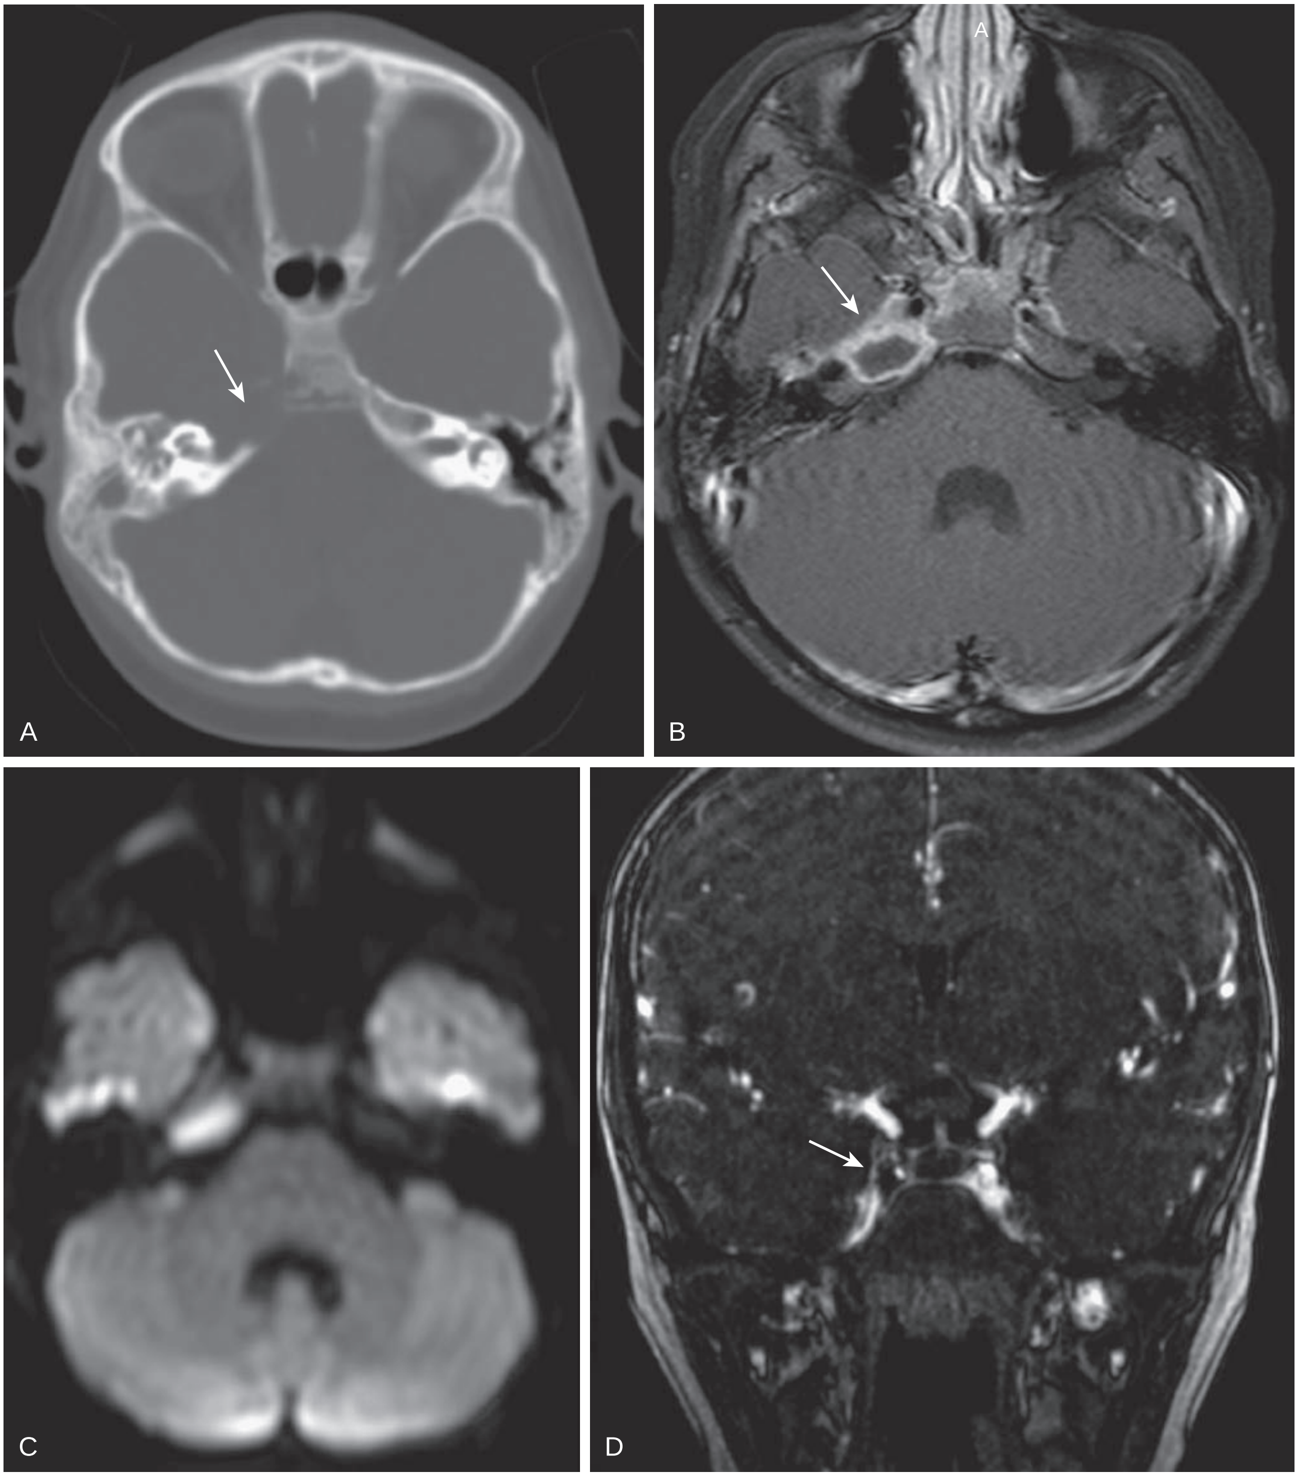


**Figure 11.8. Petrous apicitis in a 6-year-old with headache and right sixth nerve palsy.** (A) Axial CT shows absence of the right petrous apex *(arrow)*. (B) Axial postgadolinium T1-weighted MR image shows a rim-enhancing fluid collection in the right petrous apex with associated dural enhancement *(arrow)*. The left internal carotid artery is narrowed, likely relating to inflammation within the cavernous sinus. (C) Restricted diffusion is present on the axial diffusion-weighted image. (D) Gadolinium-enhanced MRV shows a filling defect in the right cavernous sinus consistent with thrombosis *(arrow)*.

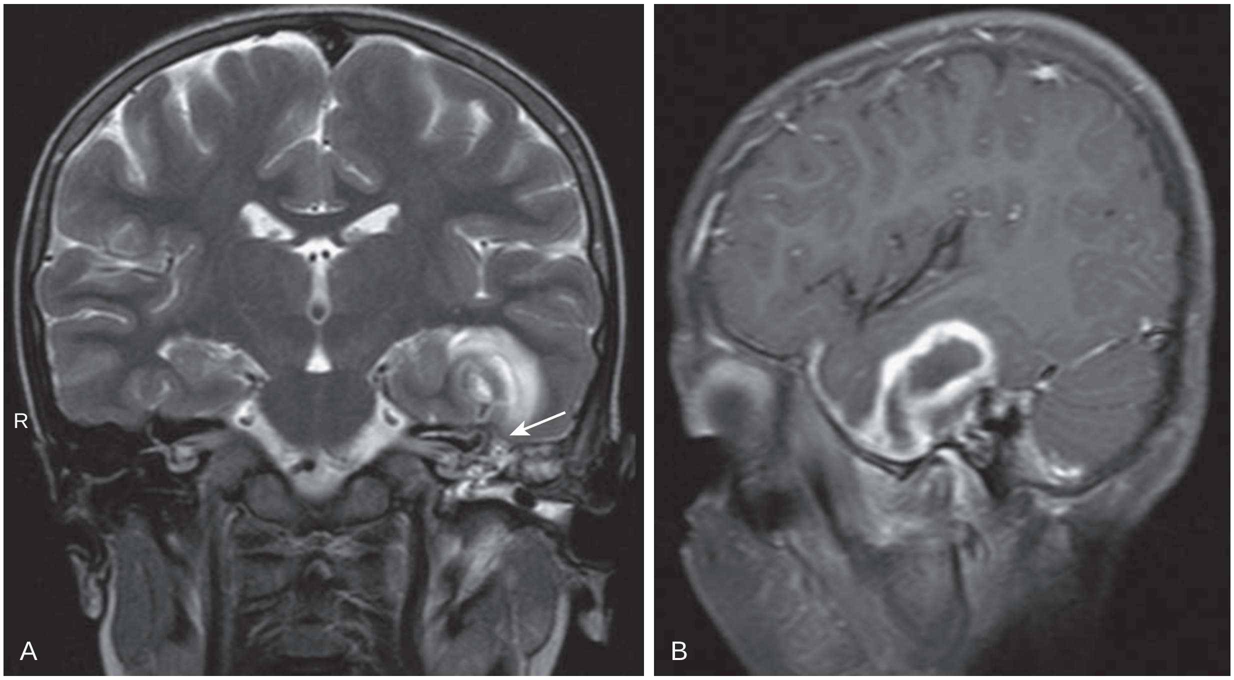

**Figure 11.11. Brain abscess in an 8-year-old with complicated mastoiditis.** (A) Coronal T2-weighted MR image shows fluid in the left mastoid and middle ear. A defect is present within the tegmen *(arrow)* associated with a large temporal intraaxial lesion. (B) Left parasagittal post-gadolinium T1-weighted MR image demonstrates rim enhancement of the temporal mass, consistent with abscess.

**BOX 11.1** Complications of Mastoiditis

Subperiosteal abscess
Central skull base osteomyelitis
Venous thrombosis
Meningitis
Epidural or subdural empyema
Intraparenchymal abscess

complicated mastoiditis.[32,33] Intracranial involvement is treated more aggressively with neurosurgical consultation and drainage of extra-axial empyemas and intraparenchymal abscesses.

## Chronic Infections

### Chronic Otomastoiditis

***Clinical Presentation and Etiologies.*** Persistent retraction of the tympanic membrane and fluid within the middle ear cavity may be associated with chronic otitis media (COM). Tympanic membrane perforations from chronic middle ear infections typically involve the pars tensa. In contrast, retraction and perforation involving the pars flaccida portion of the tympanic membrane are usually caused by Eustachian tube dysfunction. Children often present for imaging because of development of conductive hearing loss. Hearing loss may be from ossicular erosions caused by chronic suppurative otomastoiditis or may be related to ossicular fixation, tympanosclerosis, or both.

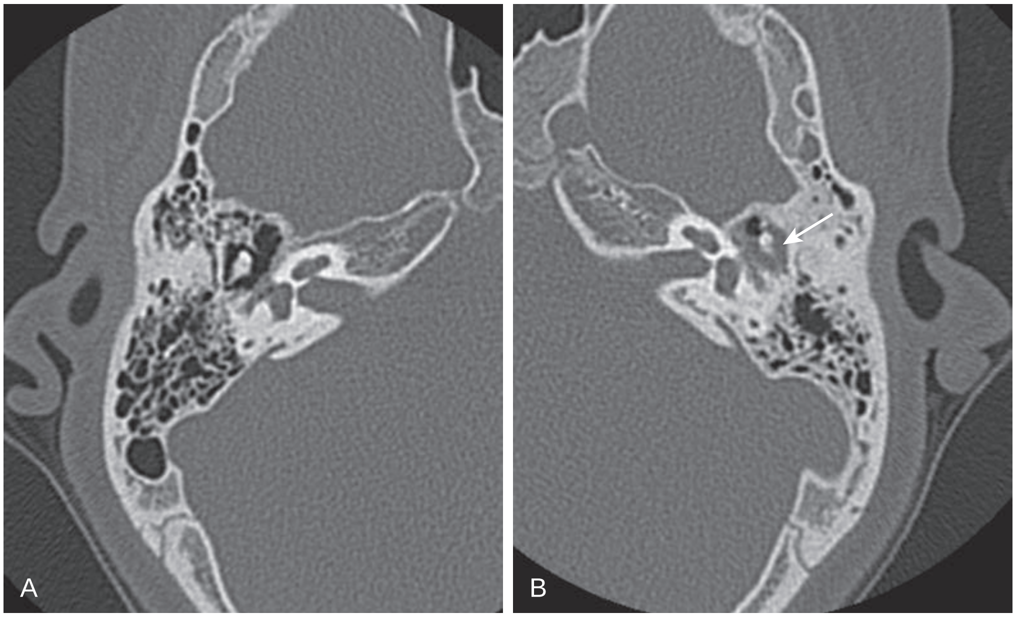
***Imaging.*** Ossicular erosions associated with COM frequently involve the distal portion of the long process of the incus and are associated with retraction rather than bulging of the tympanic membrane and lack of mass effect.[34] Tympanosclerosis is caused by the deposition of hyalinized, often calcific, granulation tissue in the middle ear cavity. On CT, tympanosclerosis may appear as multiple middle ear masses with regions of increased density. Isolated involvement of the tympanic membrane may occur or be seen in conjunction with middle ear involvement (Fig. 11.15). Increased thickness of the ossicles may be present on imaging studies, suggesting osteitis.[29,35]

***Treatment.*** Imaging is helpful in determining the extent of ossicular erosion and disease before surgical intervention in COM. High-resolution CT should be used selectively and only if complications are suspected.[36] Surgical outcome is generally poor for tympanosclerosis, but appears to depend on the extent of disease.[37]

### Acquired Cholesteatoma

***Clinical Presentation and Etiologies.*** Cholesteatoma is composed of squamous epithelium and keratin debris, most commonly introduced into the middle ear and mastoid via retractions or perforations in the tympanic membrane. A careful otoscopic examination of the ear is essential in the initial diagnosis of cholesteatoma, and CT is typically used to diagnose the extent of the lesion or associated complications.[38] These can be subdivided into pars flaccida and pars tensa cholesteatoma. Pars flaccida lesions are caused by Eustachian tube dysfunction and begin in the Prussak space before spreading into the epitympanum. Pars tensa lesions are the result of COM and perforations within the more inferior tympanic membrane, with extension of disease medial to the ossicles and into the oval window and region of the tympanic facial nerve.

***Imaging.*** High-resolution CT is the primary imaging modality in children. The differentiation of COM without cholesteatoma from COM with cholesteatoma may be difficult. Cholesteatoma usually is associated with more extensive bony erosions, including short process of the incus, lateral wall of the attic, facial nerve canal, tegmen tympani, and superior margin of the external canal or scutum (e-Fig. 11.16). Mass effect is also a significant suggestive finding, with ossicular displacement and bulging of the tympanic



**e-Figure 11.16. Cholesteatoma in a 13-year-old.** (A) Normal axial high resolution CT of the right temporal bone. (B) Axial high-resolution CT of the left temporal bone. Significant erosion of the short process of the incus is present *(arrow),* with subtle medial displacement of the ossicles.

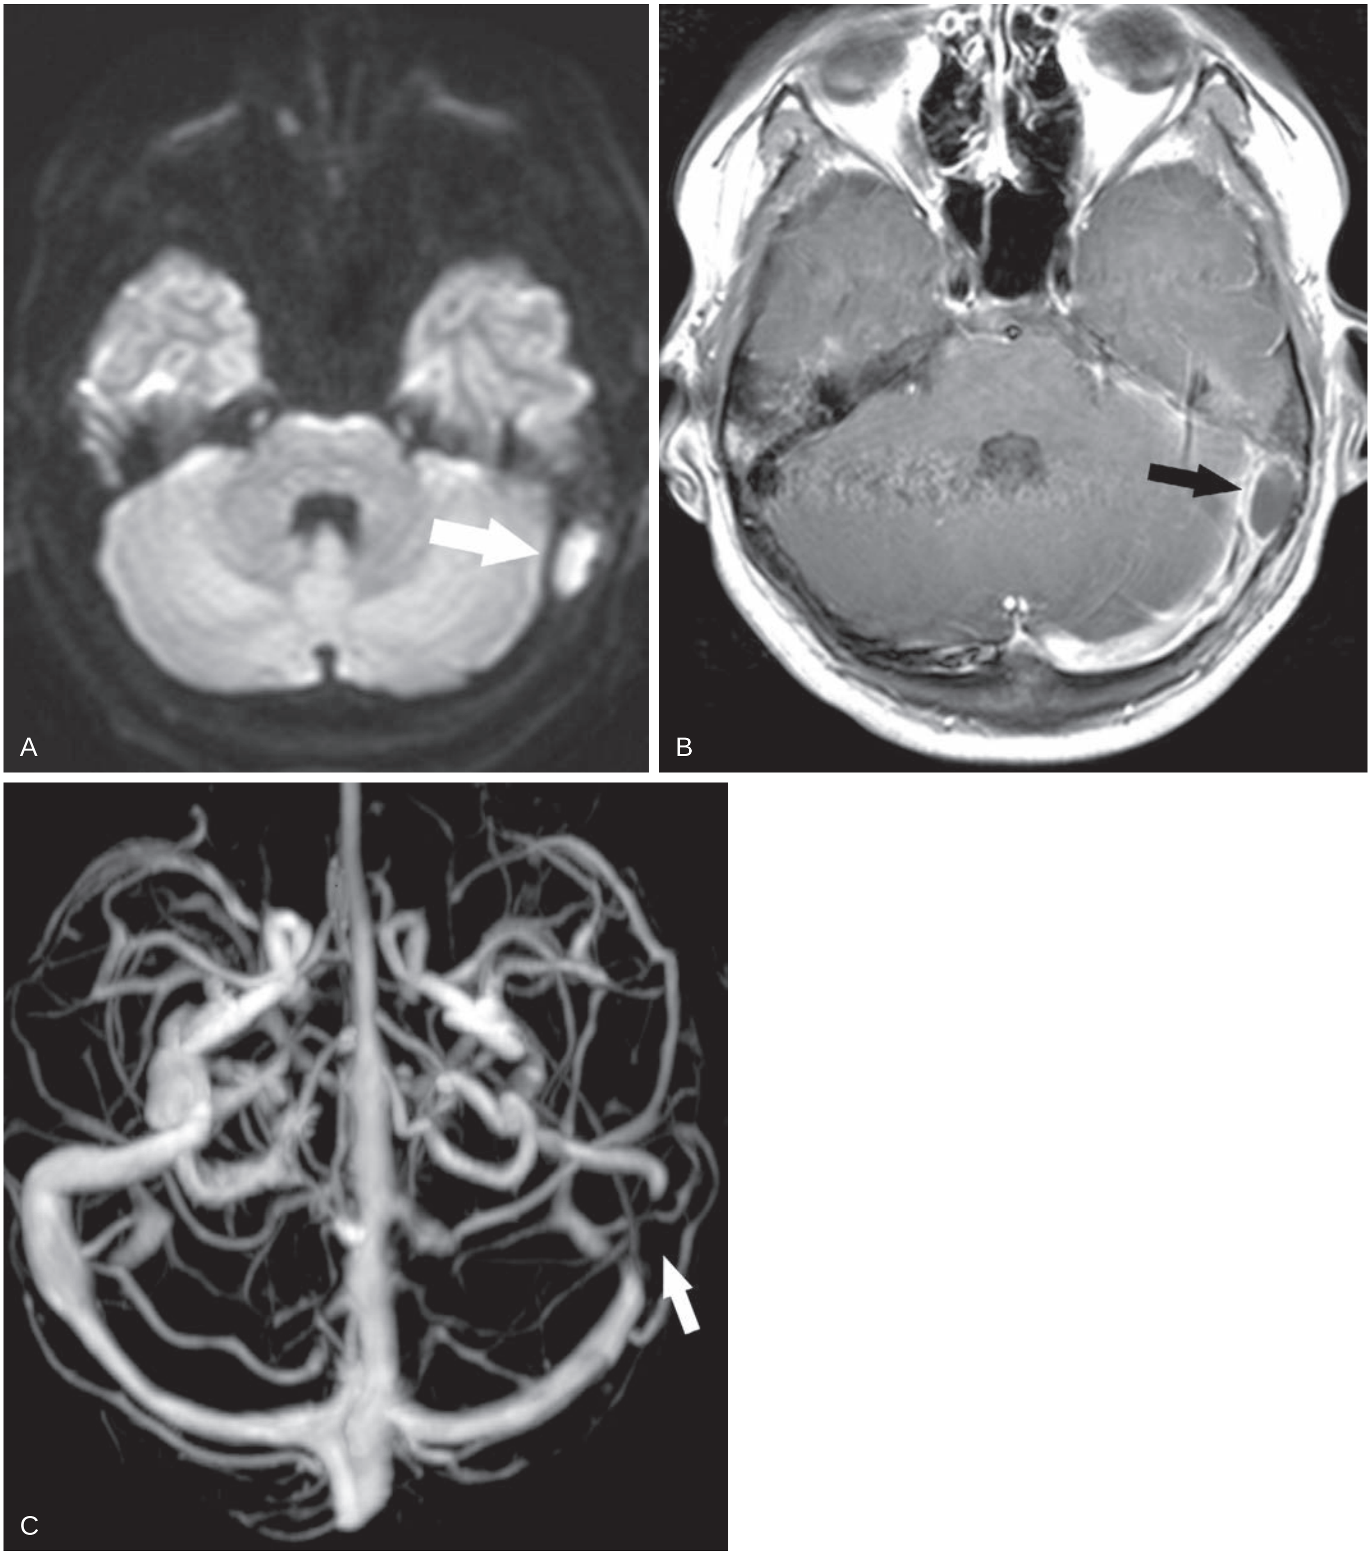


**Figure 11.13. Epidural abscess in an 11-year-old with mastoiditis.** (A and B) Axial diffusion-weighted and postgadolinium T1-weighted MR images shows restricted diffusion in a rim-enhancing fluid collection *(arrows)*. (C) Axial maximum-intensity projection image from a gadolinium-enhanced MRV shows extrinsic mass effect on the sigmoid sinus, with no intrinsic filling defect *(arrow)*. No thrombus was demonstrated after surgical drainage of the epidural abscess.

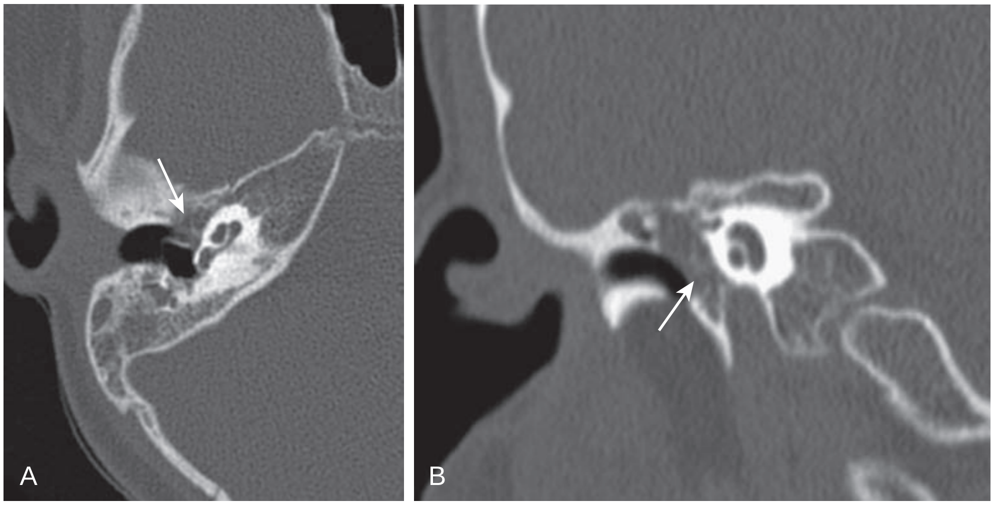

**Figure 11.15. Chronic otitis media and tympanosclerosis in a 9-year-old.** (A and B) Axial and coronal high-resolution CT images though the middle ear show abnormal soft tissue is present throughout the anterior middle ear cavity with lacelike increased density *(arrows)*.

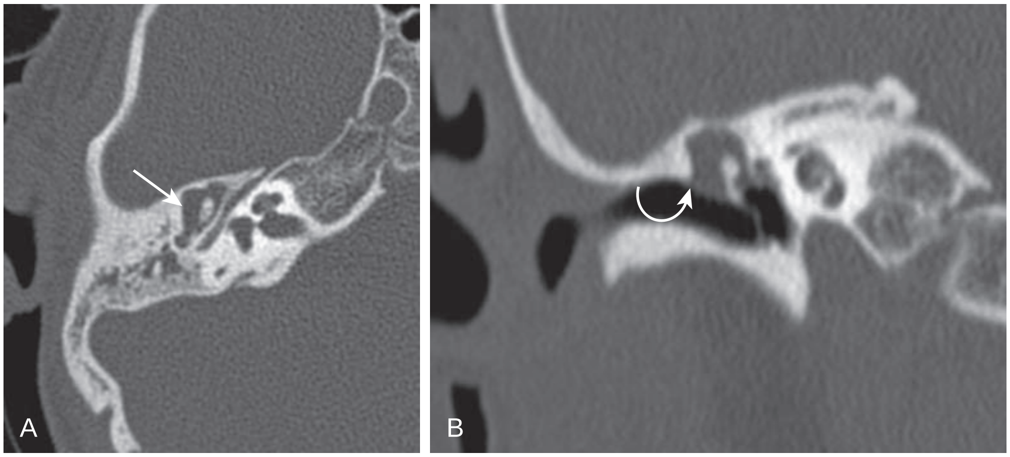

**Figure 11.17. Cholesteatoma in a 5-year-old with chronic ear infections.** (A and B) Axial and coronal high-resolution CT images through the middle ear. The ossicles are displaced medially with abnormal soft tissue in Prussak space and epitympanum *(arrow)*. The scutum is eroded *(curved arrow)*. At surgery, a pars flaccida cholesteatoma was removed.

membrane noted on CT.[34] The ossicular chain typically lies an equal distance from the medial and lateral walls of the middle ear cavity. The position of the ossicles should be evaluated on all imaging studies, with the structures displaced medially with a pars flaccida and laterally with a pars tensa cholesteatoma (Fig. 11.17). Associated erosion of Körner septum in the mastoid antrum may also be seen. Erosion may also involve the bony separation of the middle ear cavity and the cochlea or lateral semicircular canal, resulting in a gusher and complete sensorineural hearing loss (SNHL) during surgery. Cholesteatomas are histologically benign but may be locally aggressive and extend outside the confines of the temporal bone (Box 11.2).[39,40] MRI with nonechoplanar diffusion imaging may help in the diagnosis and determining the extent of disease in the initial evaluation.[41]

CT evaluation of the postoperative ear is quite difficult, and differentiation of fluid from granulation tissue and recurrent cholesteatoma is nearly impossible. Nonechoplanar diffusion MRI sequences have demonstrated cholesteatomas that are less than 5 mm in diameter and have a greater than 90% sensitivity and specificity.[42,43] Increased signal compared with regional fat on diffusion-weighted images is considered consistent with cholesteatoma. Increased signal on T2-weighted images and peripheral enhancement on postgadolinium T1-weighted images can be confirmatory (Fig. 11.18).[44] Delayed imaging can be helpful as well but not as useful in the pediatric population because of sedation issues. Fusing MRI and CT data has been investigated as a potential surgical guidance tool.[45]

**BOX 11.2** Important Structures to Evaluate in the Assessment of Cholesteatoma

Tegmen tympani and tegmen mastoidinium
Facial canal
Bony margin of lateral semicircular canal
Ossicles
Extratemporal extension
Labyrinthine involvement

***Treatment.*** Management in patients with COM and suspected cholesteatoma is usually operative. MRI, specifically diffusion-weighted imaging, has shown promise in evaluation of postoperative

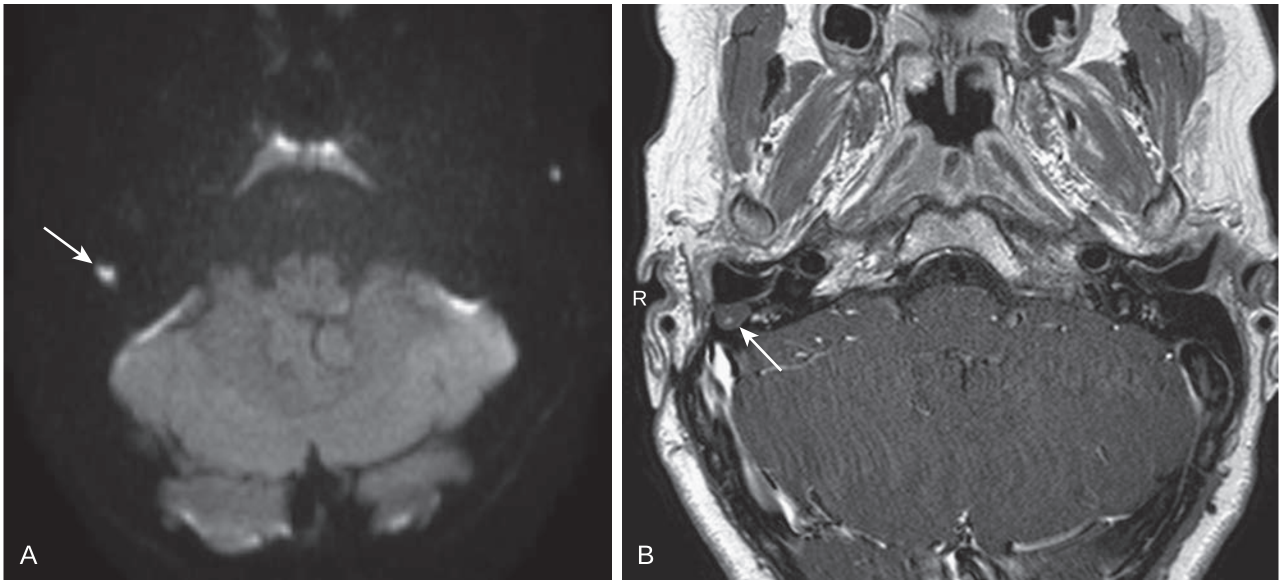

**Figure 11.18. Recurrent cholesteatoma in a 9-year-old after mastoidectomy for cholesteatoma.** (A) Axial diffusion-weighted MR image demonstrates a focus of increased signal within the right mastoid *(arrow)*. (B) Axial postgadolinium T1-weighted MR image shows the lesion to be fluid intensity without enhancement *(arrow)*. Surgery confirmed a 5-mm cholesteatoma.

patients and will likely replace the standard second-look surgery for residual cholesteatoma.[43,44]

## INNER EAR AND PETROUS TEMPORAL BONE

### Labyrinthitis

***Clinical Presentation and Etiologies.*** Bacterial labyrinthitis is most commonly a complication of meningitis but can be caused from extension of infections involving the regional mucosal spaces. Other causes of labyrinthitis include viral, syphilitic, posttraumatic with labyrinthine hemorrhage, and autoimmune disorders.[39] Cholesteatoma with resultant translabyrinthine fistula may also result in labyrinthitis.[40] Sickle cell disease has a known association with SNHL and labyrinthine hemorrhage.[46]

***Imaging.*** Labyrinthine hemorrhage manifests as increased T1-weighted signal MR images. Enhancement within the membranous labyrinth can be demonstrated on postgadolinium T1-weighted and fluid-attenuated inversion-recovery images and is predictive of the development of SNHL (e-Fig. 11.19).[47,48]

### Labyrinthitis Ossificans

***Clinical Presentation and Etiologies.*** Labyrinthitis ossificans is the end result of a labyrinthine infection, hemorrhage, or toxic insult to the membranous labyrinth. Bacterial meningitis is the most common cause and results in profound SNHL, which may occur as early as 2 weeks after the initial infection. Fibrous tissue is initially deposited within the membranous labyrinth, followed by ossification.

***Imaging.*** Acutely, MRI may demonstrate findings of labyrinthitis; however, the normal high T2-weighted signal within the cochlea and vestibular system is preserved. In the subacute fibrous phase of the inflammatory response, MRI shows loss of the normal high T2-weighted signal in the membranous labyrinth. Ossification occurs in the latter stages of labyrinthitis and is well demonstrated on CT (e-Fig. 11.20). High-resolution T2-weighted images are needed to visualize both scalar chambers of the cochlea that should be evaluated in these children, as isolated involvement of the scala tympani is common (e-Fig. 11.21).[49] A short segment of decreased signal within the proximal scala tympani of the inferior basal turn may be the only finding on T2-weighted images (e-Fig. 11.22).[50] CT shows increased density within the labyrinth late in the course of disease, and, at this stage, cochlear implantation is more difficult. Complete ossification of the cochlea must be differentiated from cochlear aplasia, which demonstrates absence of the cochlear promontory.

***Treatment.*** The only treatment available for children with labyrinthitis ossificans is cochlear implantation. The early diagnosis of fibrous cochlear obstruction on MRI caused by labyrinthitis is important because as the process continues, cochlear implantation becomes more difficult.

### Cholesterol Granuloma

***Clinical Presentation and Etiologies.*** Cholesterol granuloma is the result of inflammation and obstruction that initiates repetitive hemorrhage and subsequent formation of granulation tissue. Sites of involvement include the middle ear cavity, petrous apex, and rarely the EAC. Petrous apex cholesterol granuloma are much more common in adults, but may be found incidentally or present with headaches and deficits in cranial nerves VI, VII, IX, X, XI, and XII.[51]

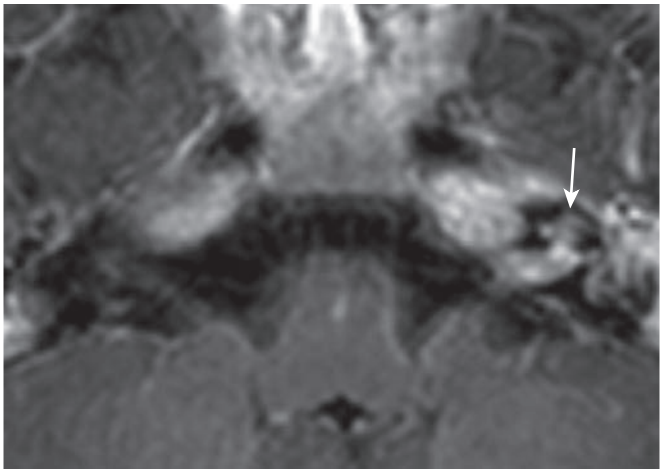
***Imaging.*** The CT appearance is that of an expansile, nonaggressive, and nonenhancing soft tissue mass. The mass is of high signal intensity on both T1- and T2-weighted MRI scans and low signal on diffusion-weighted images, which differentiates the lesion from a cholesteatoma (e-Fig. 11.23). Long term follow up imaging may be of help to differentiate from simple or proteinaceous entrapped fluid.[52,53]

***Treatment.*** Asymptomatic lesions are usually monitored. If cranial nerve palsies are present or symptoms are progressive, surgical drainage may be performed with fenestration or tube placement.

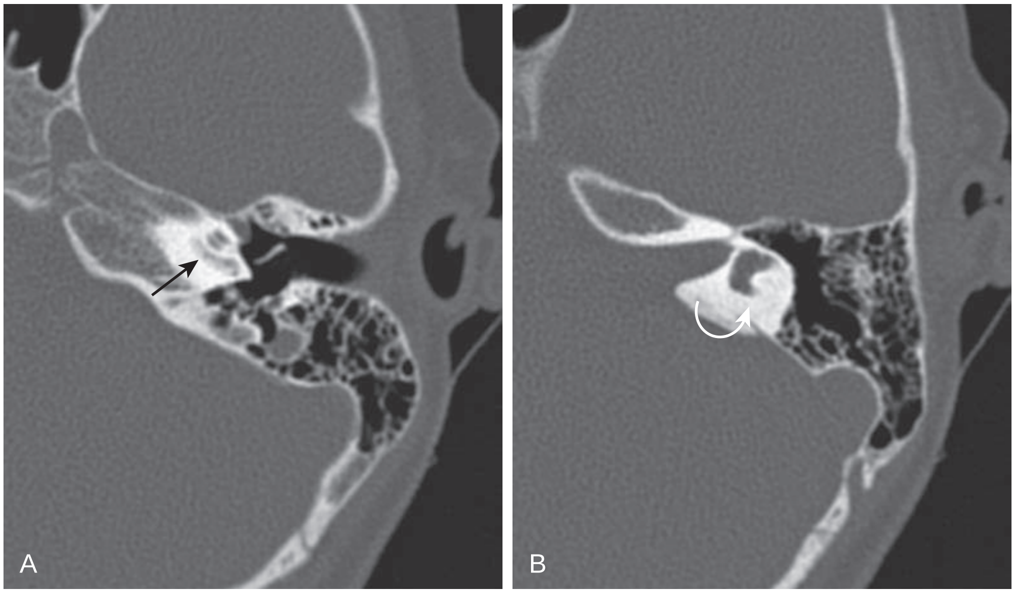
## FACIAL NERVE

### Lyme Disease

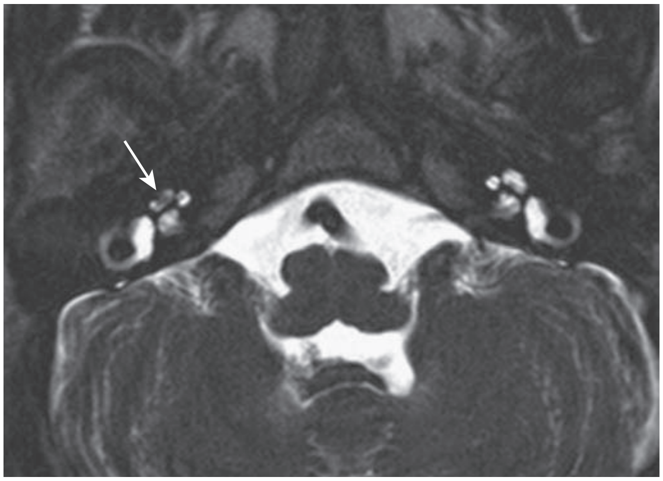
***Clinical Presentation and Etiologies.*** Lyme disease is multisystemic and caused by an infection by the tick-borne spirochete



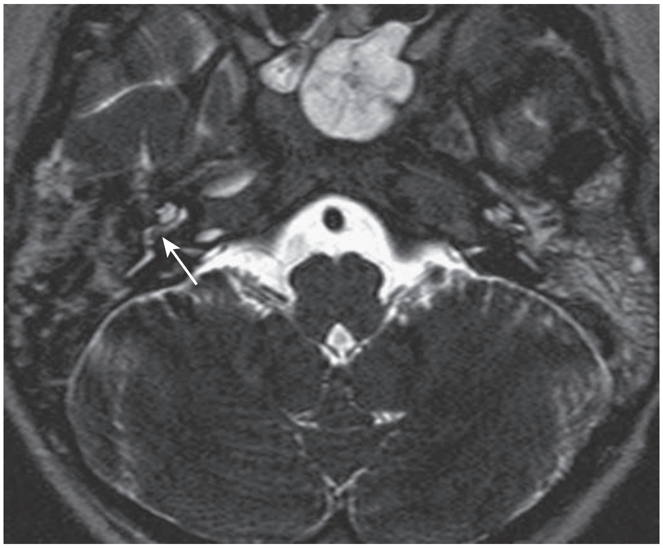
**e-Figure 11.19. Labyrinthitis due to meningitis in an 18-month-old with meningitis being evaluated for empyema.** Axial gadolinium-enhanced T1-weighted MR image through the internal auditory canal shows intense enhancement in the right internal auditory canal as well as the ipsilateral membranous labyrinth *(arrow)*. On follow-up, profound left sensorineural hearing loss was present.



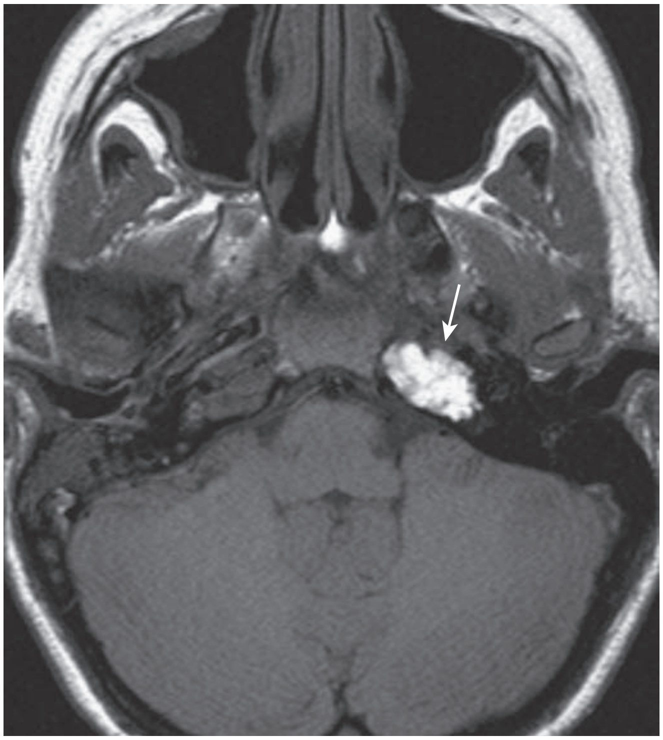
**e-Figure 11.20. Ossifying labyrinthitis in a 6-year-old with sensorineural hearing loss and remote history of prior pneumococcal meningitis.** (A and B) Axial CT images through the cochlea and vestibule, respectively. Abnormal increased density within the cochlea *(straight arrow)* and obliteration of the lateral semicircular canal *(curved arrow)* are seen.



**e-Figure 11.21. Labyrinthitis in a 3-year-old with right sensorineural hearing loss and prior meningitis.** Axial three-dimensional T2-weighted MR image through the cochlea shows low T2-weighted signal intensity within the middle and apical turns of the right cochlea *(arrow),* consistent with fibrous tissue and early labyrinthitis. CT was normal without ossification demonstrated *(not shown)*.



**e-Figure 11.22. Sensorineural hearing loss and meningitis in a 5-year-old.** Axial three-dimensional T2-weighted MR image through the right cochlea shows a hypointense plug at the junction of the scala tympani and vestibule *(arrow),* which was confirmed at cochlear implantation. Sphenoid sinus disease is also present.



**e-Figure 11.23. Cholesterol granuloma in a 12-year-old with incidental lesion left petrous apex.** Axial T1-weighted MR image at the level of the petrous apex shows an expansile T1-weighted hyperintense lesion on the left *(arrow)*.

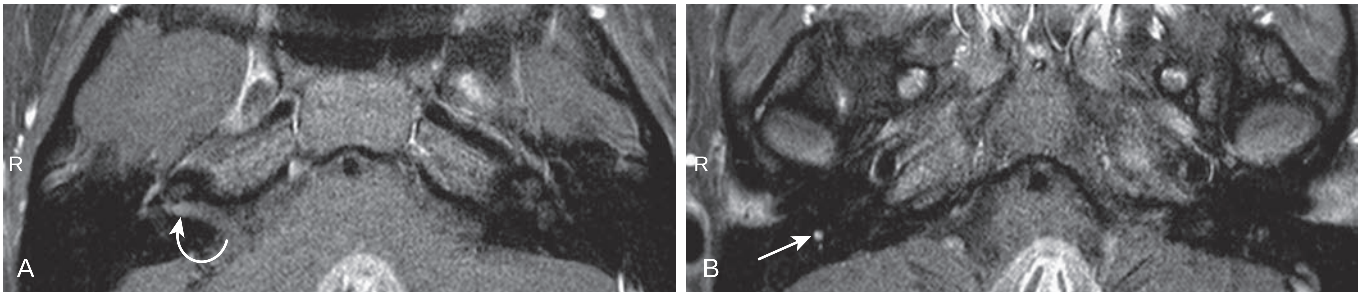


**Figure 11.26. Recurrent left facial paralysis and likely Bell palsy in a 16-year-old female.** (A and B) Axial postgadolinium T1-weighted fat-suppressed MR images show abnormal enhancement of the right intracanalicular facial nerve *(curved arrow)* and asymmetric enhancement of the tympanic and descending facial nerve on the right *(arrow)*. No mass is demonstrated and the right facial palsy eventually resolved.

*Borrelia burgdorferi.* Three stages with influenza-like symptoms exist, with a classic rash occurring in stage 1. In stage 2, cardiac and neurologic symptoms occur. Stage 3 manifests with arthritic and chronic neurologic symptoms, sometimes years later. Clinical central nervous system involvement has been reported to occur in up to 15% of patients. Neurologic symptoms include myelopathies, encephalitis, pain syndromes, cerebellar dysfunction, movement disorders, and cranial nerve palsies.[54,55] Bilateral facial nerve palsy is a common neurologic manifestation of Lyme disease and should suggest the diagnosis.

***Imaging.*** Involvement of the brain may manifest with foci of increased T2-weighted signal, but parenchymal MRI abnormalities in Lyme disease are rare. Small foci of increased T2-weighted signal are quite common, thus making the finding nonspecific.[56,57] Postgadolinium studies may show enhancement within these lesions, increasing the specificity. Meningeal enhancement may occur, but more commonly, abnormal enhancement of the involved cranial nerves is present. The facial and trigeminal nerves are most often involved, with bilateral facial nerve involvement being a classic presentation (e-Fig. 11.24).[58,59] Hearing loss has also been reported, possibly caused by cochlear nerve involvement. The differential diagnosis would include bilateral Lyme disease, autoimmune disease, demyelinating neuropathy (Miller–Fisher syndrome), and neoplastic etiologies (e-Fig. 11.25).

***Treatment.*** Oral antibiotics are the standard treatment for early-stage Lyme disease, usually doxycycline for adults and children older than 8 years. With central neurologic involvement, intravenous antibiotics are required.

## Bell Palsy

***Clinical Presentation and Etiologies.*** Bell palsy is the most common cause of acute lower motor neuron unilateral facial nerve palsy. A viral etiology has been postulated; however, ischemic and possibly autoimmune contributions are likely contributing factors.[60] Bell palsy is a diagnosis of exclusion, and other potential etiologies of facial nerve paralysis in childhood include trauma, infection, neoplasm, and congenital anomalies. Virologic tests have suggested herpes simplex type 1 and varicella-zoster as possible etiologies.

***Imaging.*** With typical Bell palsy, complete recovery usually occurs within 6 to 8 weeks, and imaging is not necessary in the acute phase. If prolonged paralysis or other neurologic signs are present, MRI evaluation is suggested.[61] Imaging of Bell palsy demonstrates abnormal, asymmetric enhancement and mild enlargement of the facial nerve. It is important to realize that the normal facial nerve segments can enhance (geniculate ganglion, tympanic, and mastoid segments). The labyrinthine segment can normally show some mild enhancement. Any enhancement of the facial nerve within the internal auditory canal and strong enhancement of the labyrinthine segment is considered pathologic (Fig. 11.26).[62,63] Mild enhancement of the normal canalicular facial nerve may be noted at 3-Tesla MRI.[64]

Varicella zoster virus infection can also result in the more severe Ramsay Hunt syndrome, manifesting clinically with facial nerve palsy, SNHL, tinnitus, vertigo, ataxia, and a painful vesicular eruption within the region of the auricle.[65] MRI demonstrates not only abnormal enhancement of the facial nerve but also the vestibulocochlear nerve and membranous labyrinth (e-Fig. 11.27).[66]

***Treatment.*** The quantitative intensity of enhancement has been correlated with the outcome for these patients.[67] Antiviral agents and corticosteroids are the preferred treatment in the acute phase; however, antiviral therapy has little effect on prognosis.[68] Surgery to decompress the facial nerve is controversial when performed in patients with complete Bell palsy that has not responded to medical therapy. Imaging can potentially direct the surgeon to the more affected portion of the nerve.[69]

### KEY POINTS

- Carefully inspect the images in patients with mastoiditis for intracranial and venous complications.
- Mastoid fluid may result from dural sinus thrombosis and not be the cause.
- A cholesteatoma demonstrates mass effect and bony erosion, and has increased diffusion-weighted MR signal.
- MRI is more sensitive in demonstrating cochlear obstruction in the fibrous stage of labyrinthitis ossificans.
- Enhancement of the labyrinth is predictive of the development of SNHL in children with meningitis.

# Neoplasia

*Korgün Koral*

## OVERVIEW

Pediatric neoplasms of the temporal bone are relatively infrequent. However, the imaging specialist has to be familiar with the common malignancies and their imaging appearances. One important task of the radiologist is to define the extent of the lesion both within the temporal bone and, if present, intracranially (Box 12.1).

## RHABDOMYOSARCOMA

Rhabdomyosarcoma is the most common soft tissue sarcoma of childhood, accounting for approximately 60% of all soft tissue sarcomas and 5% to 8% of all childhood cancers.[1] Approximately 40% of all rhabdomyosarcomas are in the head and neck region. Temporal bone rhabdomyosarcomas are relatively rare. In a study of 39 pediatric head and neck rhabdomyosarcoma, there were 6 patients (15%) with temporal bone involvement.[2] Histologically, embryonal rhabdomyosarcomas are the most common type.[3] The most common presentation of rhabdomyosarcoma is chronic otitis media that is not responsive to therapy.[2] Some patients may present with swelling or facial nerve palsy.[3]

The role of computed tomography (CT) is to demonstrate bone erosion and soft tissue mass (Fig. 12.1A). Magnetic resonance imaging (MRI) is indicated for evaluation of intracranial extension and involvement of the vascular structures (internal carotid artery, jugular vein, and dural venous sinuses). MRI generally shows a nonspecific, enhancing, destructive mass (Fig. 12.1B and D).

Treatment regimens combining chemotherapy and radiotherapy, with or without surgery, have improved the once dismal outcomes of patients with temporal bone rhabdomyosarcoma. In a study of 14 patients, a 5-year disease-free survival rate of 82% was reported.[3]

## LANGERHANS CELL HISTIOCYTOSIS

Langerhans cell histiocytosis (LCH) is a histiocytic proliferation of unknown etiology. The diagnosis of LCH is made by demonstration of the characteristic electron microscopic features or CD1a positivity in the involved tissue.[4] In children younger than 15 years, the incidence of LCH is estimated to be 0.5 in 100,000 children per year.[5] The mean age at presentation is 12 years, and there is no sex predilection. The most common form of LCH is a solitary osteolytic lesion of the skull and spine.[6]

Although ear and temporal bone involvement is relatively rare, symptoms of ear infection may be the reason to seek medical attention. The temporal bone may be involved in isolation or as part of polyostotic or systemic disease.[7] Temporal bone involvement may be unilateral or bilateral (30% of cases). Conductive hearing loss is occasionally seen.[8]

On CT, the lesion is characterized by a nonspecific, lytic soft tissue mass. As in the calvarial LCH, there is no periosteal reaction of the residual bone, which has sharp, well-defined margins (Fig. 12.2). The role of MRI is in the evaluation of hypothalamic-pituitary axis, which may be concomitantly involved in systemic LCH. The treatment of temporal bone LCH is generally with chemotherapy.

## LYMPHOMA

Primary lymphoma of the temporal bone is rare.[9] The lesions are generally lytic and may be associated with epidural components (Fig. 12.3).

## ENDOLYMPHATIC SAC TUMOR

Endolymphatic sac tumor (ELST) is a rare neoplasm arising from the epithelium of the endolymphatic sac. This adenomatous neoplasm is typically located at the posterior aspect of the temporal bone. ELST is rare in adults and even rarer in children. Patients with von Hippel–Lindau disease have an increased risk of developing ELST, particularly bilaterally.[10] Characteristic imaging findings show a retrolabyrinthine mass resulting in bone erosion (Fig. 12.4). On MR, despite the tumor's increased vascularity, signal voids are rarely seen.[11] The lesions show intense enhancement with intravenous gadolinium. The treatment is wide surgical resection.

## OSTEOSARCOMA

Primary osteosarcoma of the temporal bone is exceedingly rare.[12] The lesions can be osteoblastic, lytic, or mixed (Fig. 12.5).

## EXOSTOSIS AND OSTEOMA

Exostoses and osteomas are benign bony tumors of the external auditory canal.[11] These tumors are rarely encountered in children. Exostoses generally result from prolonged exposure to cold water and referred to as the "surfer's ear" or "swimmer's ear." Osteomas are rarer than exostoses and may also arise in the middle ear, mastoid, or petrous segments of the temporal bone.

**BOX 12.1**

The imaging report of a temporal mass should include:
- Location (external ear/middle ear and mastoid air cells/inner ear/cerebellopontine angle cistern/internal auditory canal)
- Cranial nerve and vascular involvement
- Intracranial extension

## Abstract:

In this chapter some common and less common neosplasms involving the pediatric temporal bone are discussed. Langherhans cell histiocytosis is by far the most common lesion involving the pediatric temporal bone. Rhabdomyosarcoma is seen less frequently. The role of imaging is critical in assessing the extent of the disease process and evaluating response to therapy.

## Keywords:

temporal bone
pediatric
children
tumor
magnetic resonance imaging
computerized tomography

## SCHWANNOMA

Schwannomas are rare in children, but they are encountered in children with neurofibromatosis type 2 (NF2). For NF2, the best diagnostic clue is bilateral enhancing cerebellopontine angle/internal auditory canal masses (Fig. 12.6). Both the vestibular nerve and facial nerve may be involved in the cerebellopontine angle or internal auditory canal. Treatment is resection with the goal of preservation of hearing. Schwannomas can be seen in the remainder of the cranial nerves. Intracranial and spinal meningiomas and ependymomas may be seen.[13]

## HEMANGIOPERICYTOMA

Hemangiopericytoma is a highly vascular tumor, which is rarely seen in children.[14] In the cerebellopontine angle, the main differential consideration is meningioma (Fig. 12.7). Treatment is resection usually followed with radiotherapy.

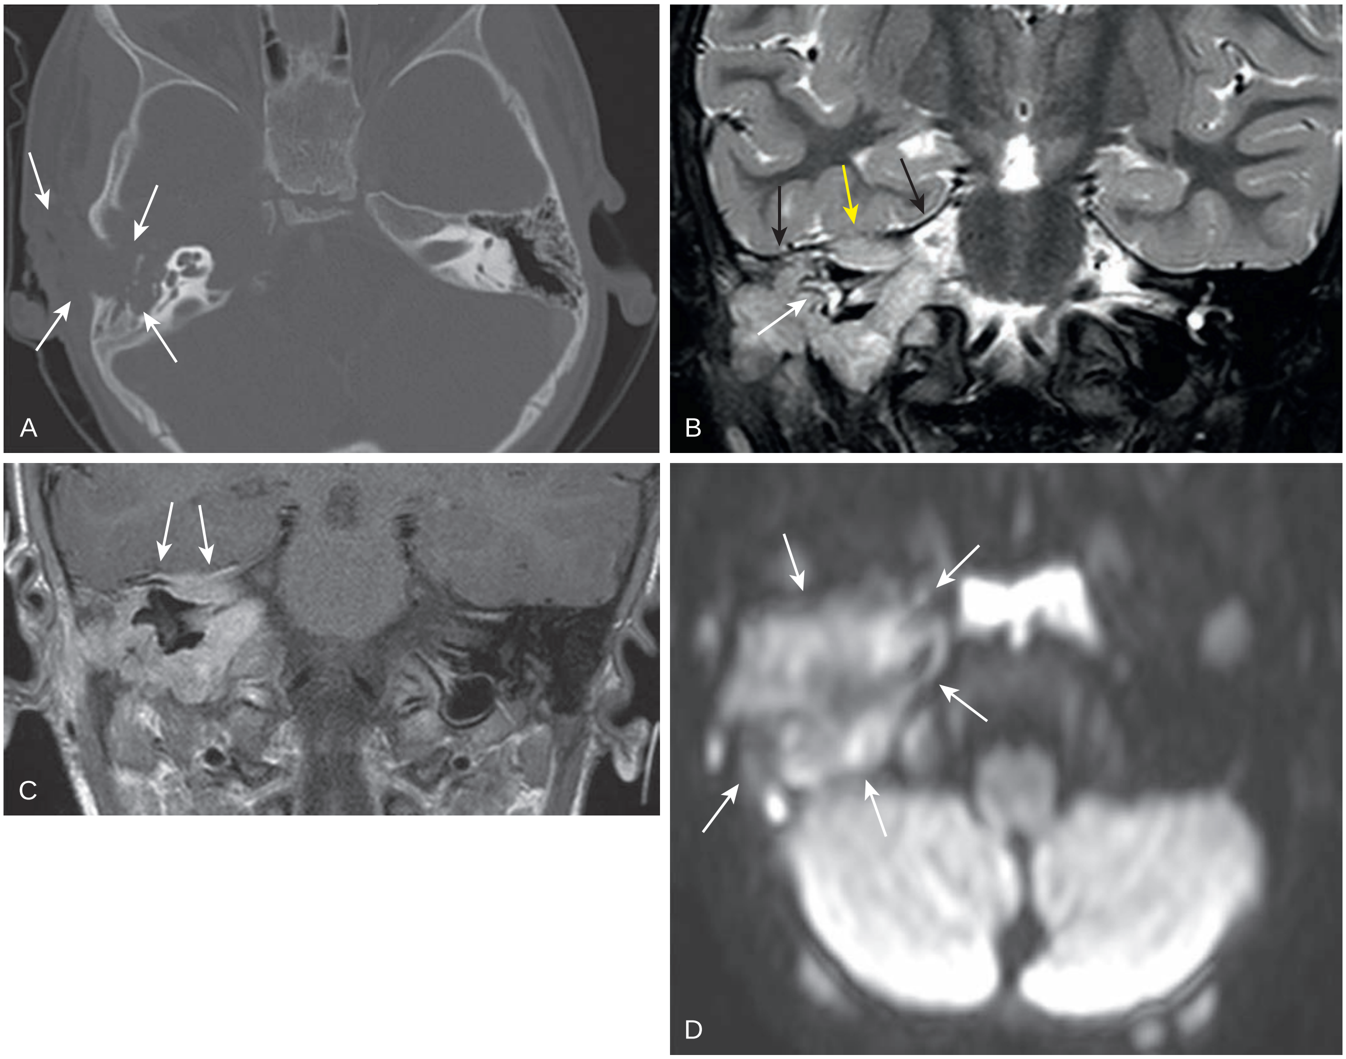

**Figure 12.1. Rhabdomyosarcoma in a 2-year-old boy with hearing loss and right periauricular swelling.** (A) Axial CT shows a large, soft tissue mass of the right temporal bone *(arrows)* with extensive osseous destruction. (B) Coronal STIR MR image shows the hyperintense mass of the right temporal bone. The focal loss of integrity of the floor of right middle cranial fossa *(yellow arrow)* and intact dura *(black arrows)* are shown. Destruction of the bony labyrinth *(white arrow)* by the mass is shown. (C) Coronal fat-suppressed gadolinium-enhanced T1-weighted MR image shows thick enhancement at the floor of the right middle cranial fossa *(arrows),* consistent with parameningeal spread. (D) Axial diffusion weighted MR image shows that the lesion *(arrows)* is predominantly isointense to adjacent brain indicative of hypercellularity.

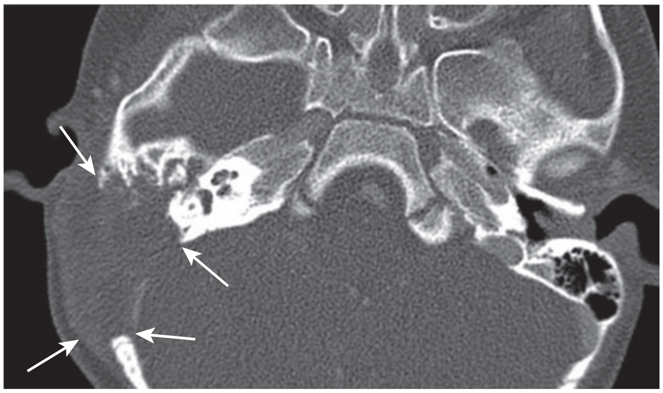

**Figure 12.2. Langerhans cell histiocytosis in 3-year-old boy with retroauricular mass.** Axial CT shows a lytic lesion *(arrows)* involving the mastoid, petrous, and squamous segments of the right temporal bone. The margins of the residual bone are sharp.

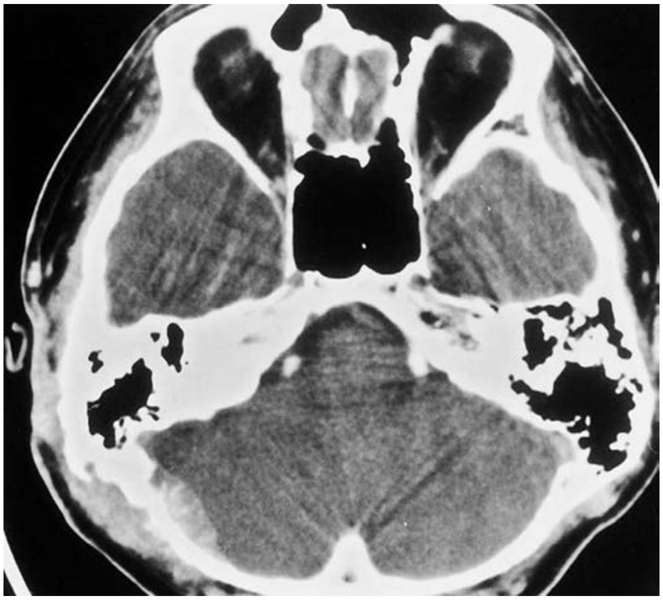

**Figure 12.3. Lymphoma in a 15-year-old boy with a retroauricular mass.** An enhancing mass is seen on CT arising from the mastoid segment of the temporal bone and involving the occipital bone (*Clin. Imaging.* 2003;27:386–388).

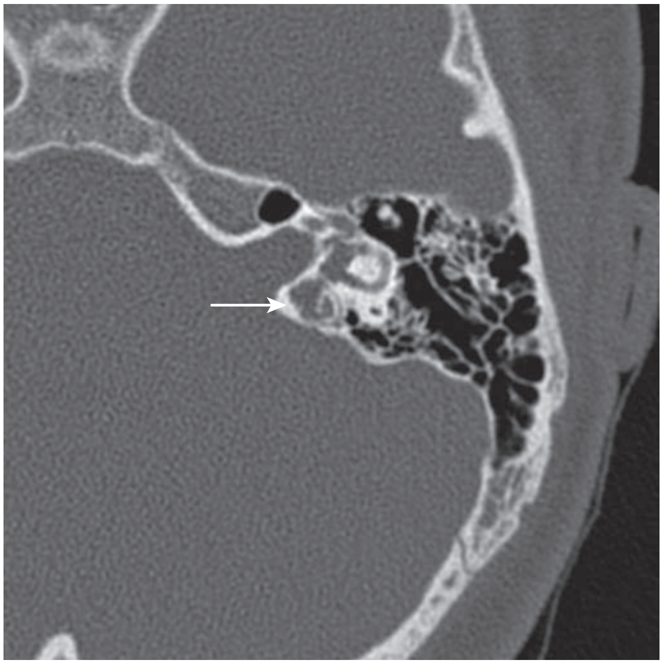

**Figure 12.4. Endolymphatic sac tumor in 14-year-old boy with sensorineural hearing loss.** Axial, noncontrast CT shows a lytic, expansile lesion *(arrow)* posterior to the vestibule, in the expected location of the vestibular aqueduct.

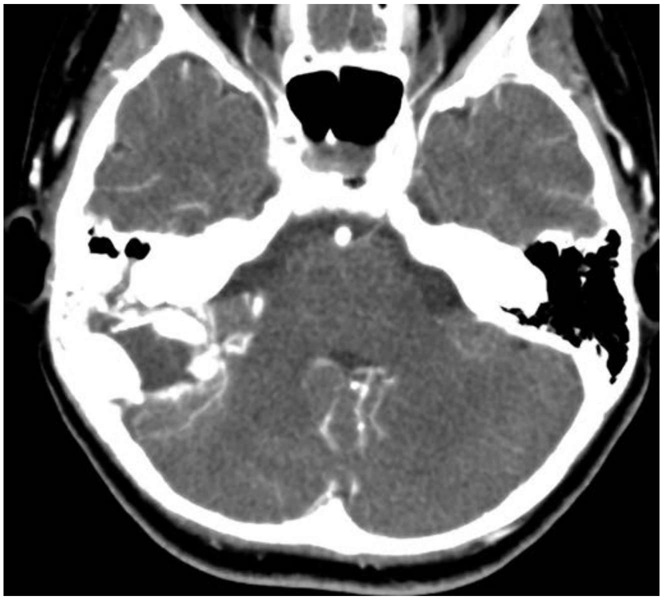

**Figure 12.5. Osteosarcoma in a 9-year-old female, with right facial nerve palsy, who underwent heart transplantation 4 years earlier.** Contrast enhanced axial CT image shows a lytic, vascular mass arising from the mastoid segment of the temporal bone with intracranial extension.

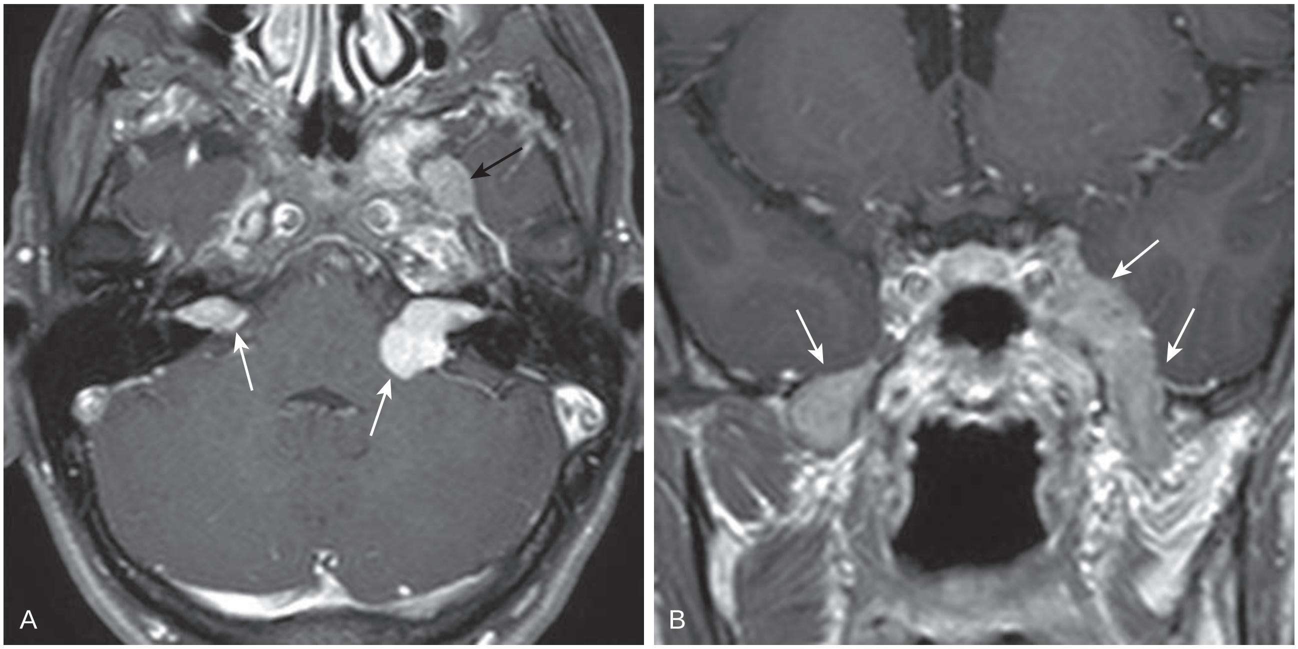

**Figure 12.6. Vestibular schwannomas in a 15-year-old male with neurofibromatosis type 2.** (A) Axial fat-suppressed gadolinium-enhanced T1-weighted MR image shows bilateral internal auditory canal schwannomas *(white arrows)*. An enhancing mass is seen in the left foramen ovale *(black arrow)*. (B) Coronal gadolinium-enhanced T1-weighted MR image shows nerve sheath tumors in the foramina ovale *(arrows)*. There is greater involvement of the left Meckel's cave.

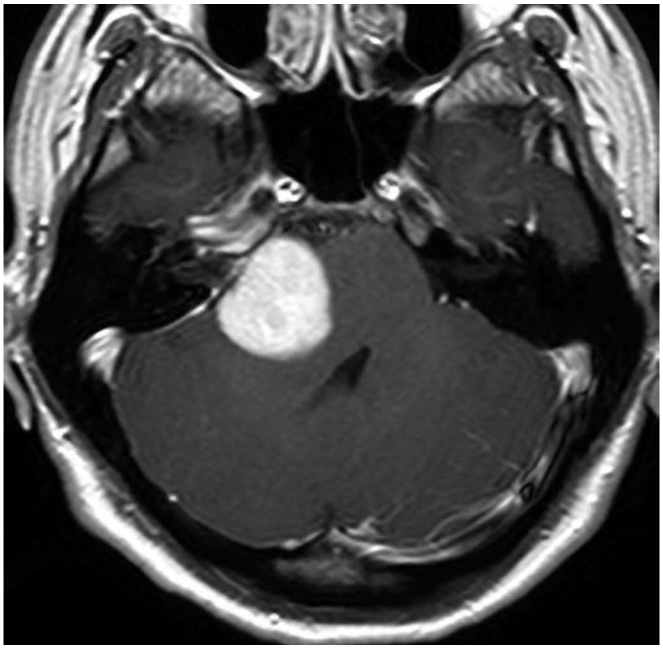

**Figure 12.7. Hemangiopericytoma in a 15-year-old male with an intensely enhancing right cerebellopontine angle mass.** The mass does not extend into the internal auditory canal. The primary differential diagnosis is meningioma.

## KEY POINTS

- Temporal bone tumors are rare in children.
- LCH and rhabdomyosarcoma are the most common neoplasms.
- Bilateral lytic temporal bone masses are almost pathognomonic for LCH.

# Embryology and Anatomy of the Neck

*Wael Abdalla and Vera R. Sperling*

## EMBRYOLOGY OF THE NECK

Accurate diagnosis and successful treatment of congenital anomalies and masses of the neck are dependent on an understanding of the complex embryologic development of this region and the anomalies that result from abnormal development.

This chapter will focus on the embryology of the neck and the oral cavity. The embryology of the orbit, face and sinuses, temporal bone, and ear are addressed in Chapters 4, 8, 9, and 18.

Many of the structures of the head and neck form from an interaction between somitomeres, somites, the mesenchyme, and the branchial apparatus.

### Development of the Mesenchyme

The mesenchyme is derived from three main sources:

1. The lateral plate mesoderm, which forms the laryngeal cartilages and regional connective tissue
2. The neural crest cells, whose migration initiates the formation of the pharyngeal arch skeletal structures and regional bone, cartilage, tendons, and glandular stroma
3. The ectodermal placodes, from which originate the fifth, seventh, ninth, and tenth cranial nerves (CNs)

### Development of the Mesoderm, Somitomeres, and Somites

After neurulation occurs, the mesoderm subdivides into the lateral, intermediate, and paraxial mesoderm. The lateral mesoderm forms most of the throat and larynx. The intermediate mesoderm does not form any part of the head and neck. The paraxial mesoderm forms the 7 somitomeres and 42 to 44 paired somites. The five most rostral somites are involved in the formation of head and neck musculature (Fig. 13.1). The somitomeres and somites form before the development of the branchial apparatus.

The branchial apparatus, that is, the branchial arches, clefts, pouches, and membrane, begin to form late in the third week of gestation. The buccopharyngeal membrane breaks down, and the mesodermal branchial bars begin to form six pairs of branchial arches. The fifth arch is rudimentary and disappears.

The fourth somitomere invades the first branchial arch and generates the formation of the muscles of mastication, that is, the masseter, pterygoid, and temporalis muscles. These muscles are innervated by the trigeminal nerve (CN V).

The seventh somitomere interacts with the third brachial arch to form the stylopharyngeus muscle, which is innervated by the glossopharyngeal nerve (CN IX).

The first four occipital somites invade the fourth and sixth brachial arches and thus stimulate the formation of the extrinsic and intrinsic laryngeal muscles innervated by the vagus nerve (CN X) and the cranial segment of the spinal accessory nerve (CN XI).

The third through seventh somites form the sternocleidomastoid muscle and trapezius and are innervated by the spinal accessory nerve (CN XI).

The intrinsic and extrinsic tongue muscles are likely derived from the second through fourth occipital somites and are innervated by the hypoglossal nerve (CN XII).

The contribution of the somitomeres and somites to the formation of muscles and their distinct innervation is unchanged throughout growth and development. Thus although many muscles migrate in location, their nerve supply is maintained and hence their branchial arch origin can always be identified (see Fig. 13.1).

### Development of the Branchial Apparatus

Formation of the branchial apparatus occurs between the fourth through seventh weeks of development. The pharynx constitutes much of the foregut during the first few weeks of development. Formation of the five branchial arches (I, II, III, IV, and VI) results from the breakdown of the buccopharyngeal membrane and segmentation of the mesoderm. Migration of neural crest cells to this location stimulates growth and development. Each arch has its own outer epithelial lining of ectoderm separated by five clefts and an inner epithelial lining of endoderm with five corresponding pouches and a central cartilaginous core, which is a mesenchymal derivative that participates in the formation of the characteristic skeletal, muscular, ligamentous, vascular, and neural components of each arch.

Shortly after formation of the branchial arches, the first and second arches undergo mesodermal proliferation, thus creating the epicardial ridge, which contains the mesodermal precursor of the sternocleidomastoid, the trapezius, and the infrahyoid and lingual muscles. The nerves of the epicardial ridge are the hypoglossal (CN XII) and spinal accessory (CN XI) nerves. The proliferation of mesenchyme overgrows branchial arches II, III, and IV and narrows branchial clefts II, III, and IV. Subsequently, an ectodermal pit is formed—the cervical sinus of His—which obliterates with further development; failure of obliteration results in formation of branchial sinus, clefts, or cysts of types II, III, or IV.

#### Branchial Apparatus and Its Contribution to the Structures of the Neck

**Branchial Arches.** The first branchial arch (Fig. 13.2) is composed of a dorsal segment known as the maxillary process and a ventral segment known as Meckel cartilage or the mandibular process; both involute. The ossification around Meckel cartilage is the precursor of the mandible and the sphenomandibular cartilage in the neck. The muscle derivatives of the first arch are the muscles of mastication (the masseter, pterygoid, and temporalis muscles), the tensor tympani and tensor veli palatine muscles, the anterior belly of the digastric muscle, and the mylohyoid muscle. The trigeminal nerve (CN V) provides motor and sensory innervation to the first branchial arch.

The second branchial arch is also known as Reichert cartilage. It gives rise to the upper body and lesser cornu of the hyoid bone, the styloid process, and stylohyoid ligament. The muscle derivatives include the platysma, the posterior belly of the digastric, and the stylohyoid. The nerve of the second brachial arch is the facial nerve (CN VII), which is primarily motor. The main sensory component is the chorda tympani branch that is carried with a branch of the trigeminal nerve (CN V3) to supply taste to the anterior two-thirds of the tongue. The artery of the second brachial arch is the stapedial artery, which normally regresses aside from some contributions to the internal and external carotid arteries.

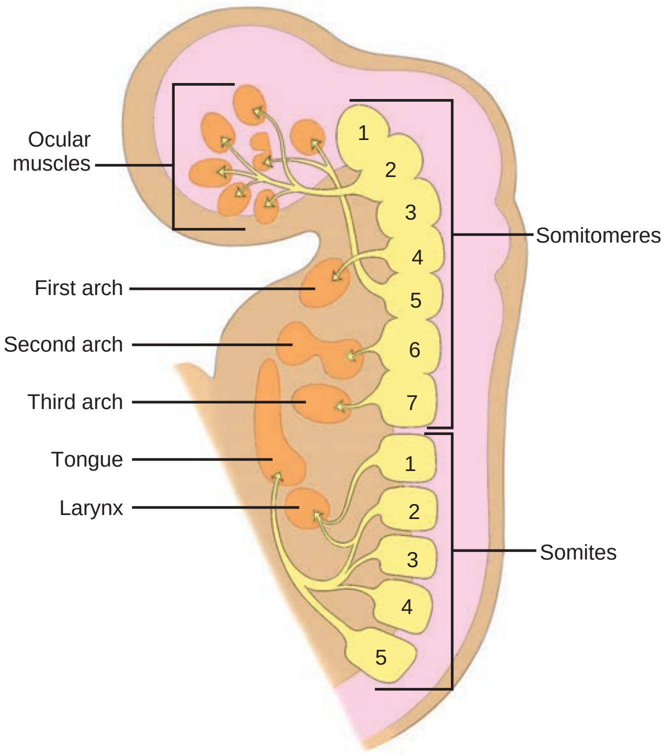

**Figure 13.1. Embryology.** A sagittal section shows the relationship of somitomeres and somites and their corresponding derivatives. *(From Som P, Curtin H.* Head and neck imaging*, 4th ed, Philadelphia, PA: Mosby; 2003.)*

The third branchial arch cartilage derivatives include the greater cornu and inferior body of the hyoid. The muscle derivatives include the stylopharyngeus and superior and middle pharyngeal constrictors. The nerve of the third brachial arch is the glossopharyngeal nerve (CN IX). The neural crest cells of the third branchial arch also form the carotid bodies. The artery of the third branchial arch contributes to the common carotid artery and the internal and external carotid arteries.

The fourth and sixth branchial arch cartilage derivatives fuse to form the larynx and the laryngeal cartilages (the thyroid, cricoid, arytenoid, corniculate, and cuneiform). Muscle derivatives include the cricothyroid muscle, the levator veli palatini, and the inferior pharyngeal constrictors. The muscle derivatives of the sixth arch are the remaining intrinsic muscles of the larynx. The nerve of the fourth arch is the superior laryngeal nerve, and the nerve of the sixth arch is the recurrent laryngeal nerve. Both are branches of the vagus nerve (CN X). The artery of the fourth branchial arch contributes to the aortic arch on the left and the subclavian artery on the right. The artery of the sixth branchial arch becomes the ductus arteriosus and the pulmonary artery. Between the branchial arches lie the paired branchial pouches and clefts.

**Branchial Pouches.** The first branchial pouch does not contribute to the structures of the neck. The second branchial pouch gives rise to the palatine tonsils and tonsillar fossa. The third branchial pouch gives rise to the inferior parathyroids and thymus. The early embryologic connections to the pharynx normally are obliterated. The fourth branchial pouch gives rise to the superior parathyroid glands and the ultimobranchial body, which contains the parafollicular cells (C cells) of the thyroid gland. The fifth branchial pouch degenerates. The branchial clefts do not contribute to any neck structures and are obliterated as development occurs (Tables 13.1 and 13.2).

**TABLE 13.1** Derivatives of the Branchial Arches

| Arch | Nerve | Muscles | Skeletal Structures | Ligaments | Artery |
|---|---|---|---|---|---|
| First (mandibular) | Trigeminal nerve (CN V) (maxillary and mandibular branches only) | Muscles of mastication, mylohyoid,; anterior belly of digastric, tensor tympani, tensor veli palatine | Malleus incus | Anterior ligament of malleus, sphenomandibular ligament | Maxillary artery |
| Second (hyoid) | Facial nerve (CN VII) | Muscles of facial expression, stapedius, stylohyoid, posterior belly of digastric | Stapes, styloid process, lesser cornu and upper body of the hyoid bone | Stylohyoid ligament | Stapedial artery (rarely) |
| Third | Glossopharyngeal nerve (CN IX) | Stylopharyngeus, superior and middle pharyngeal constrictors | Greater cornu and lower part of body of the hyoid bone | | Contributions to the carotid arteries |
| Fourth and sixth | Superior laryngeal branch of vagus nerve (CN X)—fourth arch; recurrent laryngeal branch of vagus nerve (CN X)—sixth arch | Cricothyroid, levator veli palatine, inferior pharyngeal constrictors, intrinsic muscles of larynx, striated muscles of the esophagus | Thyroid, cricoid, arytenoid, corniculate, cuneiform cartilages | | The artery of the fourth arch contributes to the subclavian artery on the right and the aortic arch on the left; the artery of the sixth arch forms the ductus arteriosus and the pulmonary artery |

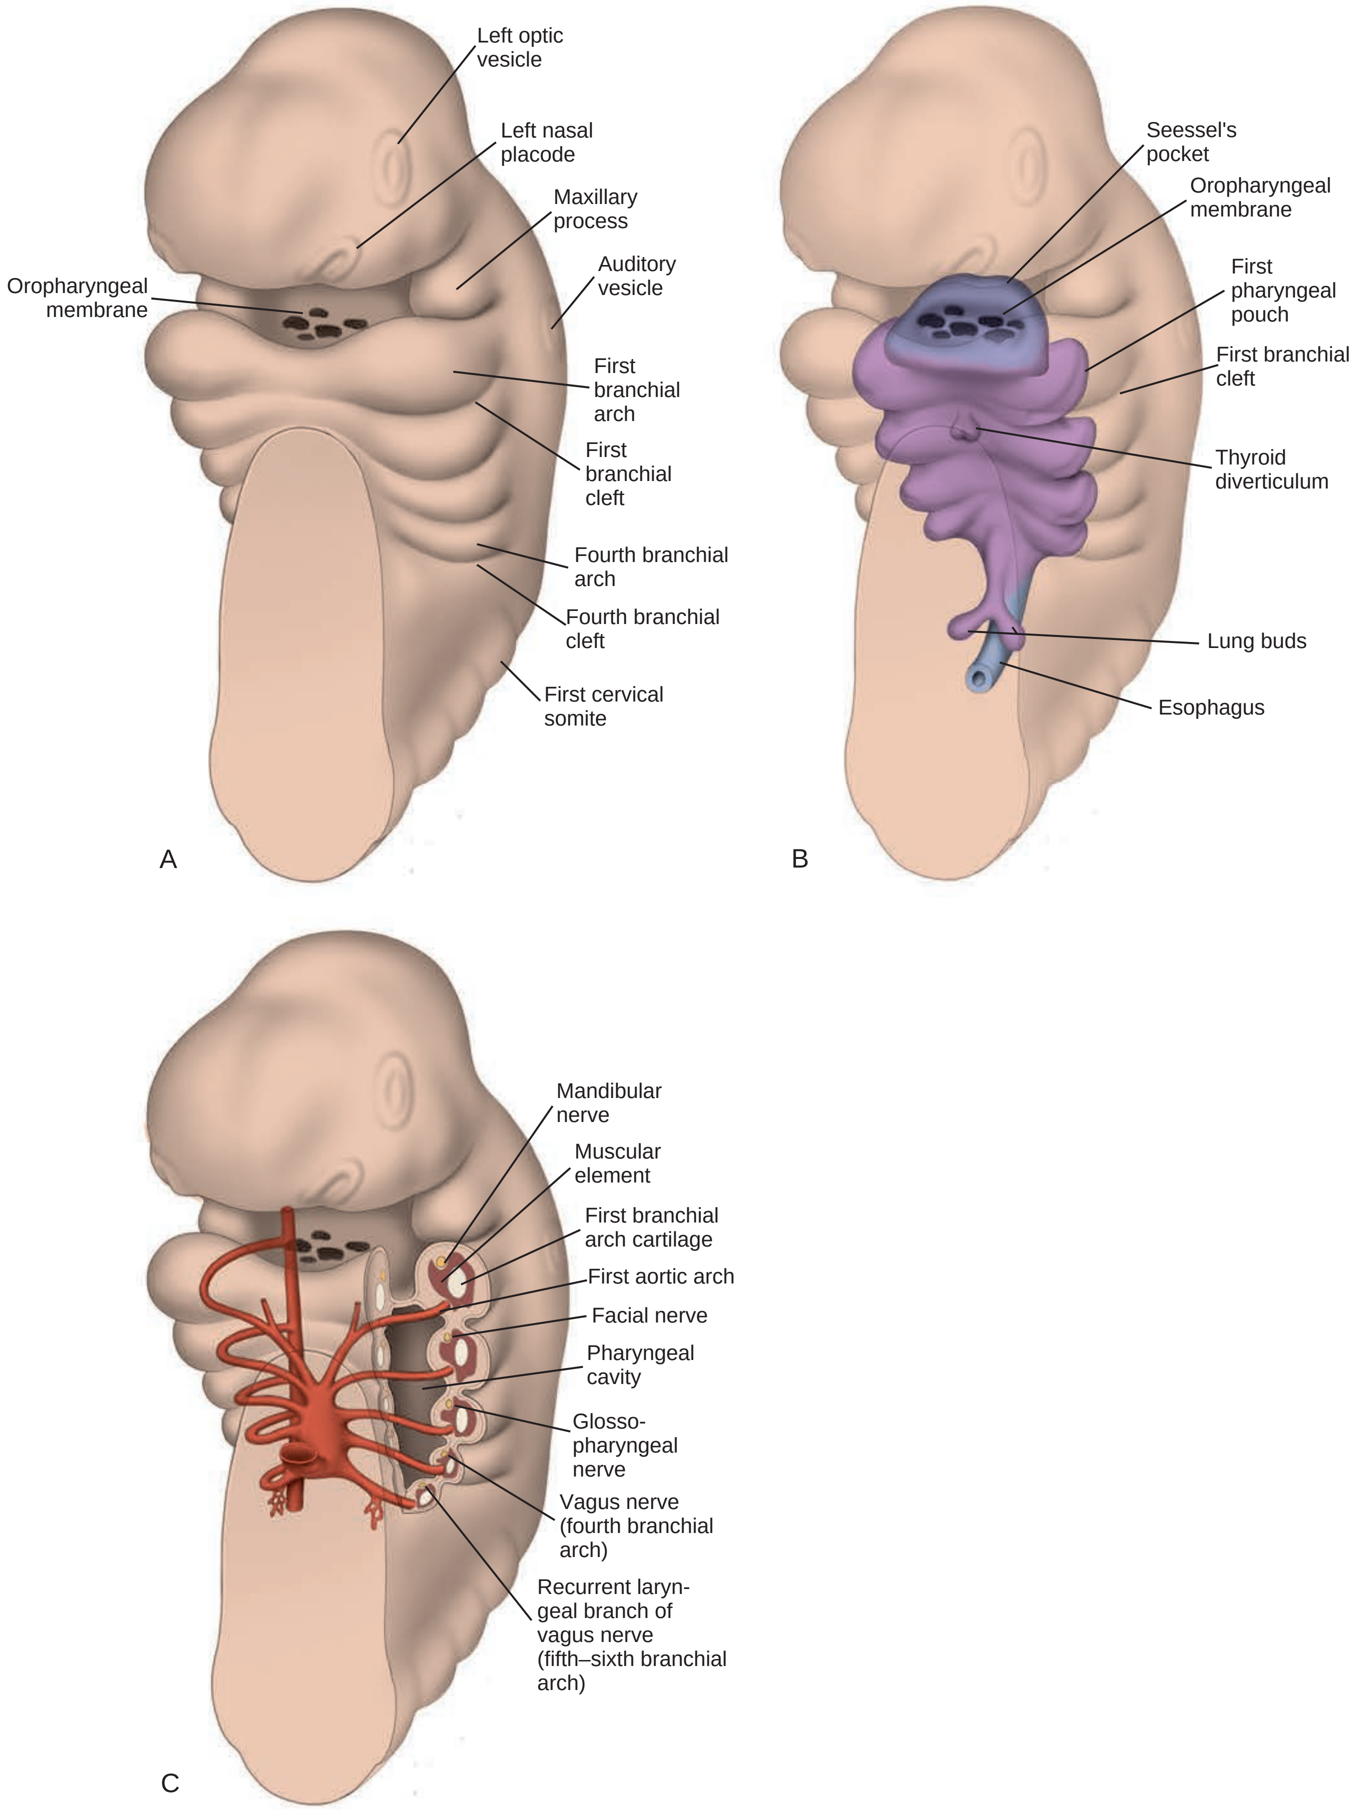

**Figure 13.2. Embryology.** Relationship of (A) branchial arches and (B) clefts and (C) subsequent derivative structures. *(From Som P, Curtin H. Head and neck imaging. 4th ed, Philadelphia, PA: Mosby; 2003.)*

## EMBRYOLOGY OF THE TONGUE

The tongue forms from the first four branchial arches. Two lateral and one central swelling, the tuberculum impar, form from the first branchial arch. A second central swelling, the copula/hypobranchial eminence, forms from the second, third, and fourth branchial arches. A third central swelling from the fourth branchial arch forms the epiglottis. Thus the anterior two-thirds or body of the tongue forms from the first branchial arch, whereas the root of the tongue forms from the second, third, and fourth branchial arches. The groove formed where the anterior and posterior portions of the tongue fuse is called the terminal sulcus.

The hypoglossal nerve (CN XII) innervates all the intrinsic tongue muscles and all extrinsic tongue muscles but the palatoglossus. Sensory innervation is by the lingual branch of CN V3, the chorda tympani branch of CN VII, the lingual branch of CN IX, and the recurrent laryngeal branch of CN X.

## EMBRYOLOGY OF THE THYROID GLAND

The thyroid gland originates from a median endodermal thickening in the floor of the primitive pharynx in the third to fourth week of development. The thyroid primordium develops between the tuberculum impar and the copula of the first and second pouches. The foramen cecum is the remnant of the thyroid primordium in this location, between the anterior two-thirds and the posterior one-third of the tongue. The thyroid gland passes anterior to the hyoid and laryngeal cartilages and descends anterior to the thyrohyoid membrane and the strap muscles. The thyroid gland reaches its final position by the seventh week of development. During its inferior migration, the thyroid anlage is connected to the tongue by the normally transient thyroglossal duct. Innervation of the thyroid gland is primarily by the sympathetic middle cervical ganglion.

**TABLE 13.2** Derivatives of the Branchial Pouches

| Pouch | Derivatives |
|---|---|
| First | Eustachian tube, middle ear, portions of mastoid bone |
| Second | Palatine tonsils, tonsillar fossa |
| Third | Inferior parathyroids, thymus |
| Fourth and sixth | Superior parathyroids, parafollicular cells of thyroid |

## EMBRYOLOGY OF THE SALIVARY GLANDS

The common pathway for salivary gland development is the ingrowth of surface epithelium (primarily ectoderm, but also endoderm for minor salivary gland formation) into the underlying mesenchyme.

The precursors of the parotid gland appear between the fourth to sixth weeks of gestation, and the submandibular and sublingual glands appear between the sixth to eighth weeks of gestation. The minor salivary glands do not develop until the twelfth week of gestation.

A process of proliferation, division, and canalization occurs. Interaction with and stimulation by the autonomic nervous system is essential for normal salivary gland development and function. The final process of encapsulation occurs in reverse to the order of development and growth. Encapsulation of the parotid gland occurs after formation of the lymphatic system, accounting for the presence of intraparotid lymph nodes.

The parotid gland is innervated by CN IX, the submandibular and sublingual glands are innervated by CN VII, and the minor salivary glands are innervated by CN V.

## ANATOMY OF THE NECK

Clinical evaluation and classic anatomy divides the neck into triangles. The largest are the anterior and posterior triangles, which are defined and separated by the sternocleidomastoid muscles. The anterior triangle is further subdivided into the paired carotid and submandibular triangles (separated by the posterior belly of the digastric muscle) and the single midline submental and infrahyoid muscular triangles. The posterior triangle consists of the paired occipital and subclavian triangles, which are separated by the inferior belly of the omohyoid muscle (Fig. 13.3). The central cavity is divided into the nasopharynx, oropharynx, hypopharynx, and oral cavity.

This approach to neck anatomy does not reflect anatomy as defined by the fascial layers, that is, the superficial and deep cervical fascia of the head and neck. The deep cervical fascia is composed of three layers:

1. The superficial layer of the deep cervical fascia (SL-DCF), also known as the investing fascia, which defines the masticator, parotid, and submandibular spaces; it also contributes to the carotid space

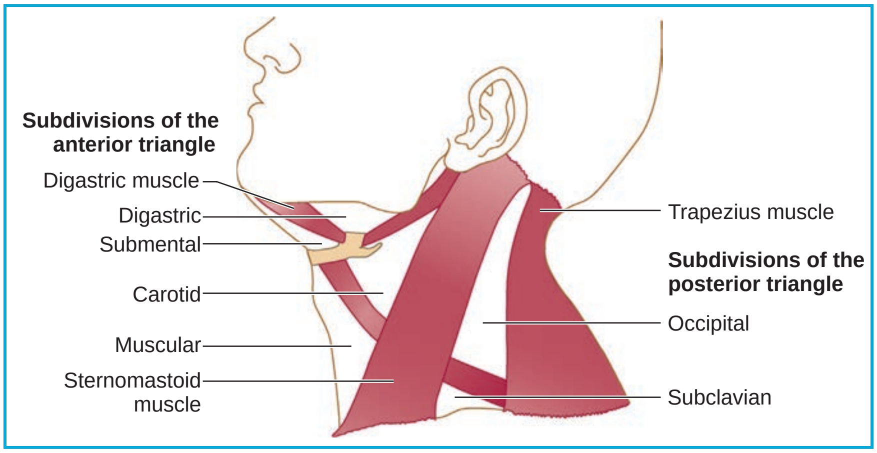

**Figure 13.3.** Traditional triangular division of neck spaces.

2. The middle layer of the deep cervical fascia (ML-DCF), also known as the visceral fascia, which primarily forms the buccopharyngeal and pharyngobasilar fascia and the fascia of the tensor veli palatine; it also contributes to the carotid space
3. The deep layer of the deep cervical fascia (DL-DCF), also known as the prevertebral fascia, which forms the perivertebral space and then is subdivided into the anterior prevertebral and posterior paraspinal compartments; the alar fascia is a small component of the DL-DCF and also contributes to the carotid sheath

The advent of cross-sectional imaging enabled a new approach to neck anatomy defined by the concept of dividing the neck into the suprahyoid and infrahyoid compartments, with further subdivision of each compartment into fascially defined spaces (Figs. 13.4 and 13.5). The resultant refined approach to differential diagnosis, combined with the use of surgically and pathologically defined common terminology and nomenclature, has improved communication between radiologists and clinicians.

The pharyngeal mucosal space, which is located in the suprahyoid neck, is the surface of pharynx. It encompasses the nasopharyngeal, oropharyngeal, and hypopharyngeal mucosa. Centrally located, it is posterior to the retropharyngeal space and lateral to the parapharyngeal space. It is not a true fascially enclosed space because only its deep margin is bound by the ML-DCF.

The parapharyngeal space is located in the suprahyoid neck; it extends from the skull base to the submandibular space. The medial fascial boundary is the visceral/buccopharyngeal fascia. The pterygomandibular raphe and masticator space is its anterior boundary. Laterally and posteriorly, it is bounded by the carotid and retropharyngeal space.

The carotid space, which is located in both the suprahyoid and infrahyoid neck, extends from the skull base to the aortic arch. All three layers of deep cervical fascia form the carotid sheath. The carotid sheath is better defined in the infrahyoid neck and more loosely formed in the suprahyoid neck.

The retropharyngeal space, which is located in both the suprahyoid and infrahyoid neck, extends from the skull base to T3. The ML-DCF constitutes the anterior wall, and the DL-DCF constitutes the posterior wall. The lateral wall is the alar fascia, a small fragment of the DL-DCF. It is posterior to the pharyngeal mucosal space in the suprahyoid neck and the visceral space in the infrahyoid neck, anterior to the danger space posterior, and medial to the carotid space.

The masticator space, which is located in the suprahyoid neck, extends from the superior aspect of suprazygomatic masticator space/temporal fossa at the level of parietal bone to the inferior aspect of the infrazygomatic masticator space/undersurface of the posterior body of the mandible. It is bounded by a sling of the SL-DCF that extends from the inferior mandible to the skull base and zygomatic arch. It is anterior to the parotid space, anterolateral to the parapharyngeal space, and lateral to the pharyngeal mucosal space. Superior to it is the skull base, including the foramina ovale and spinosum.

The parotid space, which is located in the suprahyoid neck, extends superiorly from the external auditory canal and mastoid tip to below angle of mandible. It is enclosed by the SL-DCF.

The perivertebral space, which is located in both the suprahyoid and infrahyoid part of the neck, extends from the skull base to T4 and consists of a prevertebral and a paraspinal component. It is enveloped by the DL-DCF. The perivertebral space is posteromedial to the carotid space and medial to the posterior cervical space.

The visceral space, which is located in the infrahyoid neck, lies anterior to the retropharyngeal space in the midline and is enclosed by the ML-DCF.

**TABLE 13.3** Anatomic Spaces of the Suprahyoid Neck

| Space | Contents |
|---|---|
| Pharyngeal mucosal space | Mucosa, minor salivary glands and lymphoid tissue, pharyngobasilar fascia, buccopharyngeal fascia, superior and middle pharyngeal constrictor muscles, levator veli palatini muscle, cartilaginous end of eustachian tube (torus tubarius) |
| Parapharyngeal space (prestyloid parapharyngeal space) | Deep portion of parotid gland, minor salivary glands, pterygoid venous plexus, internal maxillary artery, ascending pharyngeal artery, branches of cranial nerve V3, cervical sympathetic chain and fat |
| Carotid space (retrostyloid parapharyngeal space) | Internal carotid artery, internal jugular vein, cranial nerves IX–XII, sympathetic chain, lymph nodes—deep cervical chain |
| Retropharyngeal space | Fat, lymph nodes—retropharyngeal (medial and lateral) |
| Masticator space | Ramus and posterior body of mandible, muscles of mastication—pterygoid, masseter, and temporalis; mandibular division trigeminal nerve (V3)—inferior alveolar and lingual nerves, inferior alveolar vein and artery, pterygoid venous plexus |
| Parotid space | Parotid gland and duct, cranial nerve VII, external carotid artery, retromandibular vein, lymph nodes—intraparotid and periparotid |
| Perivertebral space | Prevertebral muscles, scalene muscles, vertebral artery and vein, brachial plexus, phrenic nerve<br>Vertebral bodies and discs |

*Adapted from Som PM, Curtin HD.* Head and neck imaging, *4th ed, St Louis, MO: Mosby; 2003.*

**TABLE 13.4** Anatomic Spaces of the Infrahyoid Neck

| Space | Contents |
|---|---|
| Visceral space | Larynx, hypopharynx and cervical esophagus, trachea, thyroid gland, parathyroid glands, lymph nodes, recurrent laryngeal nerve (branch cranial nerve X), third and fourth branchial apparatus and thyroid/parathyroid anlage remnants |
| Retropharyngeal space | Fat, remnants of third branchial apparatus |
| Carotid space | Common and internal carotid arteries, internal jugular vein, cranial nerve X, sympathetic chain, lymph nodes, carotid body, second branchial apparatus remnants |
| Perivertebral space | Prevertebral, scalene, and paraspinal muscles, brachial plexus, phrenic nerve, vertebral artery and vein<br>Vertebral bodies and discs |
| Anterior cervical space | Extension of submandibular space of suprahyoid neck<br>Composed of fat |
| Posterior cervical space | Cranial nerve XI, spinal accessory nodes, preaxillary brachial plexus, fat |

The posterior cervical space extends from the mastoid tip to the level of the clavicle. Its superficial boundary is the SL-DCF, and its deep boundary is the deep cervical DL-DCF. It lies posterior to the carotid sheath, posteromedial to the sternocleidomastoid muscle, and anterolateral to the paraspinal component of the perivertebral space (Tables 13.3 and 13.4).

## ANATOMY OF THE ORAL CAVITY

The oral cavity is located anterior to the oropharynx. It is separated from the oropharynx by the soft palate, anterior tonsillar pillars, and circumvallate papillae. The mylohyoid muscle separates the lower oral cavity into the submandibular and sublingual spaces, and forms the floor of the mouth, arising from the mandible and attaching to the hyoid.

The submandibular space, which is located inferior and lateral to the mylohyoid muscle and superior to the hyoid bone, is enveloped by the SL-DCF. Posteriorly, no fascial separation is found between the submandibular space, the sublingual space, and the inferior parapharyngeal space.

The sublingual space, which is located superior and medial to mylohyoid muscle and lateral to genioglossus-geniohyoid muscle complex, is not enclosed by fascia (Table 13.5).

**TABLE 13.5** Contents of the Submandibular and Sublingual Spaces

| Space | Contents |
|---|---|
| Submandibular | Submandibular gland, submandibular and submental lymph nodes, facial artery and vein, inferior cranial nerve XII, anterior belly of digastric muscle |
| Sublingual | Hyoglossus muscle (anterior margin), lingual nerve (sensory branches of cranial nerve V3 and the chorda tympani branch of cranial nerve VII), distal cranial nerve IX and cranial nerve XII, lingual artery and vein, sublingual gland and duct, deep portion of the submandibular gland and duct |

### KEY POINTS

- Knowledge of embryology and anatomy of the neck is essential in interpreting imaging studies and formulating an effective differential diagnosis.
- Cross-sectional imaging has resulted in replacement of the clinically oriented subdivision of neck structures by fascially based anatomic spaces that more closely correspond to surgical and pathologic landmarks.

# Prenatal, Congenital, and Neonatal Abnormalities

*Anna Shifrin and Tamara Feygin*

Congenital lesions of the neck consist of a variety of entities, some of which become apparent at birth or shortly thereafter, whereas others present later in life. This chapter will focus on congenital lesions that can be recognized in the fetus or the newborn. Many congenital cervical lesions may be diagnosed prenatally, making it essential for pediatric radiologists to be familiar with their general patterns on fetal imaging.

Presence of mass lesions in the fetal/neonatal neck may considerably influence other organs and systems because of the complex anatomy of the neck and the proximity of the lesion to vascular, upper gastrointestinal, and especially airway structures. Conditions that may result in potentially life-threatening trachea-laryngeal obstruction include extrinsic causes such as cervical teratomas, vascular malformations, and vascular rings, and intrinsic causes such as congenital high airway obstruction syndrome (CHAOS) and upper airway hemangiomas. Giant fetal neck masses may grow to obstruct the esophagus, causing an accumulation of amniotic fluid (polyhydramnios) and increasing the risk of preterm labor. Accurate depiction and distinction of these entities with imaging facilitate prenatal counseling and delivery planning. Some congenital cervical lesions may be associated with other serious anomalies and may be the first manifestation of a systemic disease or syndrome, potentially requiring further investigation. For accurate diagnosis, it may be necessary to utilize complementary imaging modalities.

## IMAGING MODALITIES

Imaging tools for the fetal neck are ultrasonography (US) and magnetic resonance imaging (MRI). The neonatal neck may be assessed by US, computed tomography (CT), and MRI. Rarely, indeterminate vascular lesions may require evaluation with conventional angiography. Lateral radiography of the neck may still be used in emergent initial evaluation of upper airway pathology but is rarely of value in the workup of congenital lesions.

### Ultrasonography

US supplemented by Doppler (for evaluation of blood flow) is a noninvasive, real-time, high-resolution imaging modality, which provides excellent anatomic images. It is equally useful for primary obstetric imaging and for portable bedside evaluation of a neck mass in the distressed child. Obstetric US includes routine evaluation of the head, face, and neck, as well as an assessment of airway patency and fetal swallowing. The swallowing pattern may be difficult to confirm with US, hence ancillary signs of upper gastrointestinal (GI) tract compromise (a small stomach or polyhydramnios) should be routinely searched for. US nicely demonstrates a lesion's morphology, reliably distinguishes the cystic and solid components, and shows fat and calcifications. Color Doppler depicts the major neck vessels, demonstrates a lesion's vascularity and blood supply, and detects possible arteriovenous shunting. Three-dimensional US clearly depicts the relationship of a cervical mass with adjacent facial and skull base structures (e-Fig. 14.1). Potential shortcomings of fetal US involve cases with poor acoustic windows or abnormal fetal position with unusual flexion and extension of the fetal neck. US imaging of neck lesions in young children is performed with high-resolution transducers and may be sufficient for immediate diagnosis. However, assessment of surrounding tissue invasion may be suboptimal.

### Computed Tomography

CT may serve as the initial imaging modality for evaluation of congenital lesions; it is widely available and offers fast data acquisition. However, suboptimal soft tissue resolution and continued concerns of radiation exposure have resulted in decreasing use in recent years.

### Magnetic Resonance Imaging

MRI is a superb imaging modality for the evaluation of fetal or neonatal neck lesions. Fetal MRI is considered safe to perform in the second and third trimesters, and is approved by the US Food and Drug Administration (FDA) for magnet field strengths up to 3.0 Tesla. Fetal MRI before 17 weeks of gestational age is typically of little value because of the relatively poor image quality in a small fetus and is avoided because of the unknown safety of exposure to magnetic fields during organogenesis. Fetal MRI is usually performed for further assessment of a cervical mass detected by routine obstetric US. The MRI protocol for fetal neck imaging includes the following: (1) half-Fourier acquisition single-shot turbo (HASTE) magnetic resonance (MR) sequence (excellent for imaging of normal anatomic structures and depiction of cervical lesions); (2) spoiled gradient echo T1-weighted sequence (helpful for imaging the thyroid gland and blood flow within the major cervical vessels, as well as for depiction of intralesional blood products and calcification); (3) gradient echo planar imaging (helpful for detection of blood products, calcification, and bony detail); and (4) dynamic steady state or balanced gradient echo sequences (valuable in the assessment of swallowing function in the fetus [see Video 14.2]). The details of fetal swallowing and possible airway compromise should always be carefully examined. Knowledge of airway status may help facilitate delivery planning, including use of the Ex Utero Intrapartum Treatment (EXIT) procedure to allow time to secure the airway while the neonate is still attached to the umbilical cord.

MRI sequences for imaging neonatal neck lesions include high-resolution thin T1- and T2-weighted and postcontrast imaging with fat-suppression in orthogonal planes. Diffusion-weighted imaging is useful for characterization of hypercellular tumors and infected cystic lesions with viscous, purulent content.

## VASCULAR NECK LESIONS

The Mulliken and Glowacki classification of vascular lesions divides pediatric vascular lesions into two major categories: (1) vascular tumors and (2) vascular malformations. These lesions have different treatments and prognoses. The classification, based on pathologic differences as well as the clinical and cellular behavior of vascular lesions, was widely accepted and adopted by the International Society for the Study of Vascular Anomalies in 1996 and was expanded in 2014. Some additional entities have since been identified that are complex and less easily classified by generic headings. Vascular tumors are classified as benign, locally aggressive or borderline, and malignant. Some known genetic

## Abstract:

Congenital lesions of the neck consist of a variety of entities, some of which become apparent at birth or shortly thereafter, whereas others present later in life. This chapter will focus on congenital lesions that can be recognized in the fetus or the newborn. Many congenital cervical lesions may be diagnosed prenatally, making it essential for pediatric radiologists to be familiar with their general patterns on fetal imaging. Presence of mass lesions in the fetal/neonatal neck may considerably influence other organs and systems because of the complex anatomy of the neck and the proximity of the lesion to vascular, upper gastrointestinal, and especially airway structures.

defects underlying vascular anomalies have been discovered. Despite the recent revisions, this classification should not be perceived as a final arrangement. A better understanding of the molecular biology and genetics of vascular anomalies may lead to further refinement of the existing classification system.

## VASCULAR TUMORS

Hemangioma is the most common vascular tumor of infancy. It is a true endothelial tumor with increased mitotic activity during the proliferative phase and eventual involution. Two major types are recognized: (1) congenital (rare) and (2) infantile (common). The previously used categorization of hemangioma types as capillary, juvenile, or cavernous is no longer accepted. All types of hemangiomas have overlapping clinical, imaging, and histopathologic features.

### Infantile Hemangioma

Infantile hemangiomas are benign vascular neoplasms with an increased incidence in premature children with low birth weight. These lesions have a predictable clinical course of growth and involution which progresses through several stages. The nascent phase, with a subtle precursor lesion (macula, multiple telangiectasias, or discoloration), may be observed in the first 2 to 4 weeks of life or may be present at birth. The proliferative phase is remarkable for rapid tumor growth in the first year of life. In the proliferative stage, the hemangioma appears as a bulky, compressible lesion of strawberry-red color and may have cutaneous as well as deep components. On cross-sectional imaging, it appears as a lobulated mass with intense uniform enhancement, usually with presence of intralesional flow voids on MRI (Fig. 14.2). Proliferation may be biphasic. Careful assessment of upper airway status is important because the deep portions of a cervical hemangioma may enlarge at this stage sufficiently to impinge on the airway and cause obstruction. The final involution phase may continue for up to 12 years, as the rate of regression is variable. Involution is never complete as there is residual fibro-fatty tissue, although the residual lesion may not be grossly visible. Infantile hemangiomas are positive for the glucose transporter 1 (GLUT-1) marker at all stages of lesion development. Most infantile hemangiomas do not cause any morbidity or mortality but may create cosmetic inconvenience. On the other hand, a hemangioma of the neck is considered an alarming lesion if it assumes a beard distribution (involvement of the lower face, anterior neck, and submandibular and parotid regions) because of the high risk of airway compromise and an increased incidence of subglottic hemangioma. In addition, cervical and facial infantile hemangiomas have a known association with PHACES syndrome (***P***osterior fossa malformations, ***H***emangiomas, ***A***rterial, ***C***ardiac anomalies, ***E***ye anomalies, ***S***ternal cleft). The arterial anomalies often seen in PHACES syndrome represent a spectrum of congenital arterial lesions ipsilateral to the cutaneous hemangioma. This necessitates careful searching (and monitoring) with imaging for potential vascular abnormalities once a diagnosis of segmental hemangioma is established. Infantile hemangiomas involving the upper airway (Fig. 14.3) become symptomatic in the proliferative phase, causing biphasic stridor, respiratory distress, and potentially life-threatening airway obstruction, which may require emergent intubation. These hemangiomas are often multifocal and occur above and below the vocal cords. Close monitoring with cross-sectional imaging is indicated because laryngoscopy may not accurately depict the degree of invasion. MRI is preferred in the setting of intubation or tracheostomy. In rare cases, mostly in the setting of underlying PHACES syndrome, segmental infantile hemangioma may be associated with central nervous system hemangiomas in intracranial (e-Fig. 14.4) or intraspinal locations. In the past, infantile hemangiomas have been confused with other vascular neoplasms, particularly kaposiform hemangioendothelioma (KHE) and tufted angioma, especially in the setting of consumptive coagulopathy (Kasabach-Merritt phenomenon). It is now generally accepted that infantile hemangiomas are rarely, if ever, responsible for this phenomenon.

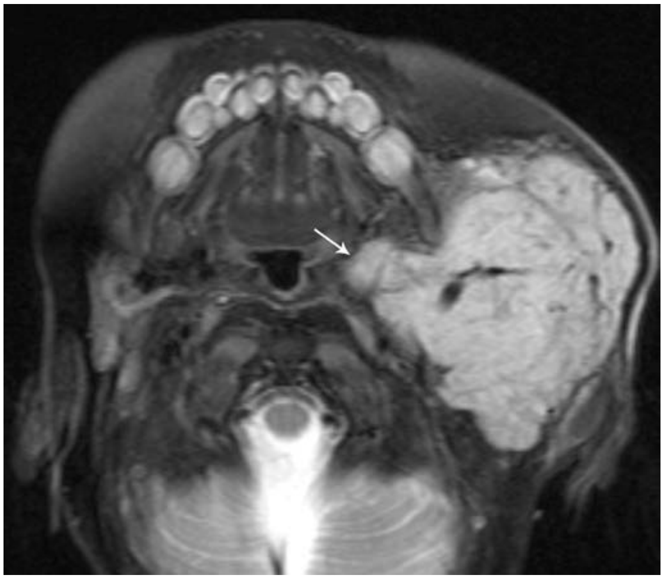

**Figure 14.2. Parotid infantile hemangioma.** Axial T2-weighted fat-saturated MR image shows a well-circumscribed lobular soft tissue mass in the left parotid with intrinsic flow voids and deep extension into the ipsilateral parapharyngeal space *(small arrow)*. The upper airway remains patent.

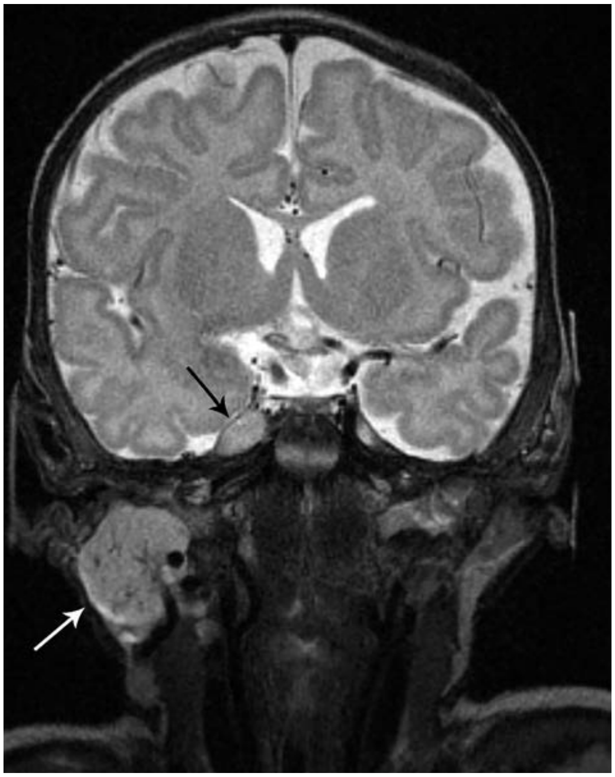
### Congenital Hemangioma

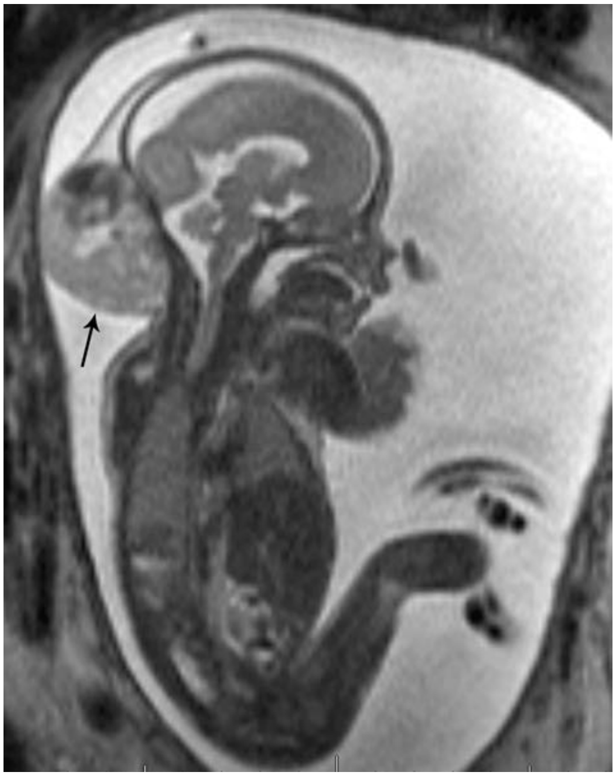
Congenital hemangiomas are uncommon lesions that are fully developed at birth and do not undergo a proliferative stage in postnatal life. These lesions may be diagnosed in utero as early as 12 weeks of gestational age. Two types of congenital hemangiomas are described: (1) rapidly involuting congenital hemangioma (RICH) and (2) noninvoluting congenital hemangioma (NICH). A partially involuting type (PICH) has also been described. RICH has a predilection for scalp and neck locations. On prenatal imaging, it appears as a large heterogeneous mass, emanating from the posterior neck (e-Fig. 14.5) with increased vascularity, best demonstrated on obstetric Doppler US and MR gradient echo planar imaging. Postnatal imaging features of RICH include large irregular flow voids and arterial aneurysms, direct arteriovenous shunts (seen on angiography), and calcifications. Their imaging appearance may occasionally resemble congenital infantile fibrosarcoma. Large RICH lesions may have a dramatic presentation at birth with high-output congestive heart failure (Fig. 14.6). Rapid involution is usually completed by 14 months of age. Usually, RICH is managed conservatively, although complications may prompt surgical excision. NICH, on the contrary, never involutes and may even grow with the child. It usually has an imaging appearance similar to infantile hemangioma, being more homogeneous with uniform parenchymal enhancement.

### Hemangioma Treatment

Most hemangiomas resolve spontaneously, however, approximately 10% to 20% require treatment, which includes pharmacologic, surgical, or laser intervention. Treatment is indicated in cases when functional or cosmetic complications arise that are worse than the side effects of intervention. Lesion size and location,



**e-Figure 14.4. Multifocal infantile hemangiomas with intracranial lesions.** Coronal fat-saturated T2-weighted MR image shows cervical *(white arrow)* and Meckel cave *(black arrow)* hemangiomas.



**e-Figure 14.5. Congenital hemangioma.** Sagittal fetal half-Fourier acquisition single-shot turbo (HASTE) MRI image shows a complex soft tissue mass in the posterior neck *(small arrow)* with internal hypointensity, indicative of blood products.

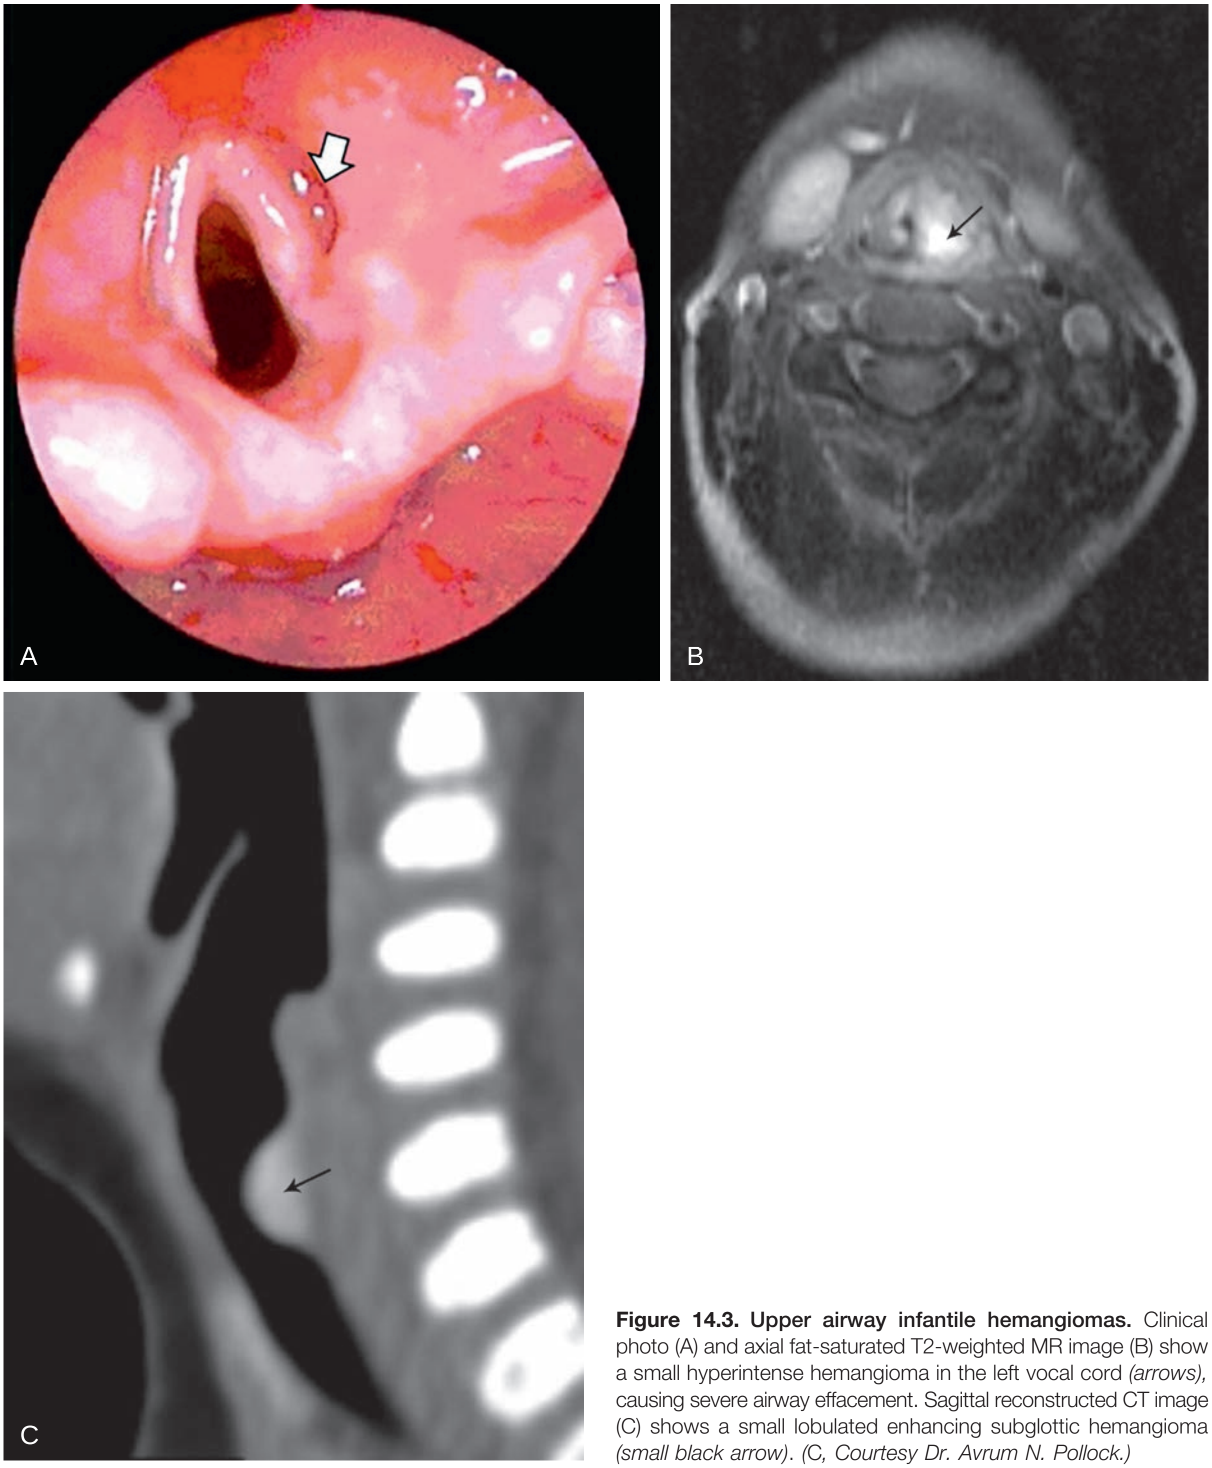


**Figure 14.3. Upper airway infantile hemangiomas.** Clinical photo (A) and axial fat-saturated T2-weighted MR image (B) show a small hyperintense hemangioma in the left vocal cord *(arrows),* causing severe airway effacement. Sagittal reconstructed CT image (C) shows a small lobulated enhancing subglottic hemangioma *(small black arrow)*. *(C, Courtesy Dr. Avrum N. Pollock.)*

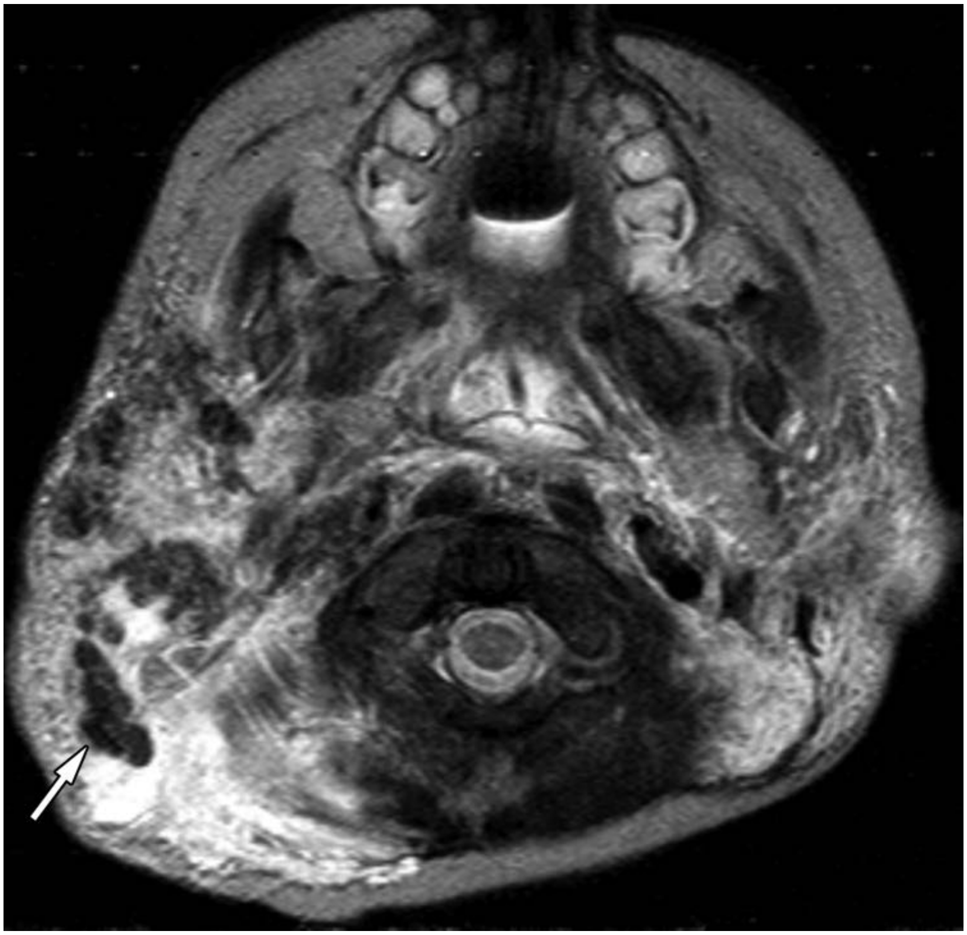
patient age, and phase of the lesion (proliferative, involuting, and mature) also influence the method and timing of intervention.

## Kaposiform Hemangioendothelioma and Tufted Angioma

KHE and tufted angioma (TA) are very rare vascular tumors of infancy and early childhood, respectively. KHE and TA may represent parts of the same neoplastic spectrum. Both tumors differ from hemangioma by histopathologic and clinical appearance. KHE is classified as a locally aggressive tumor of intermediate malignancy and presents as an ill-defined vascular mass with stranding in the subcutaneous fat, intralesional calcifications, and prominent feeding and draining vessels (e-Fig. 14.7). It tends to cause bony destruction. The head and neck are uncommon locations. Tufted angioma has benign growth potential and is typically located on the upper back and neck. These vascular tumors may both manifest as Kasabach-Merritt phenomenon, a severe thrombocytopenia with mild to moderate coagulopathy resulting from intralesional platelet trapping. Awareness of these features should



**e-Figure 14.7. Kaposiform hemangioendothelioma.** Axial fat-saturated T2-weighted MR image shows an ill-defined vascular mass with stranding in the subcutaneous fat and intralesional calcifications *(arrow)*.

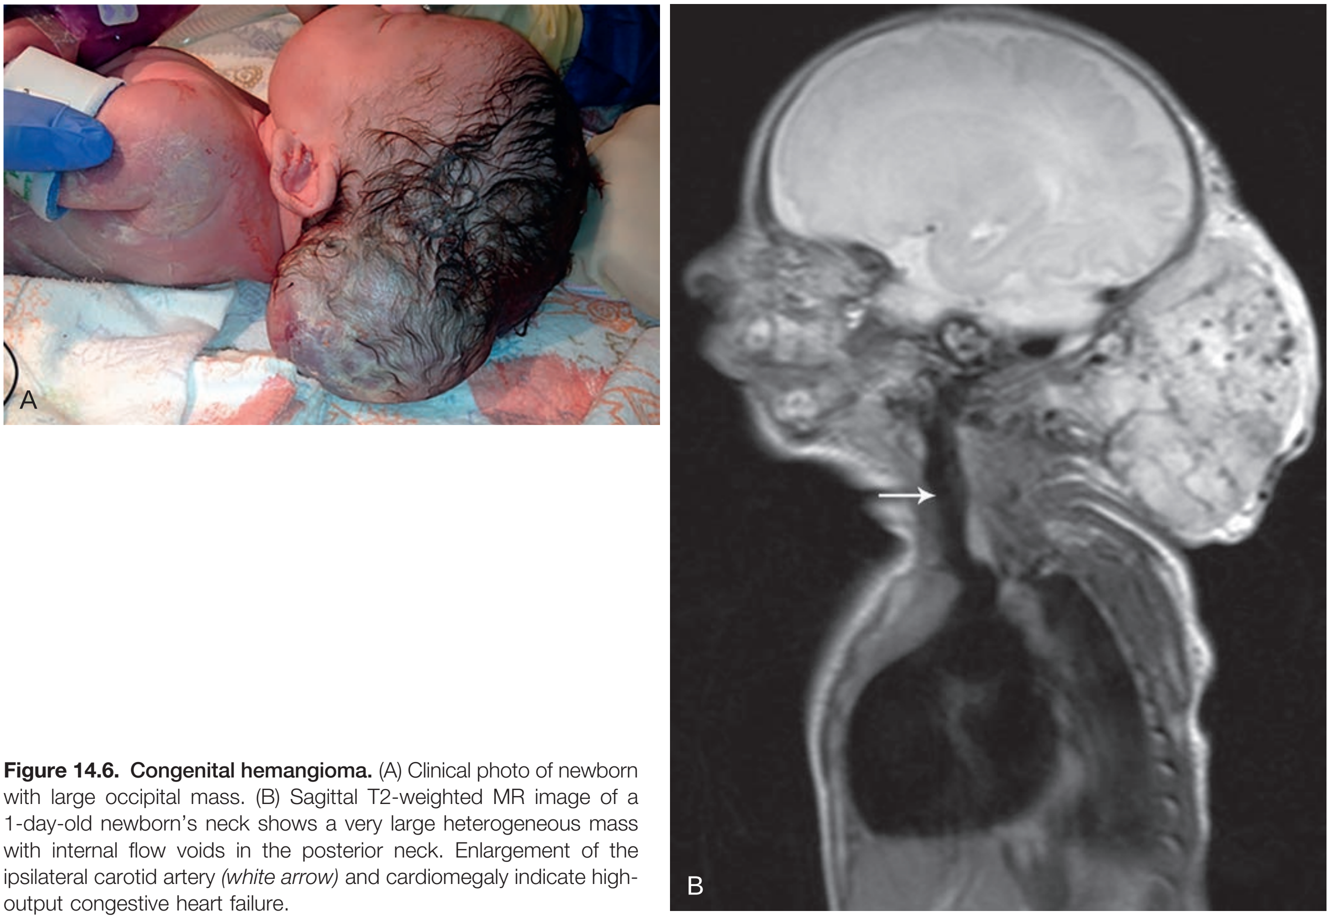


**Figure 14.6. Congenital hemangioma.** (A) Clinical photo of newborn with large occipital mass. (B) Sagittal T2-weighted MR image of a 1-day-old newborn's neck shows a very large heterogeneous mass with internal flow voids in the posterior neck. Enlargement of the ipsilateral carotid artery *(white arrow)* and cardiomegaly indicate high-output congestive heart failure.

prompt radiologists to include KHE/TA in the differential diagnosis for pediatric vascular masses. KHE/TA are GLUT-1 negative, which can be used to distinguish them from infantile hemangioma if the histologic diagnosis is uncertain.

## SPECTRUM OF VASCULAR MALFORMATIONS

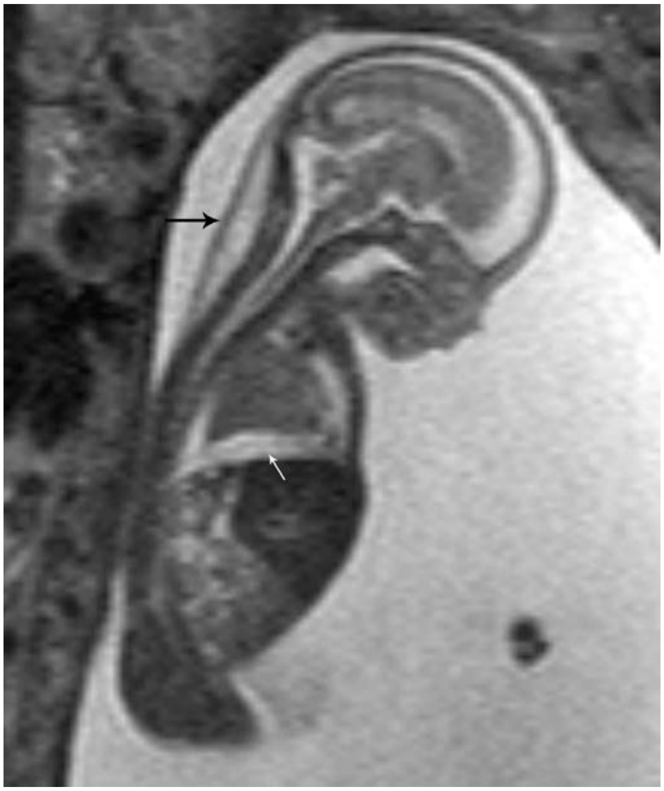
Vascular malformations are congenital nonneoplastic lesions further classified according to the type of abnormal vessel comprising the lesion. Additionally, vascular lesions are classified on the basis of their hemodynamics as high-flow and low-flow types. Low-flow lesions consist of any combination of capillary, venous, and lymphatic components, whereas high-flow lesions contain arterial components. Cervical venolymphatic malformations, similar to those located elsewhere in the body, represent a spectrum of entities consisting of a combination of anomalous lymphatic and venous channels. When the lymphatic vascular component is prevalent, lesions are called lymphatic malformations, whereas those with dominant venous components are called venous malformations. The venolymphatic lesions may be further divided into macrocystic and microcystic based on the size of the lesions' cystic components. Four histologic types are identified, but they differ only on the basis of lymphatic channel size and are otherwise pathologically identical.

Vascular malformations grow in proportion to the patient's growth but may exhibit rapid growth or expansion after infection, trauma, or hormonal changes such as during puberty or pregnancy. Vascular malformations do not involute spontaneously.

*Venolymphatic malformations* of the neck may be diagnosed prenatally or may present in the perinatal period. The most pure lymphatic malformation, which seemingly consists of lymphatic channels only, is represented by a fetal nuchal cystic hygroma. A focal nuchal translucency, perceived as a hypoechoic subcutaneous region in the posterior neck, may be identified on obstetric US at 11 to 14 weeks' gestational age; it is considered a normal finding if it measures below a defined threshold and eventually involutes by term.

A pathologic nuchal cystic hygroma develops in cases of failure of appropriate connections between the lymphatic jugular sac and jugular vein. This lesion becomes apparent as a nuchal thickening at 18 to 20 weeks' gestational age. Approximately 60% of nuchal cystic hygromas are associated with some type of chromosome abnormalities (Turner syndrome, trisomy 18 and 21), and multiple other syndromes. Abnormal accumulation of lymph may cause lymphedema and nonimmune hydrops, a condition with a high mortality rate. Cystic hygroma appears on US as translucent nuchal thickening with no identifiable arterial or venous flow by Doppler. MRI reveals focal edema of the posterior fetal neck and, in severe cases, may reveal associated lymphedema, pleural effusions, ascites, and anasarca (e-Fig. 14.8).

*Lymphatic/venolymphatic malformations* of the fetal/neonatal neck may be discovered prenatally, may be seen at birth, or may "silently" grow with a child in the first few years before suddenly becoming symptomatic after spontaneous hemorrhage or infection. These lesions usually present as large, transpatial, multicystic masses with intervening septae and fluid–fluid levels (Fig. 14.9), although a small venolymphatic malformation may occasionally be seen as a unilocular cyst. US demonstrates septated hypoechoic cystic lesions without internal vascularity, although some vascular flow may be seen within the intralesional septae. Lymphatic malformations may have a very complex appearance because of their multicompartmental nature and internal hemorrhages



**e-Figure 14.8. Fetal nuchal cystic hygroma.** Sagittal fetal half-Fourier acquisition single-shot turbo (HASTE) MR image of a 19-week-old fetus shows a unilocular cystic mass within the posterior fetal neck *(black arrow)* and moderate pleural effusion *(white arrow),* compressing the lung.

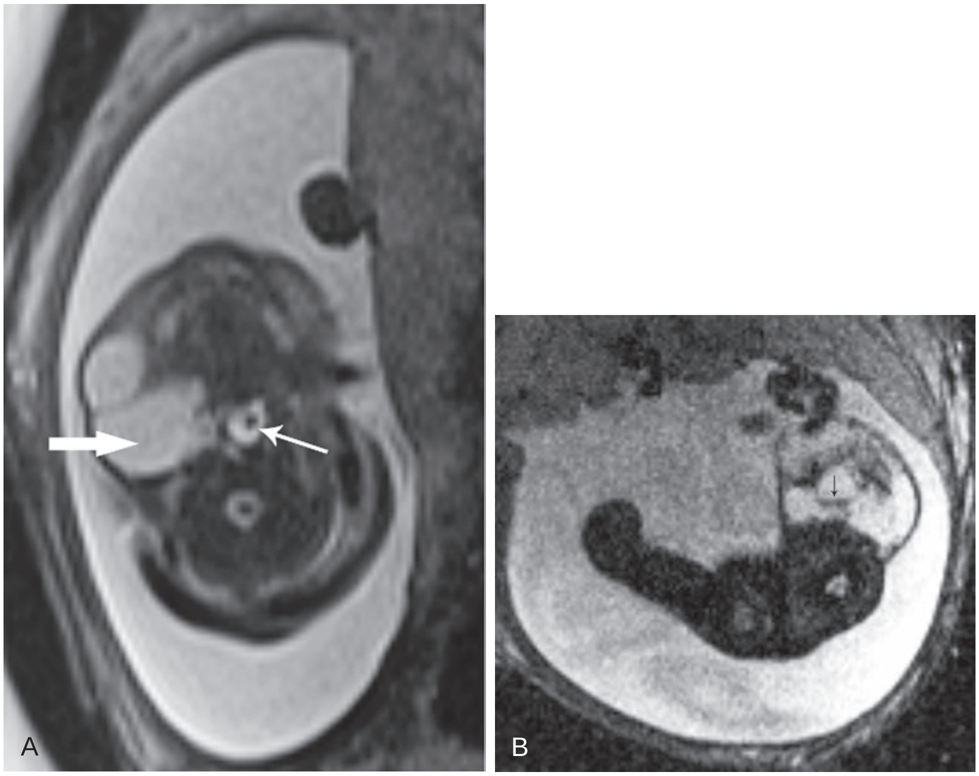


**Figure 14.9. Venolymphatic malformations.** (A) Axial half-Fourier acquisition single-shot turbo spin echo (HASTE) fetal MR image shows a multicystic mass of the lateral neck *(large arrow)*. The fetal airway remains patent *(small white arrow)*. (B) Fetal gradient echo planar MR image shows a blood-fluid level *(arrow)* within the cystic neck mass.

(Fig. 14.10). Relatively thick intralesional septations (e-Fig. 14.11) or foci of chronic hemorrhage may show enhancement and mimic solid portions of a cystic teratoma. Absence of calcifications and relatively mild mass effect onto surrounding structures despite the large size of the lesion are characteristic features. Absence or presence of calcifications is easier to establish on fetal US; blood products and calcifications may be occasionally confused on fetal MRI. The current approach to treatment of venolymphatic malformations is interventional sclerotherapy with doxycycline or other sclerosants, which provides excellent results for large macrocystic head and neck lesions. Therapy for microcystic and mixed lesions continues to be a challenge.

## VENOUS VASCULAR MALFORMATIONS

Venous malformations represent slow-growing lesions that consist of dysplastic venous channels that may have a minor lymphatic component. They are present at birth but usually manifest clinically later in life. On imaging, they appear as well-defined, ovoid, heterogeneous lesions with strong enhancement and occasional intralesional phleboliths (Figs. 14.12A and B). A calcified phlebolith may occasionally simulate a flow void on MRI, leading to an erroneous identification of the lesion as a hemangioma. Many lesions may be successfully treated with sclerotherapy, although larger and infiltrative lesions may be more challenging to treat.

## SYSTEMIC LYMPHATIC MALFORMATIONS

Systemic lymphatic malformations include rare conditions known as lymphangiomatosis and Gorham-Stout disease (vanishing bone disease). These entities are poorly understood and likely represent a spectrum of congenital disorders of lymphatic development.

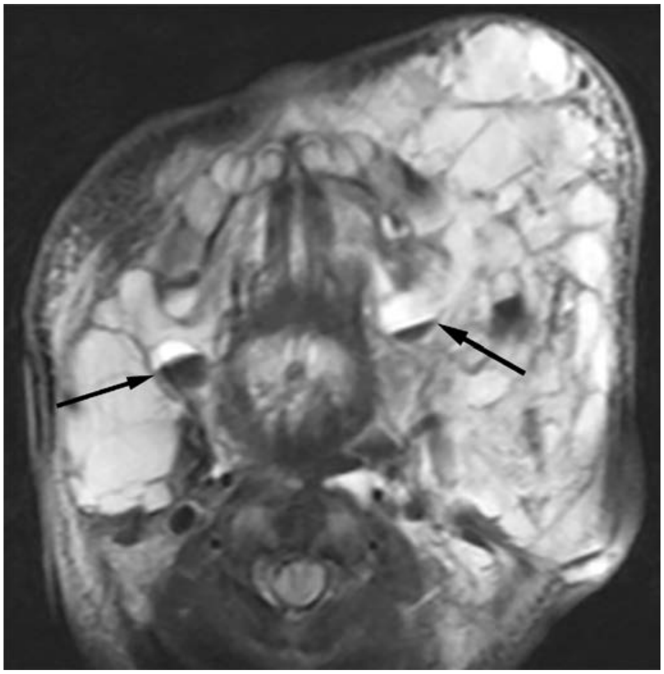

**Figure 14.10. Venolymphatic malformation.** Axial fat-saturated T2-weighted MR image in a neonate demonstrates numerous blood-fluid levels *(arrows)* within the multicompartmental neck mass.

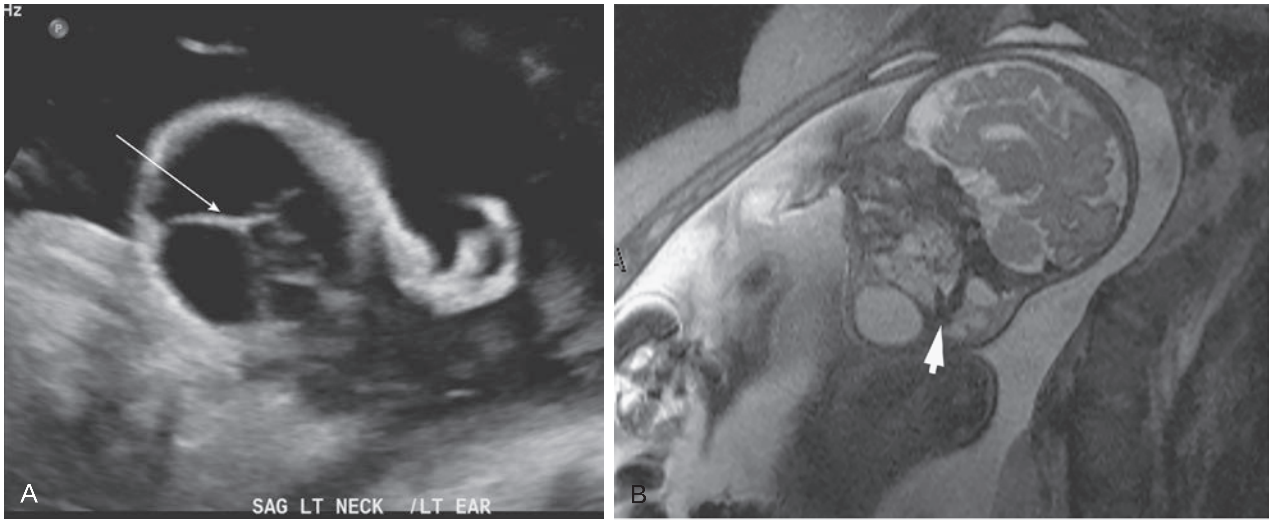

**e-Figure 14.11. Venolymphatic malformation.** (A) Fetal sonogram and (B) fetal MRI half-Fourier acquisition single-shot turbo (HASTE) imaging demonstrates multicystic lesions with thick septations *(arrows)*.

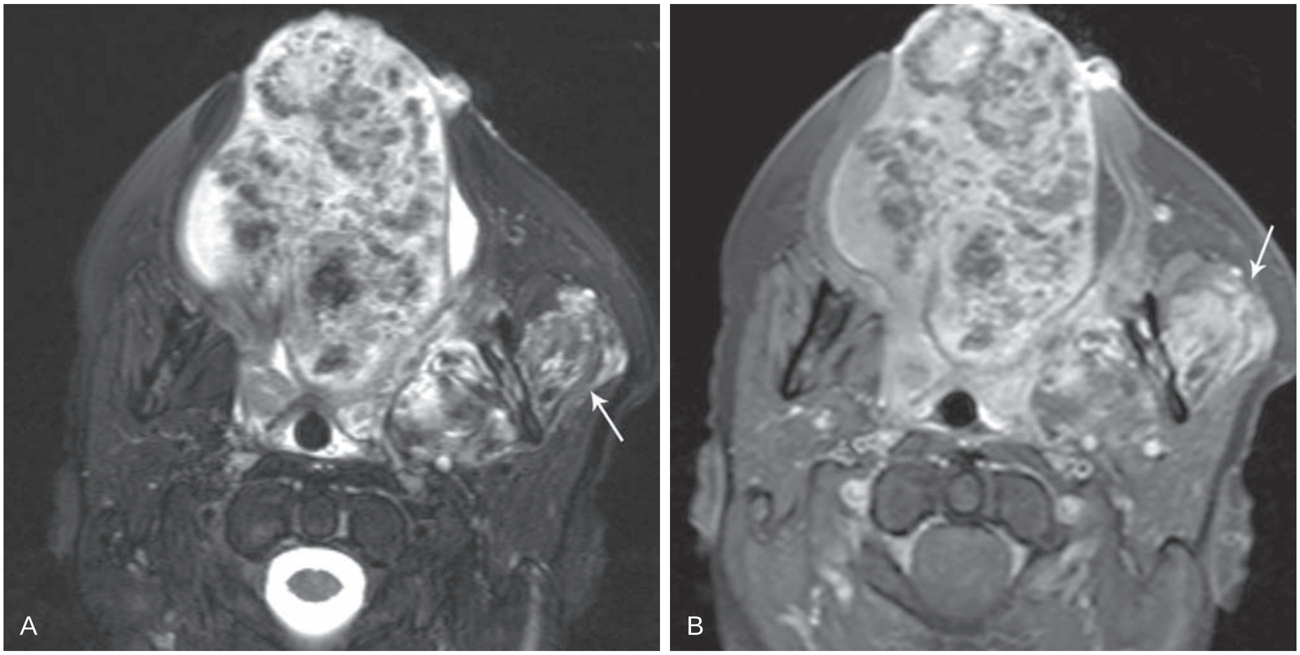

**Figure 14.12. Venous malformation.** (A) Axial fat-saturated T2-weighted and (B) axial fat-saturated postcontrast MR images show an ovoid heterogeneous enhancing lesion with numerous hypointense phleboliths, almost replacing the tongue. Superficial component is indicated by the *arrow*.

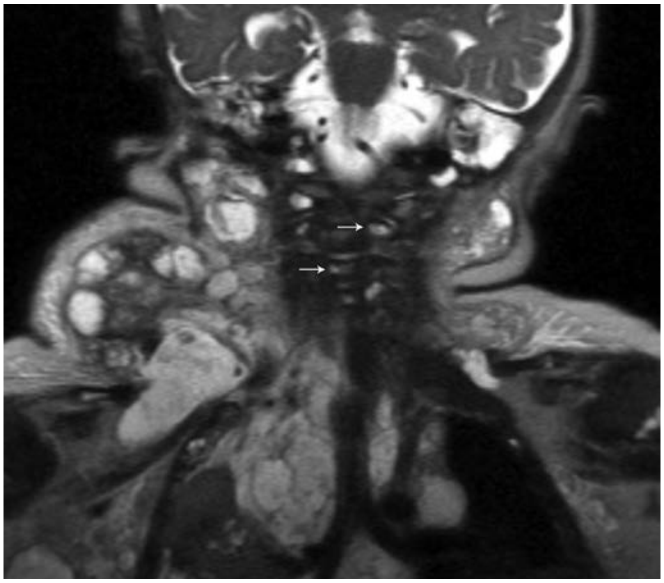

**Figure 14.13. Lymphangiomatosis.** Coronal short TI inversion recovery (STIR) MR image shows a large complex cystic mass in the lateral neck, extending into the thorax, and numerous small cysts *(small white arrows)* involving the vertebra.

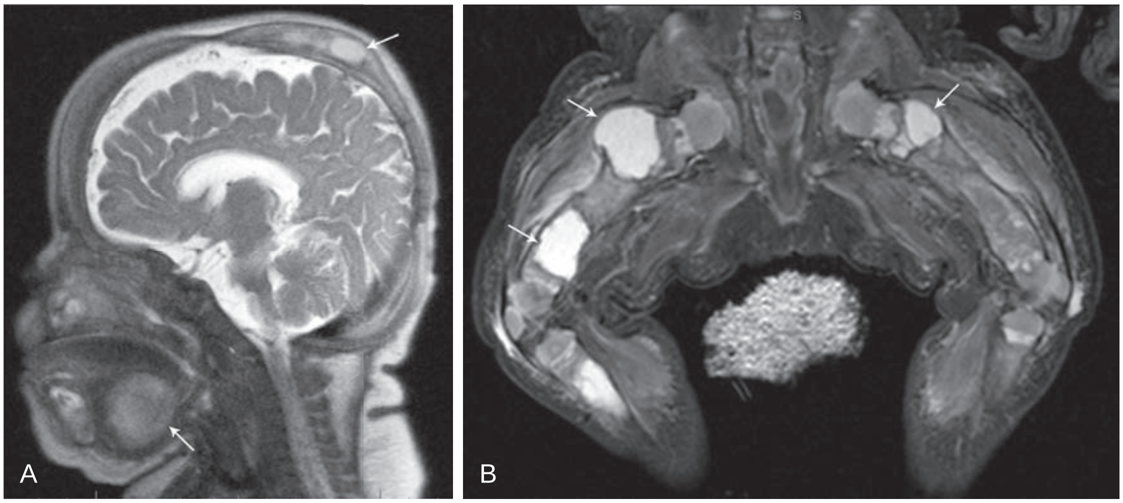
They manifest with numerous foci of vascular and lymphatic proliferation, involving multiple organs, including bones and lungs (Fig. 14.13 and e-Fig. 14.14A and B), and often cause serious consequences. Osseous involvement of the face and neck may be observed in both entities; however, spontaneous, progressive osteolysis appears more diffuse and is reported to be more symptomatic in cases of Gorham disease.

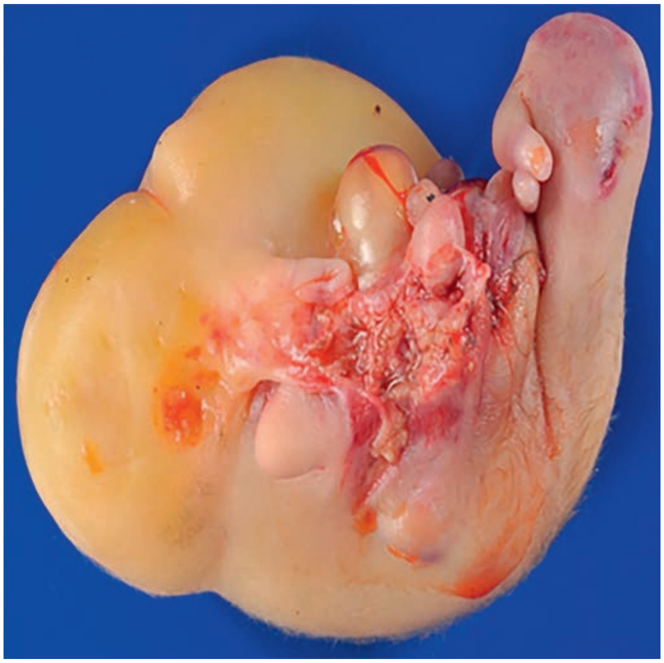
Kaposiform lymphangiomatosis is a rare, aggressive, recently described lymphatic disorder with overlapping imaging features with other lymphatic anomalies. Presence of hemorrhagic effusions and moderate thrombocytopenia (50–100,000/µl) favor this diagnosis.

## TERATOMA

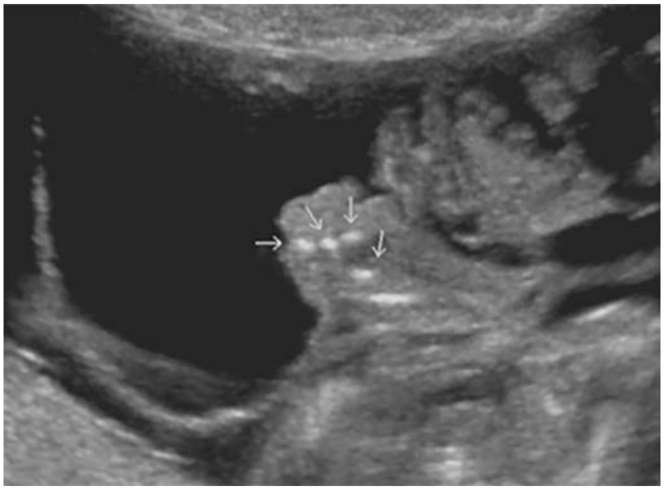
Teratoma of the neck accounts for only 5% to 10% of all fetal and neonatal teratomas. Most cervical teratomas are benign, yet it is the most common fetal neck mass with potential to cause fetal demise secondary to airway obstruction. On rare occasions, large vascular teratomas may result in nonimmune fetal hydrops and subsequent fetal death. Teratomas usually originate in the anterolateral neck and may involve the face and cranial base, sometimes extending to the thorax. Interval lesion enlargement in late gestation often causes hyperextension of the neck, which is characteristic of cervical teratoma. The lesion may be intimately associated with the thyroid gland and, in addition to tracheal compression, may cause esophageal compression. Teratomas are composed of all three germ layers with tissue differentiation that infrequently results in the presence of identifiable organs or fetal parts (e-Fig. 14.15). Oropharyngeal teratomas may grow rapidly during gestation. Teratomas are subdivided into mature, immature, and malignant types, each of which differs by histology and hence imaging appearance. Benign mature lesions are mostly cystic, whereas immature lesions tend to be more solid. Malignant teratomas are uncommonly found in the neck and are less aggressive compared with other locations. Most teratomas demonstrate a combination of cystic and solid components (Fig. 14.16). Intratumoral foci of hemorrhage and necrosis are suggestive of malignancy (Fig. 14.17A). Intralesional fat (Fig. 14.17B) and calcifications are nearly pathognomonic findings for teratoma but may not always be discernible on fetal MRI and are better seen on US (e-Fig. 14.18). Cervical teratoma and congenital hemangioma share many MRI and US features, including interval growth in utero. The diagnosis may be quite challenging and both imaging modalities are often necessary for optimal assessment. Postnatal assessment of teratoma may include CT, which is readily available and may demonstrate intralesional fat, calcifications and osseous



**e-Figure 14.14. Gorham-Stout disease.** (A) Sagittal STIR MR image through the head and (B) coronal STIR MR image through the lower extremities show numerous intraosseous and submandibular neck cystic lymphatic malformations.



**e-Figure 14.15. Oropharyngeal teratoma.** Clinical photo of pathology specimen shows a fat-containing mass with the inclusion of bony structures and fingers.



**e-Figure 14.18. Cervical teratoma.** Fetal sonogram shows punctate calcifications within a cervical mass, a typical feature of teratomas.

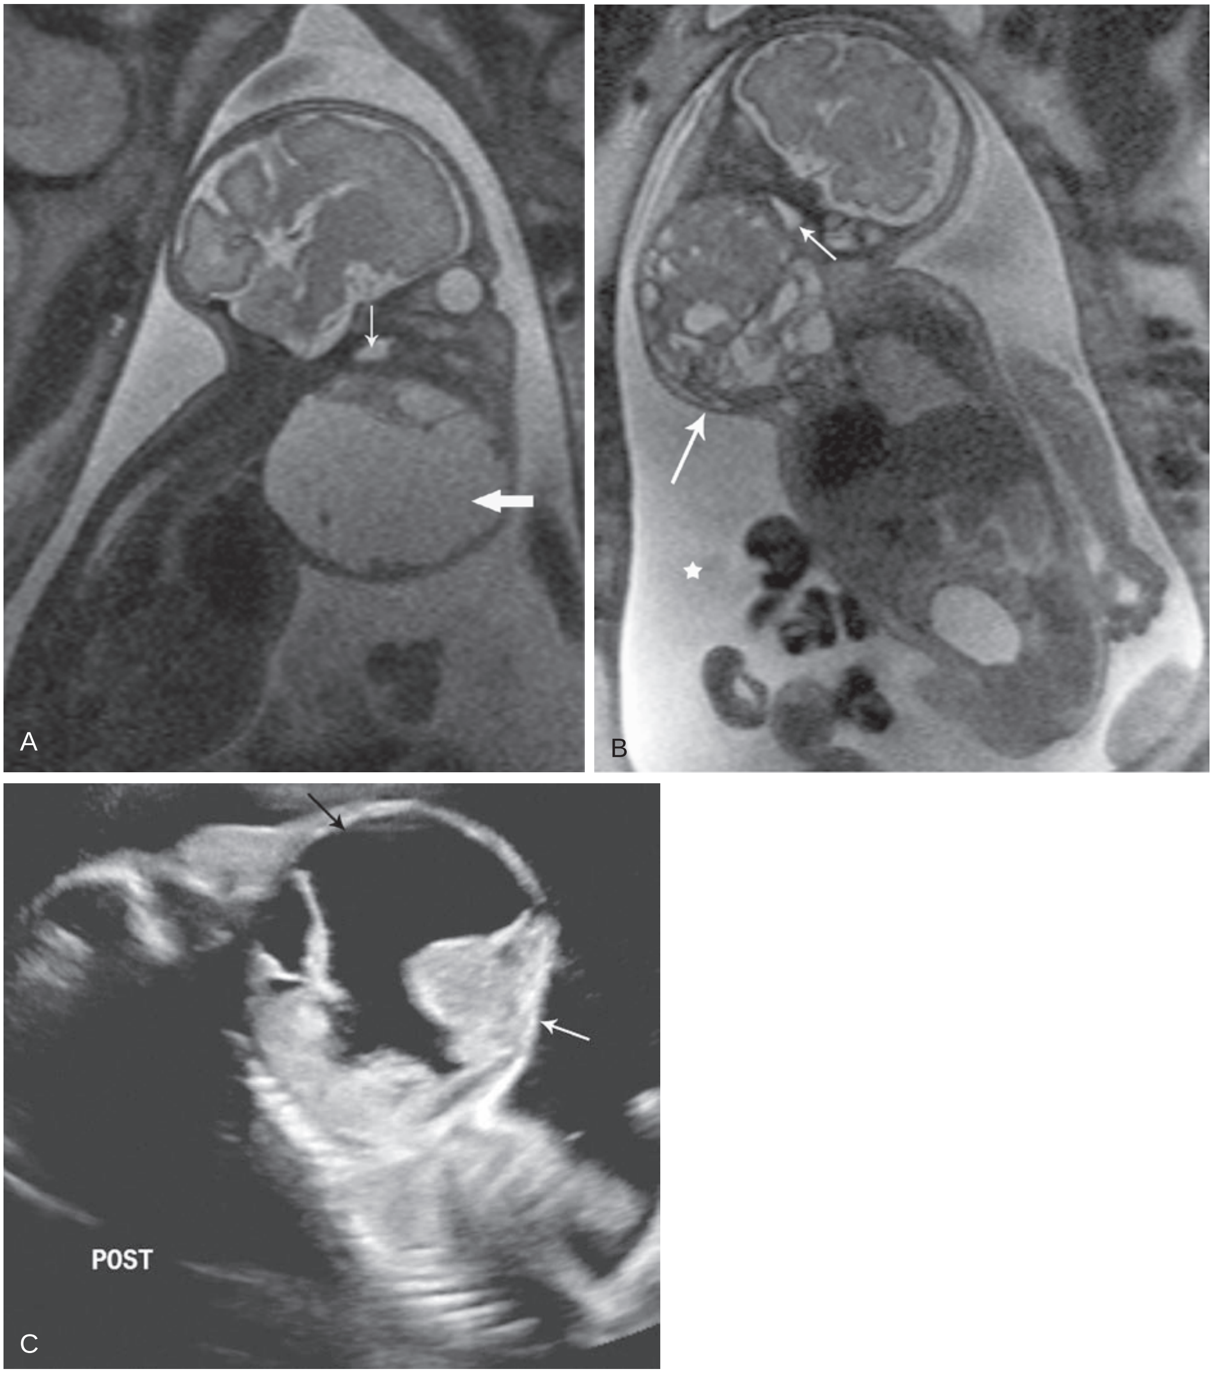


**Figure 14.16. Fetal neck teratomas.** (A) Sagittal fetal half-Fourier acquisition single-shot turbo (HASTE) MR image shows a predominantly cystic teratoma *(large arrow)* with a small solid component in the anterolateral neck. Upper airways are distended, but motion of soft palate *(small arrow)* is preserved. (B) Fetal HASTE MR image shows a mixed, predominantly solid teratoma *(large arrow)* in the anterolateral neck, which severely narrows the fetal nasopharynx *(small arrow)*. (C) Fetal ultrasound shows a mixed teratoma in the fetal neck with cystic *(black arrow)* and solid *(white arrow)* components.

involvement. MRI is, however, superb for precise depiction of lesion morphology and extension. Magnetic resonance angiography may provide crucial information about the vascular supply for surgical planning.

Surgical treatment of teratomas may be curative, although the mortality rate remains high. Persistent disfiguration of facial structure, voice issues, and hypothyroidism are among the common complications.

## CERVICAL CYSTIC MASSES

A variety of unilocular cystic neck lesions may be diagnosed on prenatal imaging or may present in neonates. These lesions are uncommon; they originate from different embryonic structures, and their precise diagnosis may be challenging, especially in fetuses. Perinatal cystic neck lesions include dermoid and epidermoid cysts, laryngoceles, foregut duplication cysts, and thymic cysts.

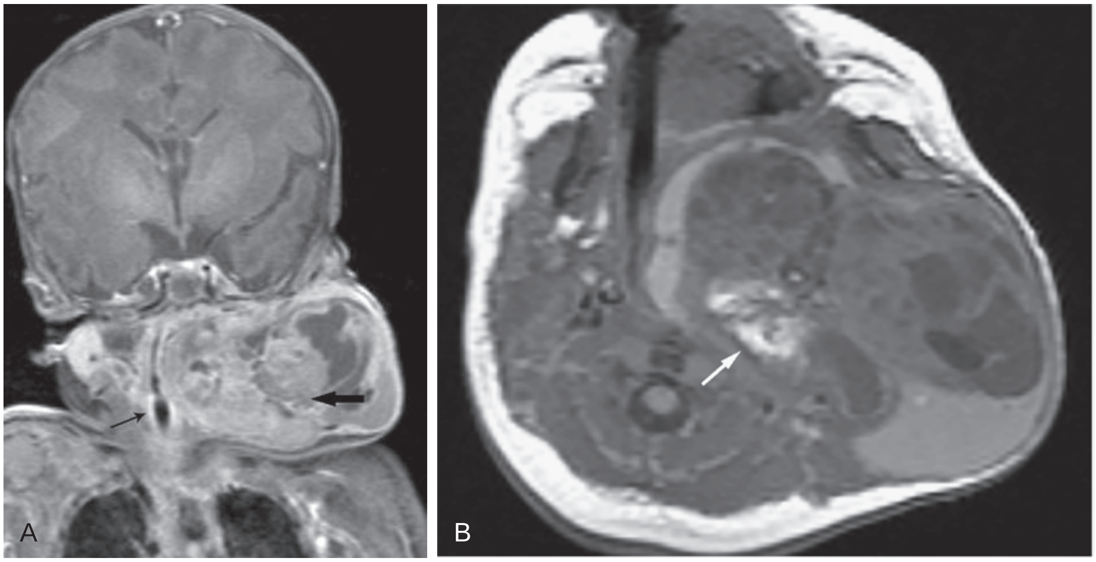

**Figure 14.17. Neonatal malignant teratoma.** (A) Coronal fat-saturated postcontrast MR image shows a large heterogeneous neck mass *(large arrow)* with necrotic areas, which severely narrows and displaces the upper airway *(small arrow)*. (B) Axial T1-weighted MR image shows a large mass of the neck that contains internal fat *(arrow),* a typical feature of teratomas.

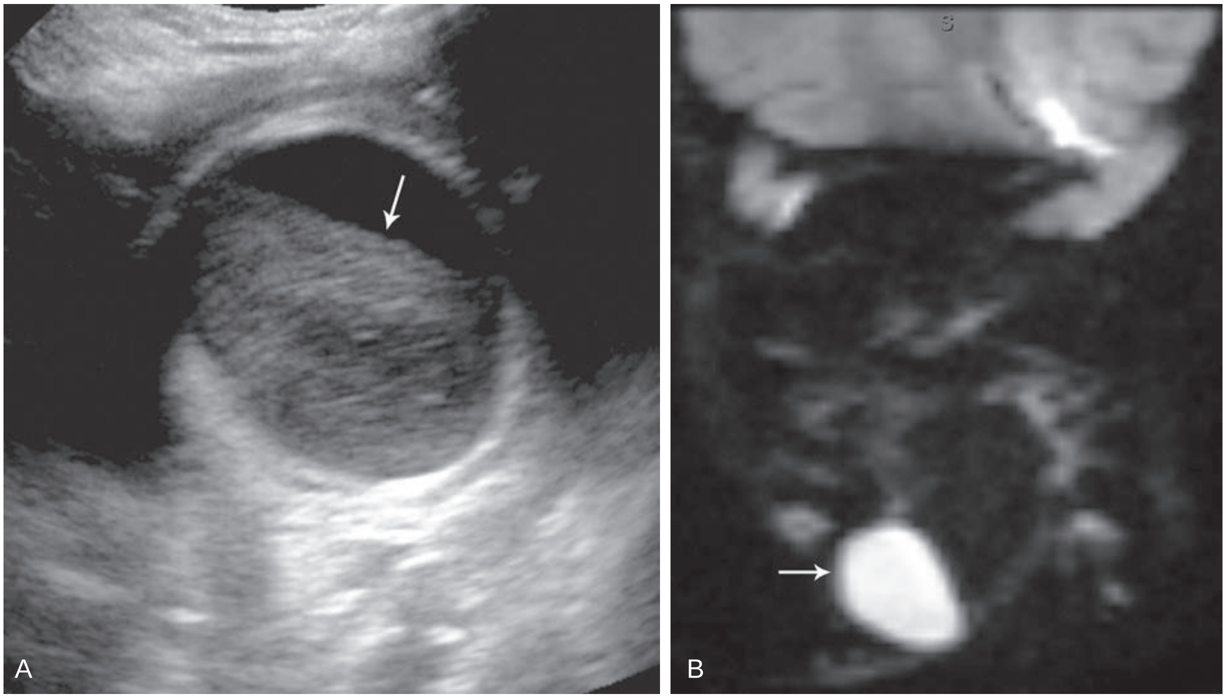

**Figure 14.19. Cervical epidermoid.** (A) Sonogram shows a submandibular unilocular cystic structure, with *arrow* pointing to layering hyperechoic cyst contents. (B) Diffusion-weighted MR image of the cystic submandibular mass, with *arrow* pointing to the restricted diffusion within the lesion.

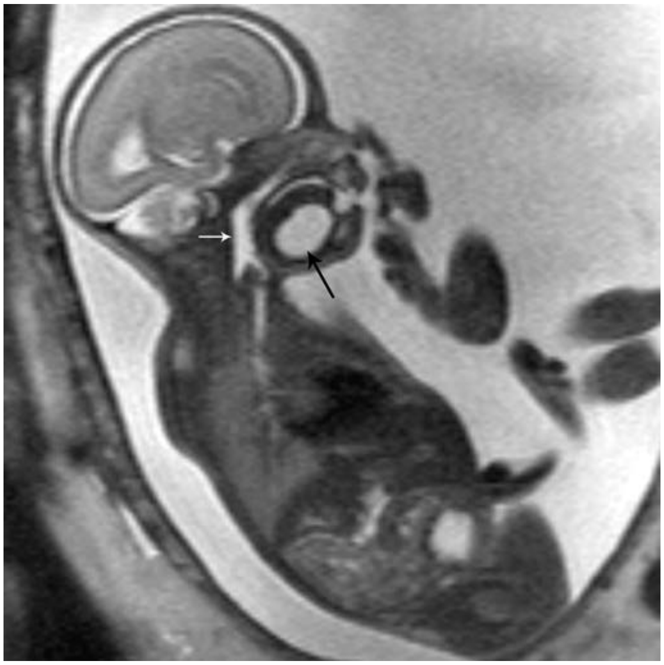
## Dermoid/Epidermoid Cysts

Dermoid cysts are benign congenital lesions that contain ectodermal elements, including hair follicles and sweat and sebaceous glands. Cervical dermoids are most commonly seen in the floor of the mouth, in the submandibular or sublingual spaces, or at the suprasternal notch. They often demonstrate fatty content with imaging. Epidermoid cysts are rare congenital unilocular lesions, which may closely resemble a thyroglossal duct cyst; however, a characteristic pattern of restricted diffusion typical for epidermoids helps distinguish these entities. Compared with dermoid cysts, epidermoid cysts appear earlier, with most lesions being evident during infancy (Fig. 14.19) or diagnosed prenatally (e-Fig. 14.20). Dermoids and epidermoids have different histology, but it is not always possible to differentiate them on imaging. It is more important to define the lesion position in relation to the oral floor muscles, as it may guide a surgical approach.



**e-Figure 14.20. Cervical epidermoid.** Fetal sagittal MRI shows unilocular submandibular epidermoid *(black arrow)*. The airways are patent; the hypopharynx is distended *(white arrow)*.

## Laryngocele

Most laryngoceles are acquired lesions, seen in middle-aged persons involved in activities that cause increased supraglottic pressure. Congenital laryngoceles are rare and likely reflect congenital enlargement of the laryngeal saccule. The three types of laryngoceles are internal, external, and combined laryngoceles. The internal laryngocele is found entirely within the larynx, whereas the external or mixed types protrude through the thyrohyoid membrane and may extend into the lateral neck. Clinically, laryngoceles may manifest as fluctuating soft tissue masses causing airway obstruction in young infants, or the masses may be diagnosed prenatally (e-Fig. 14.21). Evaluation of a laryngocele with high-resolution cross-sectional imaging depicts the anatomic boundaries of the lesion and the contents of the cyst, which may be filled with air, fluid, or proteinaceous material.

## Foregut Duplication Cyst

Foregut duplication cysts in the neck may be incidental findings; may present in the neonate with frank respiratory distress secondary to obstruction; or may be diagnosed prenatally as unilocular cystic mass in the anterior compartment of the fetal neck and mediastinum (e-Fig. 14.22). The cyst may or may not communicate with the esophagus; however, a thorough search for this communication should be performed. Detection of abnormal canalization of the gastrointestinal tract confirms the diagnosis of foregut duplication cyst. Preoperative imaging is recommended to differentiate these lesions from other congenital head and neck masses. Surgical excision with complete removal of the mucosal lining is curative.

## Thymic Cyst

Thymic cysts may rarely present within the neck, communicating with pharyngeal structures through the thyrohyoid membrane. Thymic cysts may be found in the midline or anterior to the sternocleidomastoid muscle (e-Figs. 14.23A and B), where they may resemble a branchial arch anomaly.

# CERVICAL SOFT TISSUE MASSES

## Ectopic Thymus

Ectopic thymus is usually discovered incidentally on neck imaging performed for unrelated indications. It may be seen anywhere along the course of the primordial thymopharyngeal duct, from the mandibular angle to the thoracic inlet. This lesion most often can be found along the carotid sheath but may extend to the midline (Fig. 14.24A) or may be bilateral. The imaging features are identical to orthotopic thymus (Fig. 14.24B). Ectopic thymus usually resolves with involution of the intrathoracic orthotopic thymus.

## Fetal/Neonatal Goiter

Goiter is a rare cause of fetal neck mass. It may occur in the setting of maternal thyroid disorders such as Graves disease or Hashimoto thyroiditis, or as a manifestation of primary fetal hypothyroidism/hyperthyroidism. Fetal thyroid function may be assessed by US-guided umbilical cord blood sampling (cordocentesis). The fetal thyroid may be markedly enlarged, causing

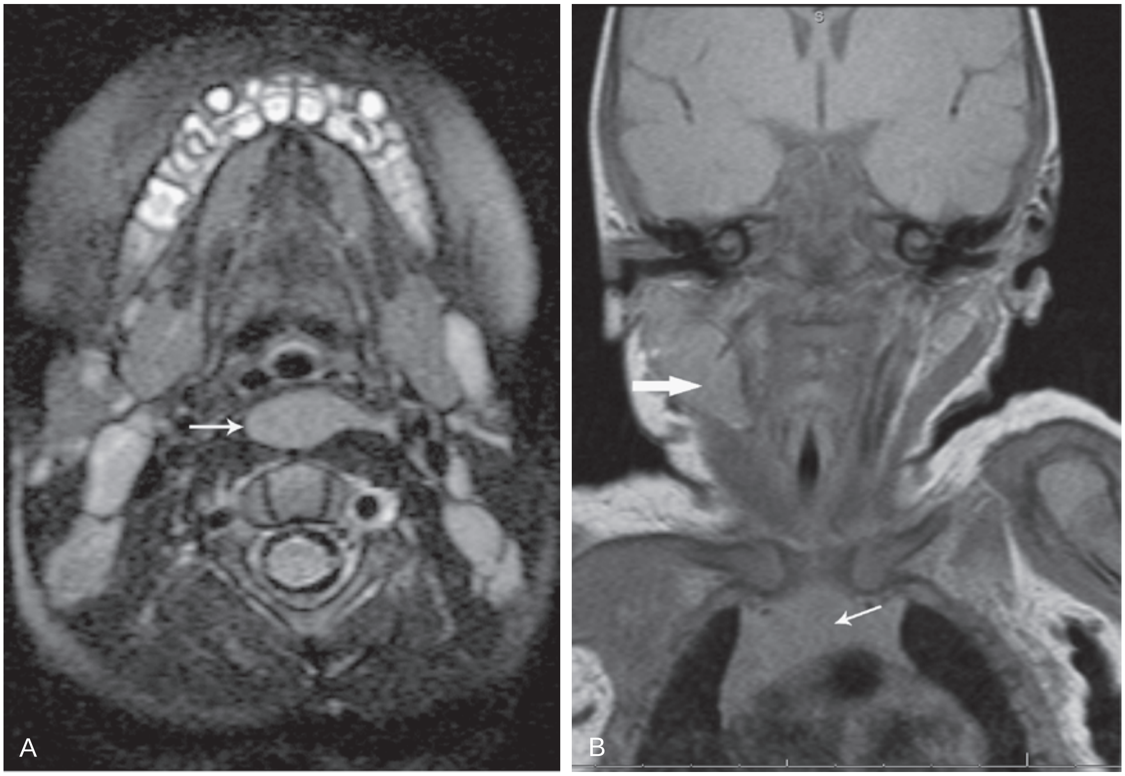


**Figure 14.24. Ectopic thymus.** (A) Axial T2-weighted MR image shows an unusual retropharyngeal location of ectopic thymus *(arrow)*. (B) Ectopic thymus *(large arrow)* in the right lateral neck of a 1-week-old infant has signal characteristics similar to the visualized orthotopic thymus *(small arrow)*. The lesion elicits no significant mass effect.

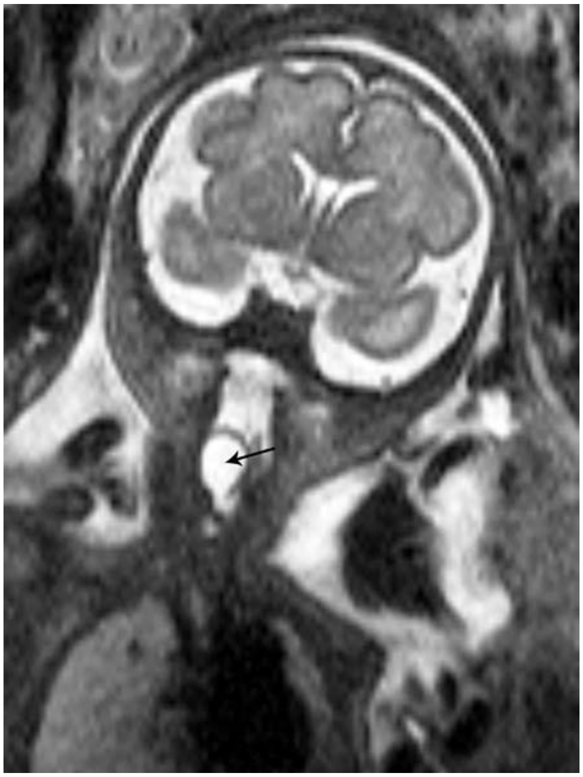
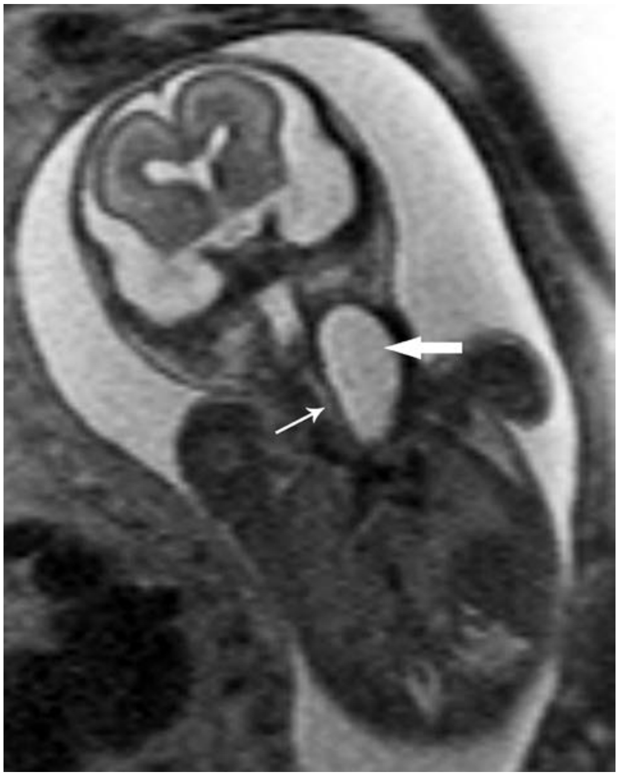
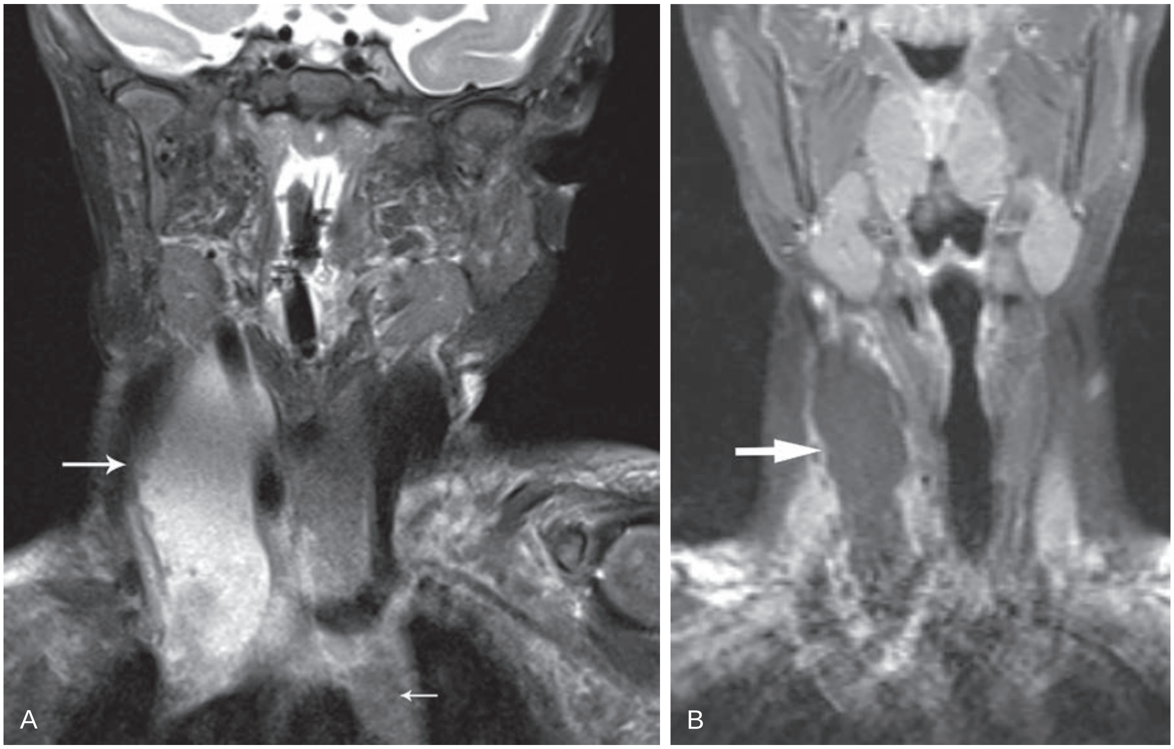


**e-Figure 14.21. Fetal laryngocele.** Coronal fetal half-Fourier acquisition single-shot turbo (HASTE) MR image shows a small cystic lesion *(arrow)* originating from the fetal larynx.



**e-Figure 14.22. Fetal esophageal duplication cyst.** Coronal fetal half-Fourier acquisition single-shot turbo MR image shows a large unilocular cystic structure in the fetal anterolateral neck *(large white arrow),* which continues into the superior mediastinum. The fetal airways appear patent *(small white arrow)*.



**e-Figure 14.23. Thymic cyst.** (A) Coronal STIR and (B) coronal fat-saturated contrast-enhanced MR images show an elongated cystic structure in the right neck, anterior to the sternocleidomastoid muscle *(arrows)*.

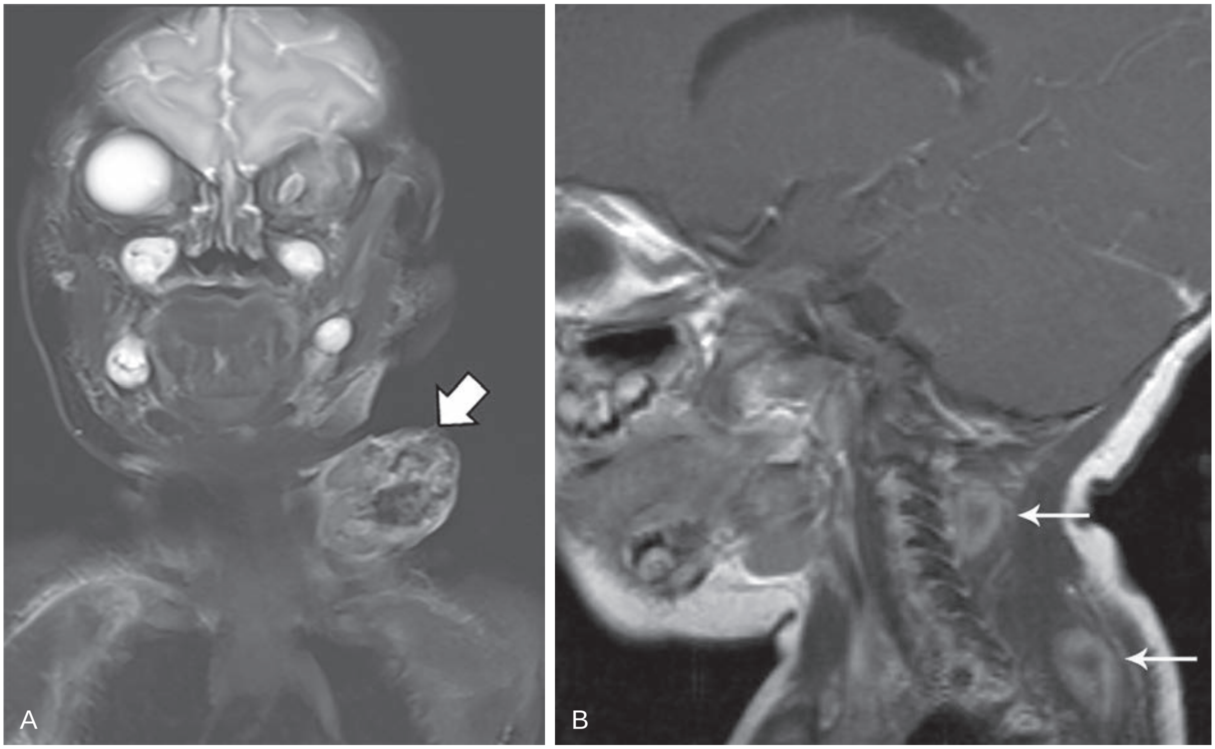


**Figure 14.26. Infantile fibromatoses.** (A) Aggressive infantile fibromatosis in a 3-day-old patient. Coronal STIR MR image shows a large heterogeneous mass in the left neck *(arrow)*. (B) Sagittal contrast-enhanced T1-weighted MR image shows multiple scattered nodular masses *(white arrows)* of the neonatal neck with typical "target" appearance of desmoid type of infantile fibromatosis.

neck hyperextension, airway obstruction, and/or esophageal compression. Fetal goiter may be diagnosed on US as a bilobed echogenic vascular mass in the anterior neck; fetal MRI demonstrates a midline mass with high signal on T1-weighted imaging (e-Fig. 14.25). Treatment of fetal goiter includes intraamniotic thyroxin injection, the main goal being reduction of the goiter's size and prevention of tracheal obstruction. Fetal goiter may be associated with congenital deafness in the setting of Pendred syndrome.

## Infantile Fibromatoses

Infantile fibromatosis represents a spectrum of rare congenital disorders that involve the skeletal and smooth muscle in very young children. It may manifest as a solitary form or as a multicentric form with visceral involvement. Aggressive infantile fibromatosis occurs in the first 2 years of life and may present as a nodular soft tissue mass in the head and neck with an imaging appearance mimicking infantile fibrosarcoma or hemangioma (Fig. 14.26A). A desmoid type of fibromatosis may present as a nodular tumor which often grows along the nerve sheath or vascular bundle and has a tendency to hemorrhage or necrotize in the central portion, producing a target appearance on imaging (Fig. 14.26B). The prognosis is favorable for solitary neck lesions. These lesions usually stop growing or spontaneously regress.

*Fibromatosis colli* is a benign condition that involves the sternocleidomastoid muscle only. It usually affects neonates and manifests as a hard unilateral soft tissue mass associated with ipsilateral torticollis caused by the muscular contraction and rotation of the chin to the opposite side. Imaging with US or MRI may be performed if the clinical presentation is unusual. Both modalities reveal diffuse or focal enlargement of sternocleidomastoid muscle (Fig. 14.27) and no discrete mass or lymphadenopathy. Congenital torticollis usually spontaneously resolves within a few months. A child with cervical lymphadenitis and retropharyngeal abscess may present with a postinflammatory torticollis known as Grisel syndrome; this condition is caused by increased ligamentous laxity.

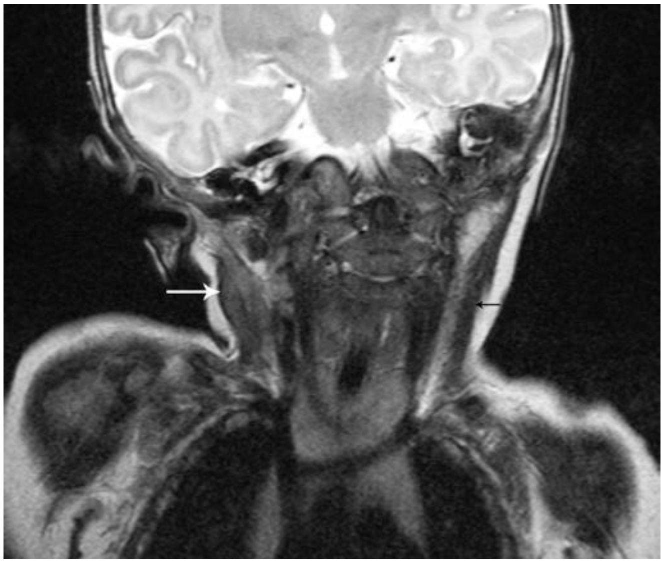

**Figure 14.27. Fibromatosis colli.** Coronal T2-weighted MR image shows diffuse thickening and hyperintensity of the right sternocleidomastoid muscle *(white arrow),* associated with ipsilateral torticollis. The left sternocleidomastoid muscle *(black arrow)* demonstrates normal thickness and signal intensity.

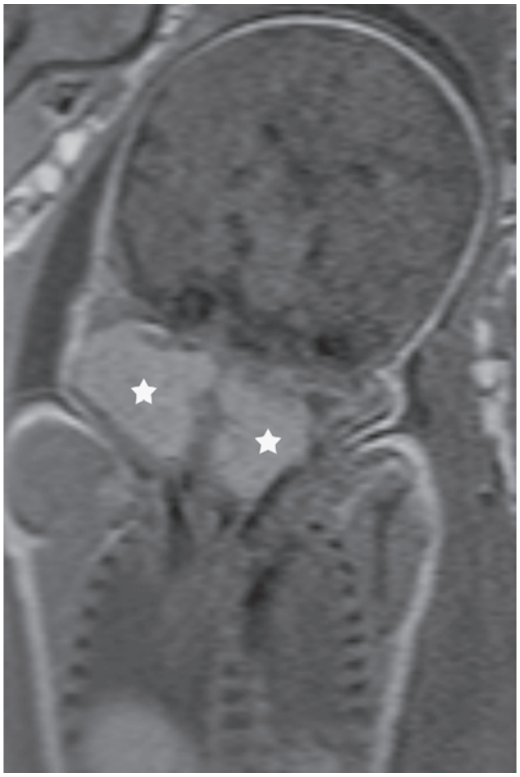

**e-Figure 14.25. Fetal goiter.** Coronal fetal T1-weighted MR image shows the bilobed, uniformly T1-hyperintense lesion *(stars),* indicative of the iodine content of thyroid gland.

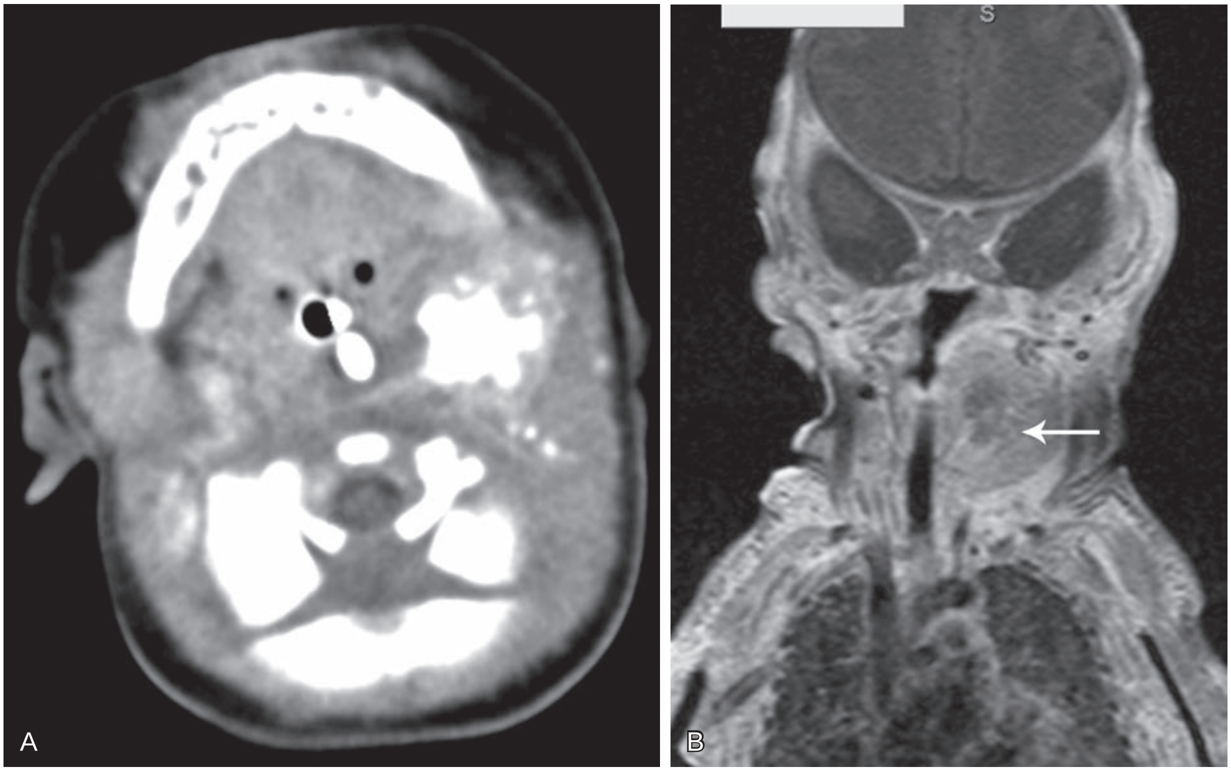

**Figure 14.28. Primary cervical neuroblastoma.** (A) CT and (B) coronal contrast-enhanced fat-saturated T1-weighted MR images show a heterogeneous mass *(small white arrow)* within the left neck, along the presumed course of the sympathetic chain with central lack of enhancement, which proves to be a chunky internal calcification on CT.

## NEONATAL NECK MALIGNANCY

### Neuroblastoma

Neuroblastoma is a common malignant tumor of childhood. Less than 5% occur within the neck as a primary site, arising in the sympathetic ganglia. Cervical location of neuroblastoma is more common in young infants, and it has been reported prenatally. This tumor has a known association with Horner syndrome. Both CT and MRI may depict tumor extension, presence of mineralization, and bony or spinal canal invasion (Fig. 14.28). Restricted diffusion on MRI confirms the hypercellular, malignant nature of this tumor. Intratumoral dystrophic calcifications are observed in 50% of cases. The prognosis and treatment plan depends on tumor genetics. Low- and intermediate-risk *MYCN* negative patients generally have a favorable outcome and usually are treated with surgical resection and chemotherapy, while high-risk *MYCN*-amplified patients require a combined and aggressive treatment with surgery, chemotherapy, radiotherapy, and immunotherapy.

### Congenital Infantile Fibrosarcoma

Congenital infantile fibrosarcoma, a rare tumor of infancy, has a markedly different clinical course and a more favorable prognosis compared with adult fibrosarcoma. It may present at birth or soon after, or may be diagnosed in utero. Infantile fibrosarcoma has unique cytogenetic findings that help to distinguish this tumor from other infantile tumors such as embryonal rhabdomyosarcoma and infantile fibromatosis. The tumor appears as a large solid soft tissue mass of the neck (e-Fig. 14.29), which may be rather homogeneous or have central necrosis and hemorrhage.

KEY POINTS

- The majority of congenital neck lesions are benign.
- Many congenital lesions may be diagnosed prenatally.
- Some congenital lesions may be associated with systemic disorders, potentially requiring further investigation.
- Vascular masses are classified into vascular tumors and vascular malformations.

# 15

# Infection and Inflammation

Tyson R. Finlinson, Grace S. Mitchell, and Lisa H. Hutchison

Primary inflammatory processes in the pediatric neck are common, and contrast-enhanced computed tomography (CT) allows for characterization of the involved spaces, detecting complications, and determining appropriate clinical management.

## PHARYNGOTONSILLITIS AND PERITONSILLAR ABSCESS

***Overview.*** Acute infectious pharyngitis and tonsillitis are common and do not require imaging for diagnosis. However, when a peritonsillar abscess is suspected, imaging is used for diagnosis and to guide management.[1]

***Etiology.*** Most pharyngitis cases are self-limited viral infections. However, up to 30% are bacterial, most often secondary to group A β-hemolytic *Streptococcus* (GAS).[1] These patients present with fever and odynophagia. If symptoms do not improve with antibiotics, the possibility of peritonsillar abscess should be considered.[2]

***Imaging.*** Routine pharyngitis and tonsillitis do not require imaging.[1] However, if complications are suspected, contrast-enhanced CT is performed.[3] Findings of uncomplicated tonsillitis include unilateral or bilateral enlarged, enhancing tonsils with parapharyngeal fat inflammation. A peripherally enhancing, hypodense fluid collection within or adjacent to the tonsil suggests abscess (Fig. 15.1).[3]

***Treatment.*** Viral tonsillitis is self-limiting and treatment is supportive. If GAS infection is confirmed by rapid antigen test or throat culture, the patient will receive antibiotics. Recurrent tonsillitis is treated with tonsillectomy.[4] Focal fluid collections identified by CT may require surgical drainage.

## LEMIERRE SYNDROME

***Overview.*** An uncommon complication of oropharyngeal infection is suppurative thrombophlebitis of the internal jugular vein, also known as Lemierre syndrome. This often occurs in previously healthy teenagers.[5] Rare complications include septic emboli, osteomyelitis, and arterial vasospasm or occlusion leading to infarction.[6]

***Etiology.*** Lemierre syndrome is most commonly caused by *Fusobacterium necrophorum* infection, an anaerobic gram-negative bacterium found in normal oral flora.[6] Recognition is important because of high rates of morbidity and mortality.[5,7] Patients present with sore throat, lateral neck pain, swelling, and fever.[5] Tachypnea, tachycardia, and hypoxia may occur with pulmonary involvement. Infection spreads from the peritonsillar space to the carotid space, causing internal jugular vein thrombosis.[5] Septic embolic may then seed other organs.[7,8] Spread to the retropharyngeal space and osseous structures can cause osteomyelitis.

***Imaging.*** Contrast-enhanced CT findings include inflammatory changes that may involve multiple neck spaces and jugular vein thrombus.[5] Inflammatory findings range from cellulitis with soft tissue enhancement to abscess formation (Figs. 15.2 and 15.3). Color Doppler ultrasound (US) is useful to diagnose and follow thrombophlebitis, but does not reliably evaluate deep neck inflammation.[5,6] Acute neurologic symptoms may be evaluated with cranial CT or magnetic resonance imaging (MRI).[7-9]

***Treatment.*** High-dose intravenous antibiotics are the mainstay for treatment of *Fusobacterium* infection. Anticoagulation therapy is used in up to 27% of patients; however, its use is controversial.[5] The rates of morbidity and mortality are higher than with other head and neck infections, with an estimated mortality rate of 6%.[2,9]

## RETROPHARYNGEAL ABSCESS

***Overview.*** Suppurative lymphadenitis associated with tonsillitis, sinonasal infection, and dental infection are common causes of retropharyngeal abscess. Rarely is abscess secondary to pharyngeal or esophageal perforation.[10,11] The retropharyngeal space is a potential space that extends from the nasopharynx to the superior mediastinum.[10] Morbidity rates increase if an abscess extends below the T4 vertebra into the mediastinum, termed a *danger space* infection. Uncommonly, retropharyngeal tissue thickening may be due to hemorrhage (especially in hemophilia), neuroblastoma, and, rarely, anterior myelomeningocele.

***Etiology.*** Retropharyngeal abscesses are the sequelae of GAS, but *Staphylococcus aureus* and anaerobes have also been reported.[2,10] Symptoms include fever, pain, dysphagia, neck swelling, and sore throat. Cervical lymphadenopathy and torticollis are also common.[11,12]

***Imaging.*** Lateral radiographs may show thickening of the prevertebral tissues (>8 mm at C2) and anterior airway and esophagus displacement (Fig. 15.4). CT is needed to distinguish cellulitis from abscess.[4] Grisel syndrome is an inflammation-induced laxity of the atlantoaxial joint, which results in atlantoaxial rotatory subluxation of C1 and C2 that is self-limiting. Contrast-enhanced CT can evaluate for rim-enhancing abscesses, mediastinal involvement, thrombophlebitis, and osteomyelitis and guide surgical drainage if needed.[4,10]

***Treatment.*** Surgical drainage is often required, as conservative medical management only has a success rate between 18% and 57%.[10]

## CERVICAL LYMPHADENITIS

***Overview.*** Cervical lymphadenitis is common, and acute cases can be caused by viral or bacterial pathogens. Imaging is used when there is no clinical improvement after standard therapy, or if abscess is suspected.[13]

***Etiology.*** Cervical lymphadenitis is secondary to infection from a head and neck source, such as tonsils, pharynx, or teeth. Symptoms include a tender, focal neck mass and fever.[13] Lymph node enlargement is often due to a self-limiting reactive hyperplasia from viral infection.[14] Bacterial causes include *S. aureus* and streptococcal species and may lead to nodal suppuration. Kawasaki disease can also present with acute cervical lymphadenitis, but other features such as rash are also present.[13-15]

***Imaging.*** Involved nodes are enlarged, measuring greater than 1 cm in short axis. Suppurative or necrotic nodes are characterized by central hypoechogenicity or hypodensity on US and CT (Fig. 15.5).[12] Infectious nodes and malignant adenopathy cannot be distinguished by imaging; however, infectious adenopathy is more common.

***Treatment.*** Viral lymphadenitis is usually self-limiting, and acute bacterial lymphadenitis generally responds to antibiotic therapy.[12] Lymphadenopathy unresponsive to medical therapy may require follow-up imaging, surgical intervention, or biopsy to exclude malignancy.[2,14]

## Abstract:

Primary infectious and inflammatory processes in the pediatric neck are common and usually diagnosed clinically. However, imaging is often necessary to evaluate for associated complications and to help guide appropriate management. Some such conditions include pharyngotonsillitis, peritonsillar abscess, Lemierre syndrome, retropharyngeal abscess, cervical lymphadenitis, mycobacterial lymphadenitis, cat scratch disease, infectious mononucleosis, human immunodefiency virus, and sialoadenitis. The ability to distinguish between these conditions can help direct clinical outcomes, as potential treatments can range from supportive care to surgical management. The varied presentations of infectious and inflammatory conditions of the pediatric neck can be evaluated by imaging to determine the extent of disease, assess for potential complications, and direct appropriate treatment.

cervical lymphadenitis
retropharyngeal abscess

## MYCOBACTERIAL LYMPHADENITIS

***Overview.*** Mycobacterial infection is an important cause of chronic cervical lymphadenitis. In the United States, 70% to 95% of cases of mycobacterial lymphadenitis are caused by nontuberculous mycobacteria (NTM).[13] NTM lymphadenitis typically affects children between 1 and 5 years of age.[16] It is important to differentiate tuberculous and nontuberculous causes, as the treatments differ.

***Etiology.*** Cervical mycobacterial lymphadenitis, also known as *scrofula*, may be caused by various species, including *Mycobacterium tuberculosis*, *M. bovis*, and *M. avium-intracellulare*. The illness is often indolent with nodal enlargement that slowly develops over several weeks. A strongly positive tuberculin skin test suggests *M. tuberculosis*, whereas a weakly positive test suggests NTM.[13] The diagnosis is made with aspiration and culture.

***Imaging.*** On CT, *M. tuberculosis* lymphadenitis key features include a nodal mass with central low-attenuation fluid surrounded by a thick rim of enhancement (Fig. 15.6).[17,18] Unlike other nodal infections, atypical TB shows little to no surrounding inflammation. Nodal calcification may be noted. On MRI, the thick enhancing rim demonstrates T1 intermediate signal and T2 hypointensity. The central necrotic areas are T2 hyperintense and T1 intermediate signal.[18] Differential diagnoses include lymphoma and metastatic disease.[18] CT of NTM also shows low-attenuation ring-enhancing nodes. Unlike *M. tuberculosis* lymphadenitis, calcifications are uncommon, although it is often impossible to distinguish between them by imaging alone (Fig. 15.7).[19]

***Treatment.*** Multiantibiotic therapy for 12 to 18 months is the preferred treatment for *M. tuberculosis*,[13] whereas NTM adenitis requires complete excision.[16] Prognosis for both conditions is excellent with appropriate therapy.

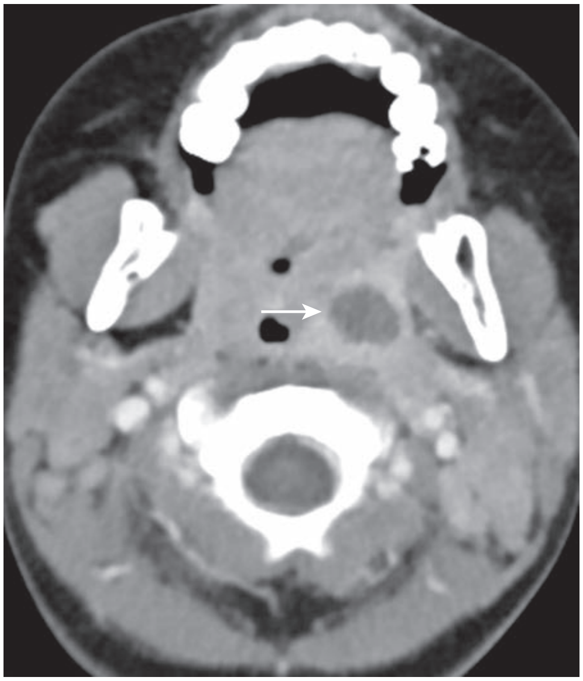

**Figure 15.1. Peritonsillar abscess in a 3-year-old girl with fever, pain, and fussiness.** Axial contrast-enhanced CT of the suprahyoid neck shows a peripherally enhancing low-attenuation fluid collection *(arrow)* lateral to the left tonsil.

## CAT SCRATCH DISEASE

***Overview.*** Cat scratch disease is a self-limiting, granulomatous infection most common in patients under 18 years.[20] Rarely, disseminated disease can cause granulomas in the liver or spleen, osteomyelitis, discitis, encephalitis, meningitis, ophthalmitis, and cranial neuritis.

***Etiology.*** Cat scratch is caused by *Bartonella henselae*, a gram-negative bacillus. The most common presentation is painful lymphadenopathy at the site of inoculation with lack of fever and constitutional symptoms. Disseminated disease can occur in 5% to 10% of cases.[21] The diagnosis is often confirmed with serologic testing.

***Imaging.*** Findings are nonspecific, with US showing enlarged hypoechoic lymph nodes with posterior acoustic enhancement and surrounding soft tissue hyperechogenicity.[21] Hyperemia is seen on Doppler US, and CT reveals enlarged nodes with central hypodensity (e-Fig. 15.8).[22]

***Treatment.*** Most cases resolve without antibiotics, although disseminated disease can be treated with antibiotics.[23]

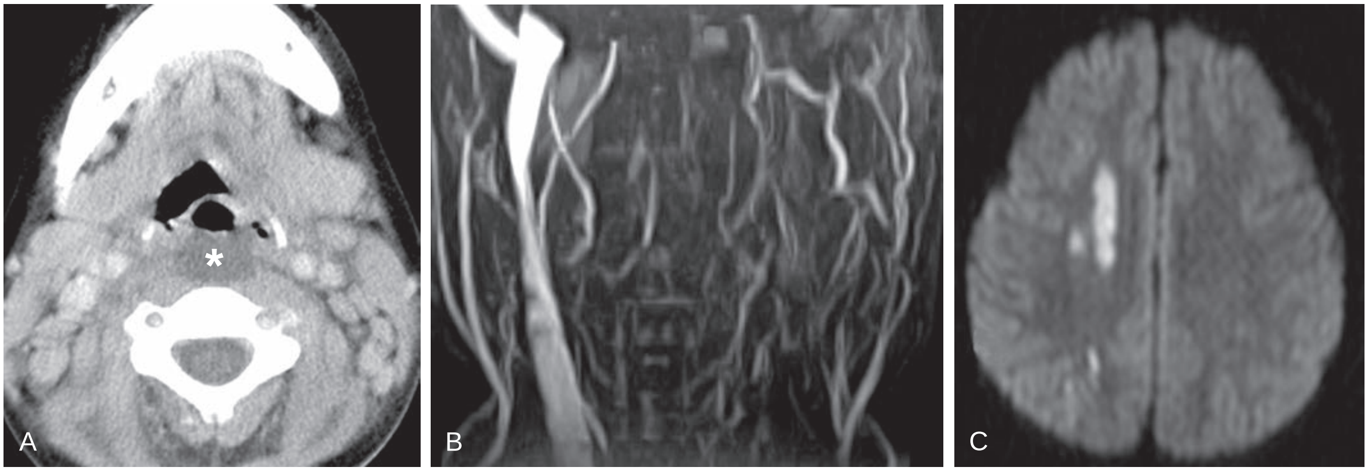

**Figure 15.2. Lemierre syndrome (*Fusobacterium necrophorum* infection) complicated by stroke in a 6-year-old girl with fever, difficulty swallowing, and nuchal rigidity.** (A) Axial contrast-enhanced CT shows low-attenuation retropharyngeal fluid *(asterisk).* (B) Magnetic resonance venogram 2 days later confirms lack of left internal jugular vein patency. (C) Diffusion-weighted MRI of the brain reveals multiple small foci of hyperintensity secondary to emboli.

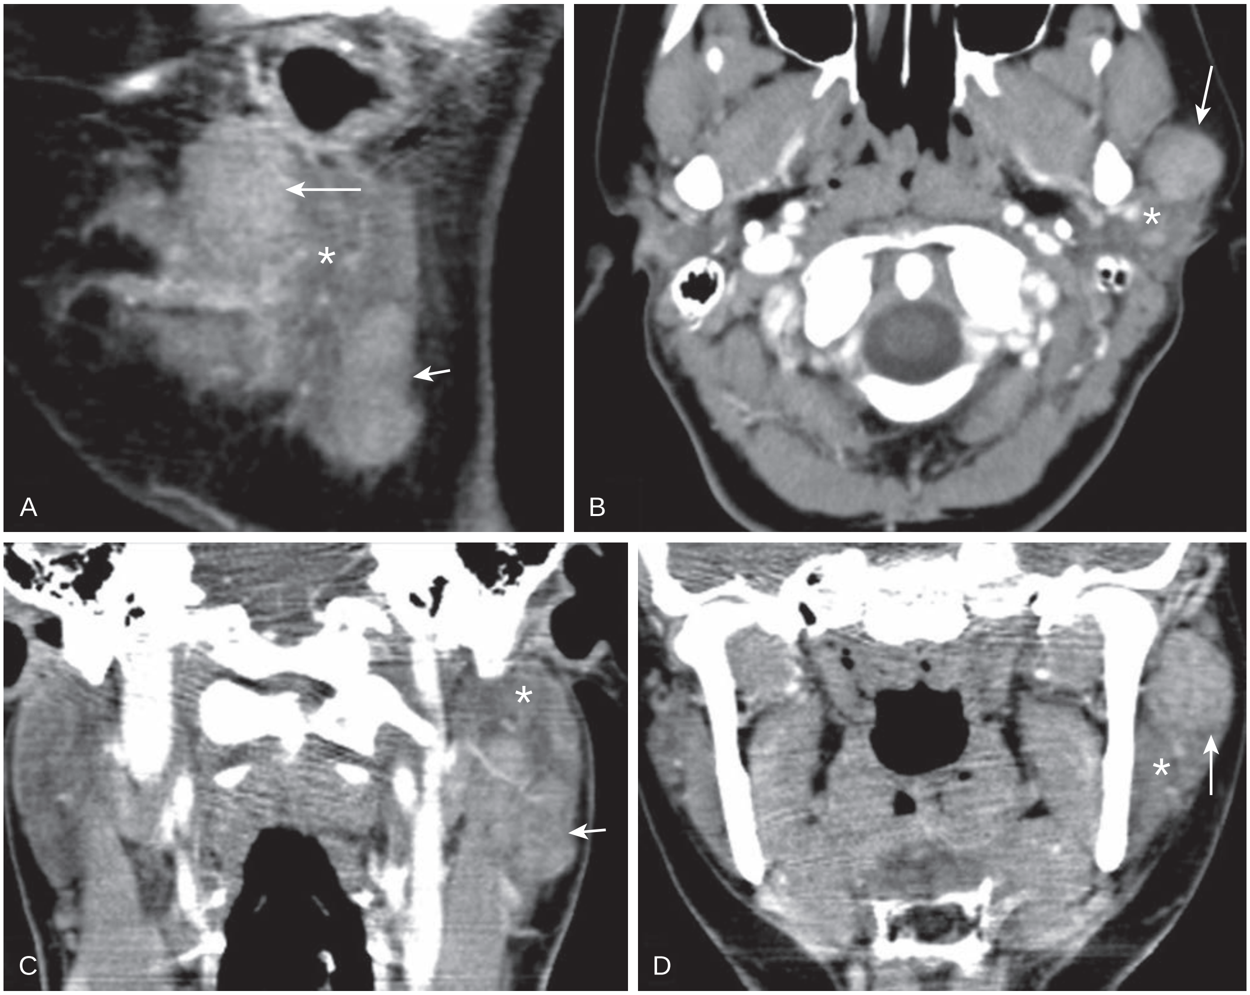

**e-Figure 15.8. Cat scratch disease in a 16-year-old girl with a left-sided neck mass for 6 weeks.** (A) Sagittal, (B) axial and (C–D) coronal contrast-enhanced CT images show enhancing lobular masses anterosuperior *(arrow)* and posteroinferior to the left parotid gland *(asterisk).*

## INFECTIOUS MONONUCLEOSIS

***Overview.*** Infectious mononucleosis is a common disorder usually seen in teenagers and young adults. The annual incidence in the United States is 500 cases for every 100,000 persons.[24] The diagnosis is clinical and can be confirmed with a rapid monospot test for heterophile antibodies. Imaging is rarely indicated.

***Etiology.*** Infectious mononucleosis is an acute self-limiting disorder caused by Epstein–Barr virus, characterized by acute pharyngotonsillitis, fever, malaise, and cervical or generalized lymphadenopathy. Splenomegaly is common.

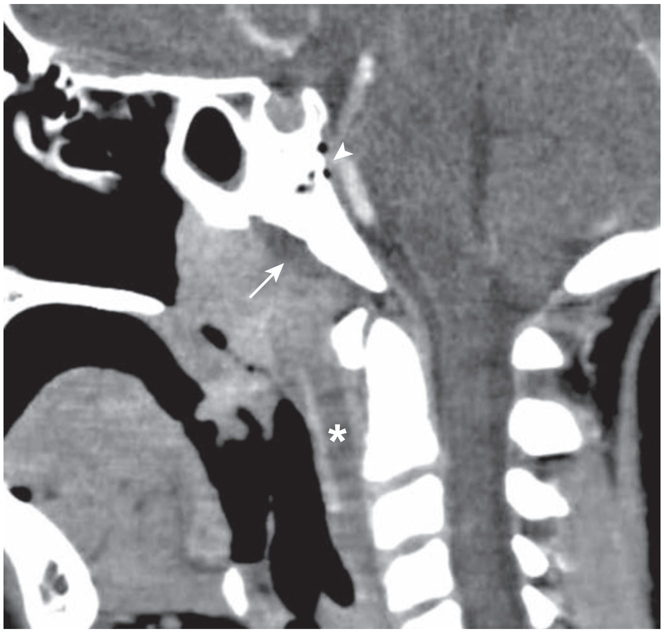

**Figure 15.3. Lemierre syndrome complicated by osteomyelitis in a 9-year-old with fever, neck pain, and sore throat.** Sagittal reconstructed contrast-enhanced CT demonstrates enlarged adenoids, a low-attenuation retropharyngeal fluid collection *(asterisk),* and a subperiosteal fluid collection along the ventral clivus *(arrow).* Air within and dorsal to the clivus due to osteomyelitis *(arrowhead)* and venous occlusion *(not shown)* were also present.

***Imaging.*** Imaging is unnecessary; however, this disease may mimic other infectious or malignant processes, and imaging may be obtained to determine the extent of disease. CT findings are nonspecific and including tonsillar and lymph node enlargement, with little surrounding inflammation (e-Fig. 15.9).[25]

***Treatment.*** Treatment for infectious mononucleosis is supportive. It is recommended that contact sports be avoided for at least 3 weeks following diagnosis to reduce the risk of splenic rupture.[24] The prognosis is excellent, except in cases complicated by splenic rupture.

## HUMAN IMMUNODEFICIENCY VIRUS

***Overview.*** Children infected with human immunodeficiency virus (HIV) often have cervical, mediastinal, or generalized lymphadenopathy. Since these findings are nonspecific, imaging is not required for the diagnosis, but may be considered along with biopsy to rule out malignancy if a neck mass persists or worsens.

***Etiology.*** Lymphadenopathy of HIV is usually symmetric, painless, and extensive. The differential includes Kaposi sarcoma, non-Hodgkin lymphoma, metastatic disease, or reactive lymphadenopathy from underlying head and neck infections.[26] Children with HIV may present with parotid enlargement from lymphocytic infiltration.

***Imaging.*** Prominent adenoids are present in 35% of HIV positive patients.[27] Numerous bilateral enlarged nodes are also common. Parotid US and CT may show multiple cystic and solid (lymphoproliferative) lesions of varying size.[26,27]

***Treatment.*** Highly active antiretroviral therapy (HAART) with multiple antiretroviral drugs is the frontline therapy for HIV treatment. HIV-associated lymphadenopathy does not require specific treatment; however, biopsy may be necessary to rule out other etiologies.

## SIALOADENITIS

***Overview.*** Sialoadenitis most often affects the parotid and submandibular glands in children. It is usually self-limiting. The diagnosis is typically clinical and imaging is usually not indicated.

***Etiology.*** Sialoadenitis presents as a swollen, enlarged gland with fever, most commonly caused by viruses and sialoliths. Mumps is by far the most common viral cause, and affects both parotid glands.[28-30] Other viruses include HIV, influenza, and Coxsackie. Acute bacterial (suppurative) sialoadenitis is uncommon in children.

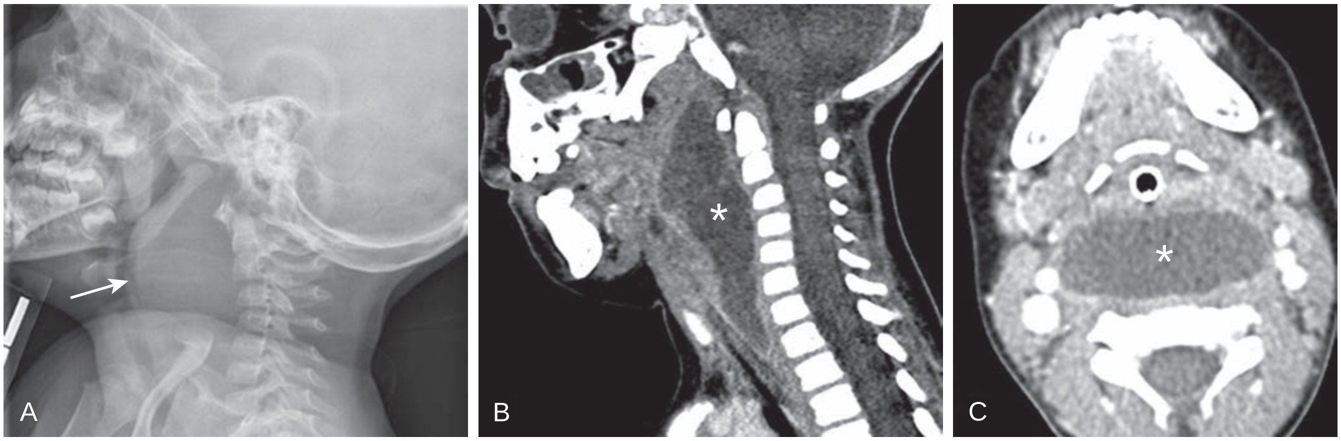

**Figure 15.4. Retropharyngeal abscess in a 2-year-old girl with sore throat, muffled voice, drooling, stridor, and intermittent fever.** (A) Lateral soft tissue neck radiograph reveals extensive swelling displacing the airway anteriorly *(arrow).* (B) Sagittal and (C) axial contrast-enhanced CT confirm a large peripherally enhancing low-attenuation retropharyngeal fluid collection consistent with abscess *(asterisk).*

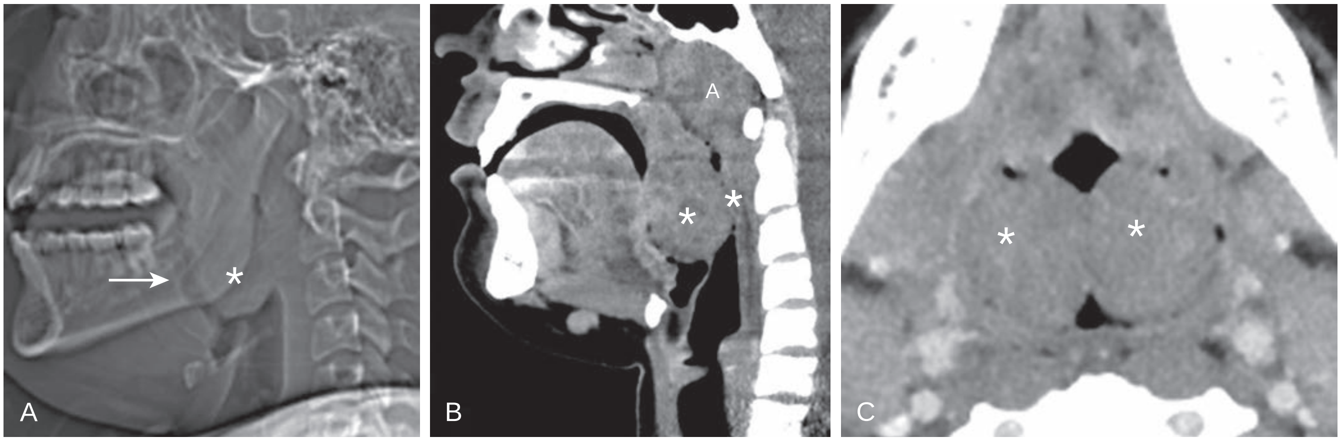

**e-Figure 15.9. Infectious mononucleosis in a 17-year-old girl with sore throat.** (A) Scout image and subsequent (B) sagittal and (C) axial contrast-enhanced CT images show nonspecific marked palatine tonsil *(asterisks)* and adenoid enlargement *(A),* with resultant airway narrowing *(arrow).*

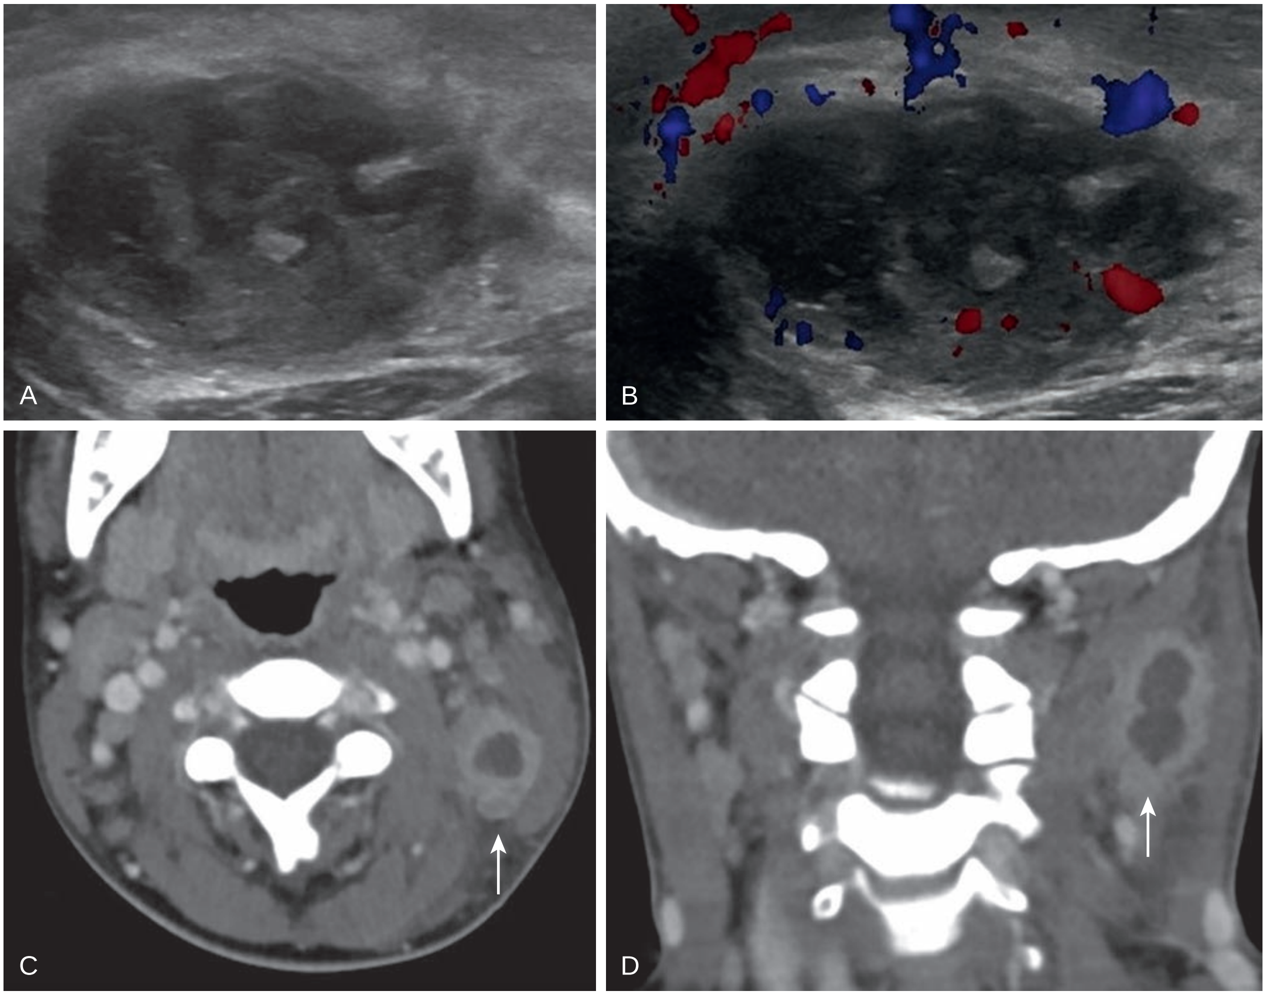

**Figure 15.5. Suppurative lymphadenitis in a 13-year-old boy with a history of combined B-cell immunodeficiency and neck pain.** (A) US with (B) color Doppler images show a heterogeneously hypoechoic mass with surrounding hyperemia. (C) Axial and (D) coronal CT images reveal a conglomerate of enlarged nodes in the left posterior triangle with central necrosis *(arrows).*

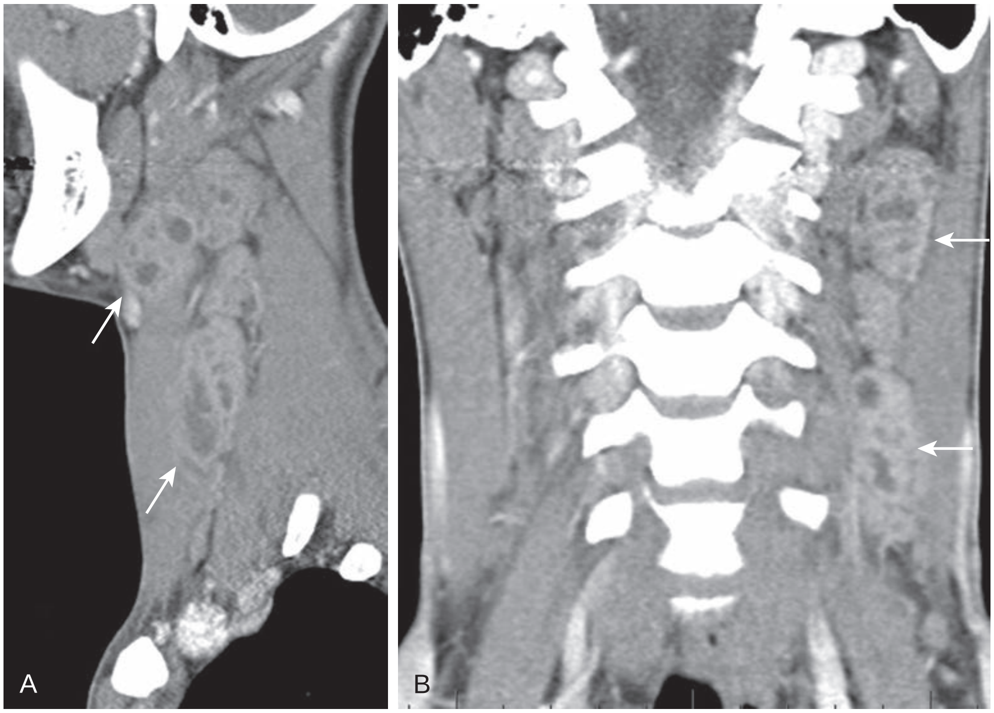

**Figure 15.6. Extrapulmonary tuberculosis in a 15-year-old boy with persistent lymphadenopathy for 5 months despite antibiotics and normal chest radiograph, who emigrated from Thailand 2 years prior.** (A) Sagittal and (B) coronal contrast-enhanced CT images show enlargement and enhancement of the left cervical chain lymph nodes, with central necrosis.

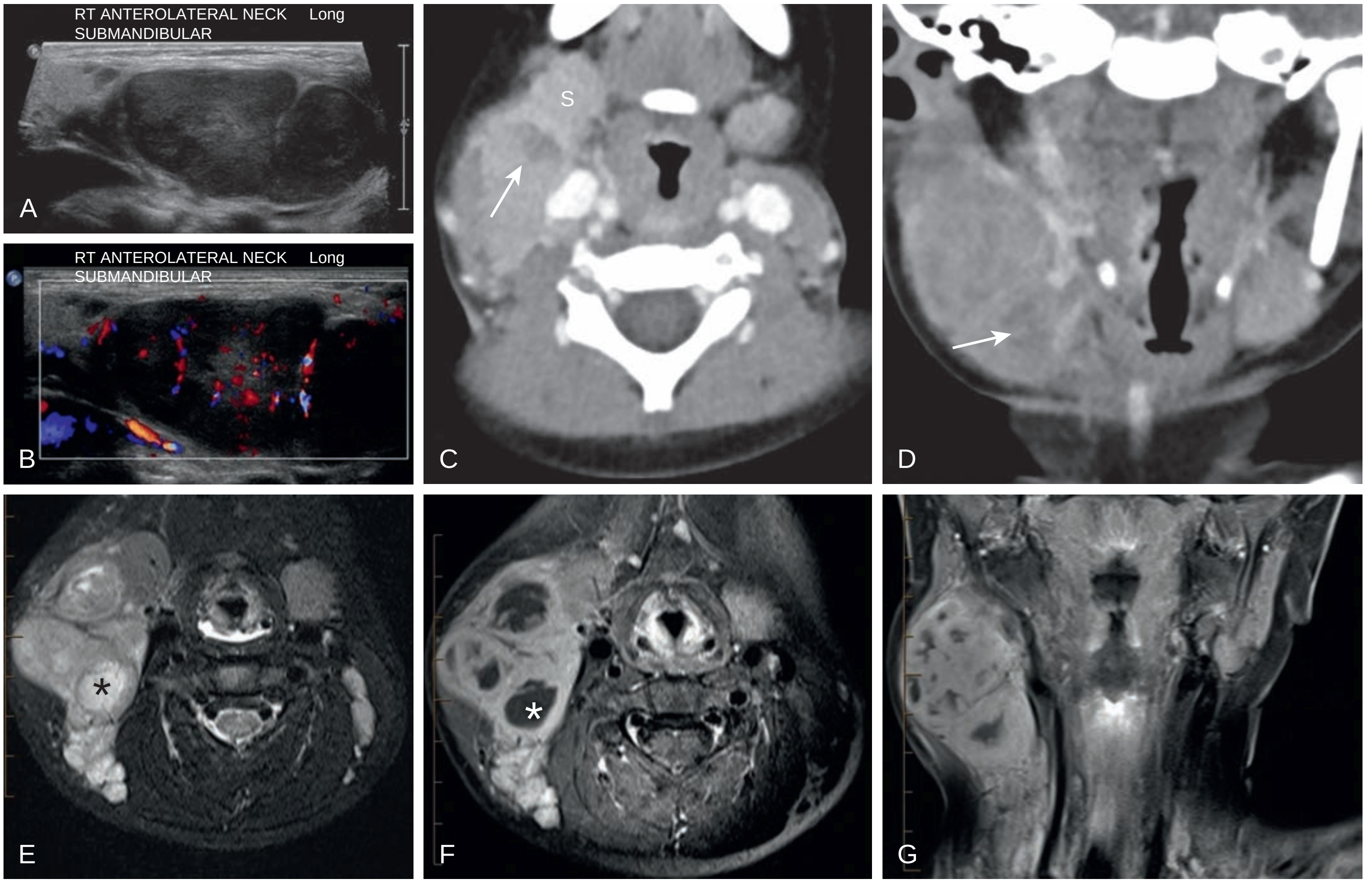

**Figure 15.7. Nontuberculous mycobacterial infection in a 3-year-old boy with fever, upper respiratory symptoms, and right-sided neck swelling.** (A) Gray scale and (B) color Doppler US images show an enlarged and heterogeneous lymph node with internal vascularity. (C) Axial and (D) coronal contrast-enhanced CT images show an aggregate of enlarged nodes in the right neck displacing the submandibular gland anteriorly *(S).* Note a small central low-attenuation necrotic component *(arrows).* At that time, no pathogen was identified. Due to lack of symptomatic improvement, (E) axial T2, (F) axial T1 postcontrast, and (G) coronal T1 postcontrast MRI images were obtained 2 months later, which show increased size of the nodal aggregate, now with multiple fluid pockets *(asterisks).* Excisional biopsy revealed *Mycobacterium avium-intracellulare*.

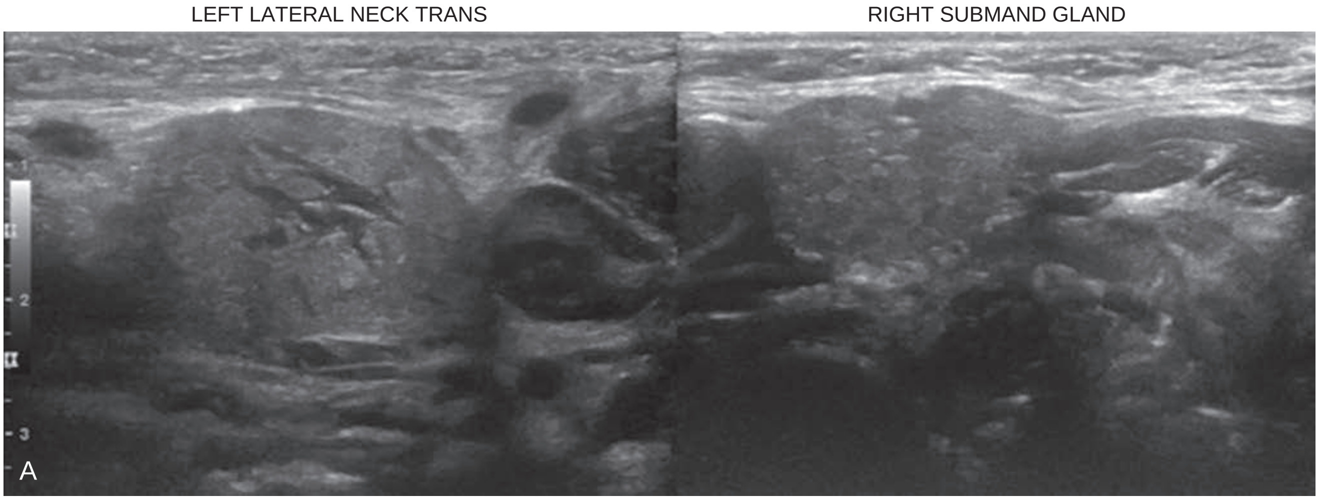

**Figure 15.10. Sialoadenitis in a 4-year-old boy with left-sided jaw swelling.** (A) Gray scale and (B) color Doppler US comparing the submandibular glands demonstrate asymmetric enlargement, edema, and hyperemia on the left.

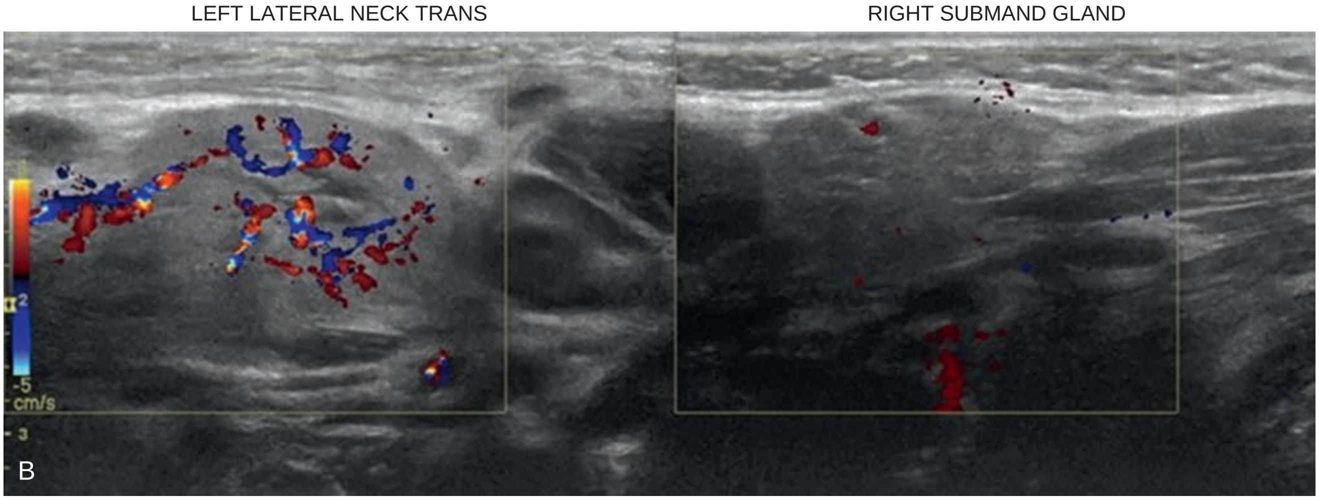

**Figure 15.10, cont'd**

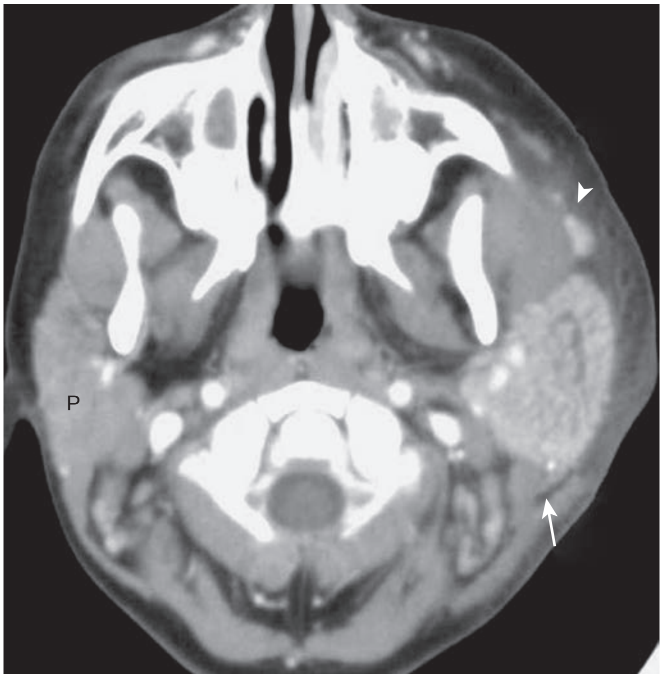

**Figure 15.13. Parotitis in a 6-year-old boy with painful left cheek swelling.** Axial CT demonstrates an enlarged enhancing left parotid gland *(arrow),* with similar changes in the accessory parotid tissue *(arrowhead)* along the course of the parotid (Stensen) duct. Note inflammatory stranding in the left cheek subcutaneous fat and the normal right parotid gland *(P).*

Recurrent submandibular sialoadenitis is most often caused by Wharton's duct sialoliths.[28] Chronic salivary gland inflammation is caused by recurrent bacteria including *Streptococcus viridians*, autoimmune disorders such as Sjögren syndrome, or sarcoidosis. Enlargement of intraparotid nodes can occur due to lymphadenitis affecting other regions of the neck.

***Imaging.*** On US, parotitis reveals as an enlarged gland, with heterogeneous decreased echogenicity and irregular margins. Small intraparenchymal hypoechoic foci may be present, representing salivary fluid, nodes, or abscesses (Fig. 15.10).[29,30] Hyperemia is seen on color Doppler. CT is best to identify salivary calculi (e-Fig. 15.11). Contrast-enhanced CT shows gland enlargement with enhancement (e-Fig. 15.12A). A low-attenuation collection with peripheral enhancement suggests an abscess (see e-Fig. 15.12B and Fig. 15.13).[29]

***Treatment.*** Viral sialoadenitis usually only requires supportive treatment. Patients with sialoliths can be treated medically with hydration, gland massage, and sialogogues to increase saliva production and flush out stones. If medical therapy is unsuccessful, surgery may be required. Total gland excision may be necessary if multiple stones are present.[28]

## KEY POINTS

- Many infectious and inflammatory conditions of the neck do not require imaging for diagnosis; however, imaging may help limit the differential diagnosis.
- Imaging is useful to determine disease extent and identify complications such as abscess, osteomyelitis, thrombophlebitis, and septic emboli, which require more aggressive treatment.
- Abscesses may require drainage for symptom relief, accelerated recovery, and determination of appropriate antibiotic therapy.

# Neoplasia

Karen K. Moeller

Cancer is a leading cause of death during childhood, second only to trauma in children between the ages of 5 and 14 years. Head and neck involvement can be seen in up to 12% of childhood cancers.[1]

Lymphoma (50%) and rhabdomyosarcoma (30%) account for the majority of primary malignant pediatric head and neck tumors. Other malignant head and neck tumors include thyroid carcinoma, nasopharyngeal carcinoma, other sarcomas, and salivary gland tumors. Important benign tumors are hemangioma, juvenile angiofibroma, teratoma, and nerve sheath tumors. Ultrasound is frequently the initial study for evaluation, especially in lesions involving the thyroid gland. Subsequently, computed tomography (CT) and magnetic resonance imaging (MRI) provide a more complete evaluation and often offer complementary insights into the tumor type and disease extent. Positron emission tomography (PET) is utilized for malignant tumor staging.

## MALIGNANT TUMORS

### Non-Hodgkin Lymphoma

Non-Hodgkin lymphoma (NHL) occurs over a wide age range, although it is rare in children under the age of 2 years. It is a malignant neoplasm of B or T cells that is further classified as low, intermediate, or high grade. The vast majority in childhood are high grade[2] and of B cell origin. The histologic subtypes encountered in children include Burkitt, large B cell, lymphoblastic T or B cell, and anaplastic large cell. NHL in the head and neck can be nodal, nonnodal lymphatic (tonsils and adenoids), or nonnodal. Burkitt lymphoma is more common in children compared with adults and has an established association with Epstein-Barr virus (EBV). Furthermore, the development of Burkitt lymphoma is dependent on B cells acquiring a translocation involving the c-Myc proto-oncogene located on chromosome 8.

NHL initially presents in the head and neck in up to 10% of cases.[3] Children most commonly present with cervical lymphadenopathy and are otherwise asymptomatic. At imaging, the cervical lymphadenopathy is typically bilateral and symmetric. The enlarged lymph nodes are homogeneous and lack stranding of the surrounding fat on CT (Fig. 16.1). On T2-weighted MRI, the lymph nodes are lower in signal compared with reactive nodes and can show decreased diffusivity. These imaging characteristics are also true for nonnodal NHL. NHL disease is fludeoxyglucose (FDG) avid, and PET has a higher sensitivity compared with MRI and CT alone in establishing disease extent.[4] Unlike in adults, radiation therapy is not typically indicated, and these patients are treated primarily with combination chemotherapy.

### Hodgkin Lymphoma

Hodgkin lymphoma (HL) is the most common childhood cancer in the 15- to 19-year age group. It is histologically classified as nodular lymphocyte-predominant or classical. The classical type has four subtypes and is characterized by the presence of Reed-Sternberg (HRS) cells. Up to 50% of cases are found to have an EBV association, and the virus can be detected in HRS cells. When it occurs in the head and neck, HL is rarely extranodal. The most common presentation for pediatric head and neck HL is marked unilateral and painless cervical lymphadenopathy. Although imaging cannot distinguish NHL from HL, and both commonly present with cervical lymphadenopathy, an extranodal mass suggests NHL, and markedly asymmetric cervical lymphadenopathy favors the diagnosis of HL (Fig. 16.2). Hodgkin lymphoma in children is treated with chemotherapy and radiation therapy.

### Rhabdomyosarcoma

Rhabdomyosarcoma (RMS) is the most common soft tissue tumor of childhood, and up to 35% of these cancers occur in the head and neck. RMS has an incidence that peaks in children under the age of 6 years and then again in adolescence. It typically occurs in children who are otherwise healthy; however, it also has an increased occurrence in patients with Noonan syndrome, neurofibromatosis type 1 (NF-1), Beckwith-Wiedemann syndrome, and Li-Fraumeni syndrome (P53 gene mutation). This tumor has its origin from immature mesenchymal cells that are destined to form skeletal muscle, but it can arise in sites where skeletal muscle is not typically found. At histology, these tumors have small round blue cells, similar to other childhood tumors, so advanced immunohistochemical staining and molecular genetic evaluation are needed to establish the diagnosis. The histopathologic subtypes are embryonal, alveolar, and undifferentiated anaplastic. In head and neck RMS, the histology is most often embryonal, and regional lymph nodes are rarely involved.

Head and neck RMS is divide into three types based on location: orbit, parameningeal (masticator space, middle ear, sinus, parapharyngeal space, and pterygopalatine fossa), and nonorbit nonparameningeal. Of these, the most commonly encountered locations are masticator space and orbit. Recognizing parameningeal tumors is important because 55% of tumors at these sites will have intracranial extension. Patients with parameningeal tumors are treated with more aggressive protocols due to an increased incidence of central nervous system (CNS) relapse even in the absence of intracranial extension at presentation. All patients with parameningeal rhabdomyosarcoma are evaluated with lumbar puncture and brain MRI to assess for possible intracranial disease. Intracranial extension is defined as tumor that touches, displaces, invades, or distorts the dura.

On CT, these tumors lack calcification and are isoattenuated compared with muscle. They can remodel or erode bone. RMS is isointense on T1-weighted and hyperintense on T2-weighted MRI compared with muscle with homogenous or heterogeneous contrast enhancement (Fig. 16.3). Decreased diffusivity is often but not always seen. In the temporal bone, RMS can be distinguished from Langerhans cell histiocytosis (LCH) by its tendency to occur more anteromedial involving the middle ear or petrous apex, compared with LCH that has a predilection for the mastoid temporal bone.

Depending on disease extent and location, treatments include resection and chemotherapy. Almost all patients also require radiation therapy.[5] Cure rates for RMS now approach 70%. These improved outcomes are the direct result of risk-based multimodality therapeutic protocols developed by large international cooperative groups.

### Nasopharyngeal Carcinoma

Nasopharyngeal carcinoma (NPC) has a peak incidence during middle age where it is endemic in Southern China and to a lesser

## Abstract:

Cancer is a leading cause of death during childhood, second only to trauma in children between the ages of 5 and 14 years. Head and neck involvement can be seen in up to 12% of childhood cancers. This chapter reviews the imaging findings for common and less commonly encountered head and neck tumors in the pediatric population. Benign and malignant tumors are reviewed with an emphasis on cross sectional radiographic findings that can aid in diagnosis of these lesions.

extent in Southeast Asia, Northern Africa, and the Arctic. There is a smaller incidence peak in adolescence that is not confined to these endemic areas and also includes the United States. It is more frequently encountered in boys and in the United States is more common in African Americans. The histologic subtype encountered in pediatrics is nonkeratinizing undifferentiated NPC, which has an association with previous EBV infection. In general, adolescents with NPC present with advanced stage disease. Imaging findings for these patients include asymmetric adenoid enlargement and mastoid fluid. Adenopathy and skull base invasion are also commonly encountered at presentation (Fig. 16.4).[6] Radiation is the mainstay of treatment for nasopharyngeal carcinoma due to the radiosensitivity of this tumor and because its anatomic location limits surgical resection.

## Thyroid Carcinoma

It is important to remember that an incidentally discovered thyroid nodule in a child is more likely to be malignant (20%) compared with an incidental nodule encountered in an adult (5%) (see also Chapter 17).[7] Fine needle aspiration is the best way to distinguish malignant from benign nodules, and the accuracy is similar to

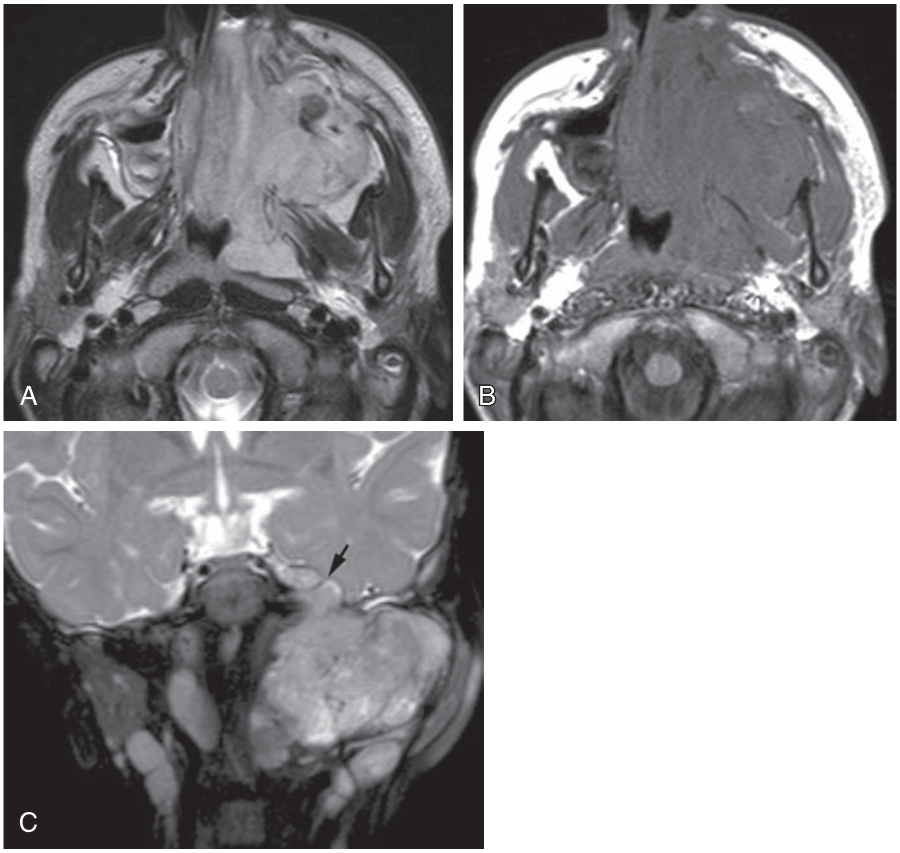

**Figure 16.3. Maxillary sinus rhabdomyosarcoma in a 14-year-old boy.** (A) Axial T2-weighted MR image shows a large left maxillary sinus mass extending into and filling the nasal cavity and nasopharynx. It is hyperintense compared with muscle. (B) The lesion is isointense compared with muscle on T1-weighted MRI. Notice displacement and destruction of surrounding structures. (C) In a different 18-month-old boy, coronal fat-saturated T2-weighted MR image shows a masticator space rhabdomyosarcoma with intracranial extension and tumor reaching the cavernous sinus via a widened foramen ovale *(arrow)*.

that achieved in adults. The majority of thyroid carcinomas in children are of the differentiated type with most of those having papillary or mixed papillary-follicular histology. Differentiated follicular carcinoma is less common and is also less likely to have metastatic lymphadenopathy at presentation compared with papillary thyroid carcinoma.

Patients most often present with an enlarging neck mass that can be from the thyroid tumor itself or from nodal metastases. Ultrasound features that are concerning for thyroid carcinoma include nodules that are tall compared with their width, microcalcifications, and hypervascularity. On pre- and postcontrast CT, the tumors are typically hypodense compared with the rest of the gland. Nodal metastases can vary in size and density (Fig. 16.5) and not uncommonly appear cystic. Because tumors are often multifocal, treatment includes total thyroidectomy. This allows for postoperative administration of radioactive iodine and the use of serial thyroglobulin measurement for surveillance. Children with primary tumors confined to the thyroid with no or only microscopic metastases to central compartment nodes do not require I-131 therapy.[8]

Medullary thyroid carcinoma is rare and is typically sporadic in adults. In pediatrics, it is almost always inherited in the setting of one of the multiple endocrine neoplasia syndromes. These syndromes, which include MEN2a, MEN2b, and the familial medullary thyroid carcinoma syndrome (a subtype of MEN2a), have an autosomal dominant inheritance pattern resulting from a mutation of the *RET* proto-oncogene located on the long arm of chromosome 10. In these patients, the leading cause of morbidity and mortality is the medullary carcinoma since this tumor spreads early and is resistant to chemotherapy. The treatment in children with these syndromes is prophylactic thyroidectomy, and preoperative imaging is typically not obtained.

## Primary Cervical Neuroblastoma

Neuroblastoma most often arises in the retroperitoneum, and primary cervical neuroblastoma is rare, making up less than 5% of cases.[9] This tumor arises from primitive neural crest cells of the sympathetic nervous system. The key to considering this diagnosis is to remember that the sympathetic chain lies very near the common and internal carotid artery, typically medial or posteromedial to it. At imaging, calcifications and/or adjacent adenopathy may be seen. In the neck, these tumors tend to displace vessels rather than encase them (Fig. 16.6). Treatment involves surgery, in most cases, with adjuvant chemotherapy. Radiotherapy is reserved for unresectable tumors or for those that progress despite chemotherapy.

Neuroblastoma is the most common malignancy to metastasize to the head and neck, especially in children under the age of 2 years,[10] and is encountered more frequently than primary cervical neuroblastoma. At imaging, enhancing soft tissue masses with an aggressive periosteal reaction are seen, which can involve the skull base, orbits, temporal bone, or calvarium. This finding can lose its conspicuity when it is bilateral and symmetric

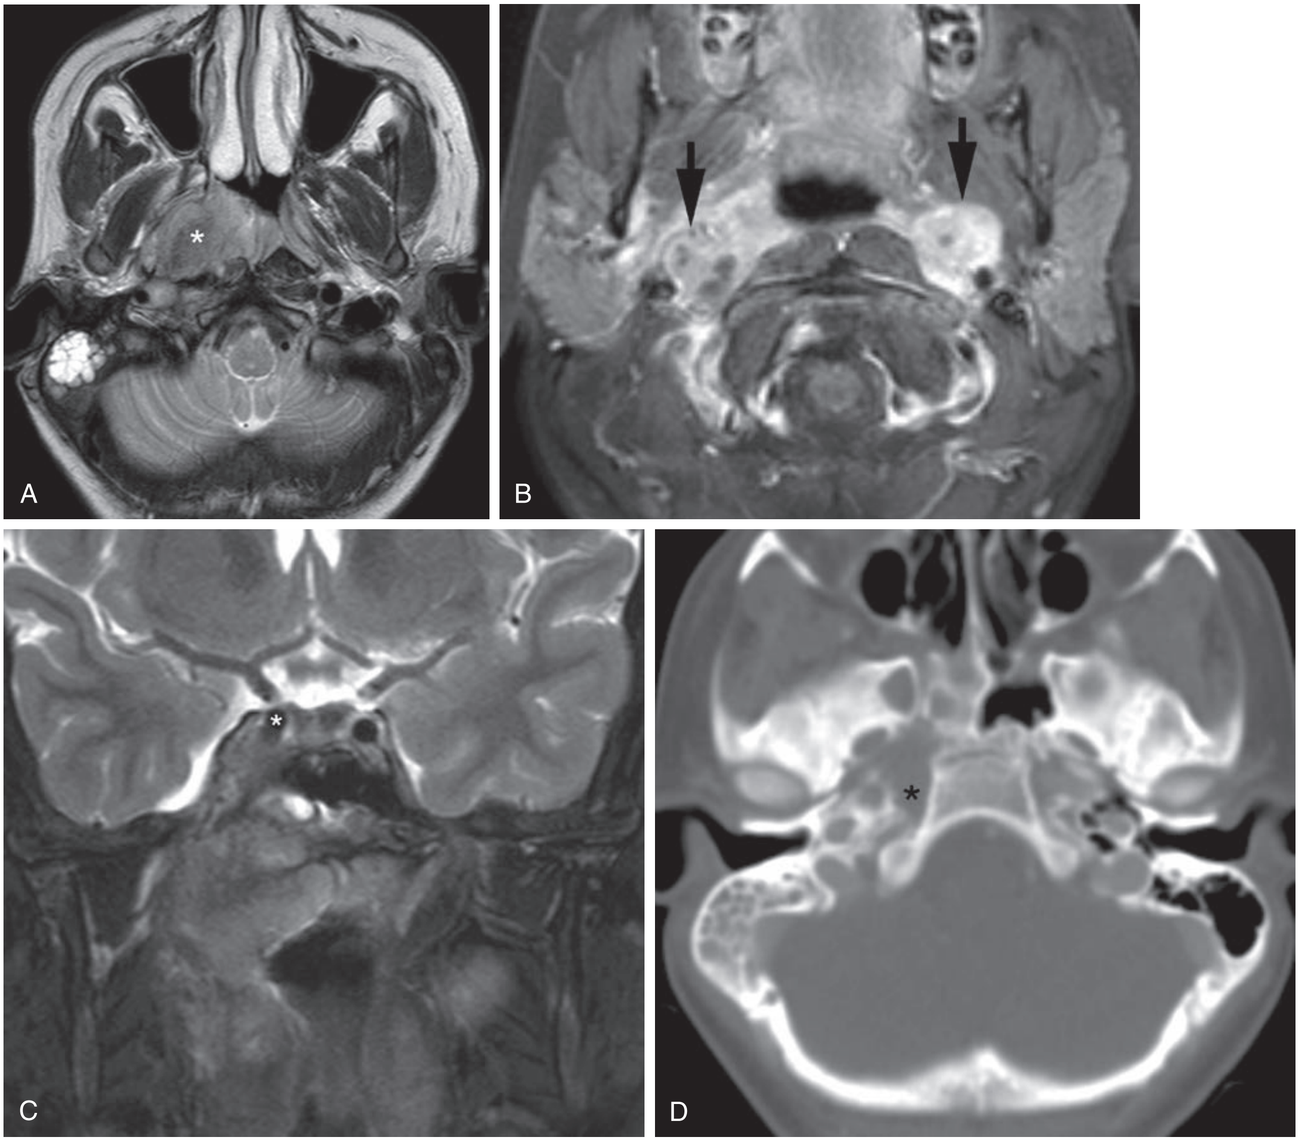

**Figure 16.4. Nasopharyngeal carcinoma in a 13-year-old boy.** (A) Axial T2-weighted MR image shows asymmetric adenoid enlargement *(asterisk)* and right mastoid fluid. (B) Axial contrast-enhanced fat-saturated T1-weighted MR image more inferiorly, there are abnormal necrotic retropharyngeal nodes *(arrows)*. Notice the skull base erosion posteromedial to right foramen ovale.

(Fig. 16.7). Less commonly, metastatic cervical lymphadenopathy is visualized.

## BENIGN TUMORS

### Juvenile Angiofibroma

Juvenile angiofibroma (also called *juvenile nasopharyngeal angiofibroma*) is a benign, highly vascular, locally aggressive neoplasm that occurs almost exclusively in males. It typically occurs in adolescents with a median age of 15 years. Juvenile angiofibroma is a biphasic tumor that has vascular and fibroblastic components. The etiology for this tumor is debated, but a variety of growth factors (including vascular endothelial growth factor) and chromosomal alterations are thought to play a role.[11] One theory is that a persistent fetal vascular malformation or hamartoma grows in response to hormonal surges that occur during puberty. It has an increased incidence in patients with the familial adenomatous polyposis syndrome.[12] This tumor originates in the posterolateral nasal cavity, specifically at or near the sphenopalatine foramen. It has the propensity to grow into the pterygopalatine fossa, where it can extend intracranially or gain access to the masticator space or orbit. At imaging there is a soft tissue mass in the posterolateral nasal cavity with variable extension into the pterygopalatine fossa. Surrounding bone can be remodeled or destroyed. It has variable signal on T2-weighted MRI, sometimes appearing hypointense, presumably from the fibrous content. Punctate or serpentine flow voids may be seen within the tumor. It has vivid enhancement on postcontrast images (Fig. 16.8, and see Fig. 8.27). Angiography shows an intense capillary tumor blush with vascular supply typically from internal maxillary and ascending pharyngeal branches of the external carotid artery, and occasionally from internal carotid artery

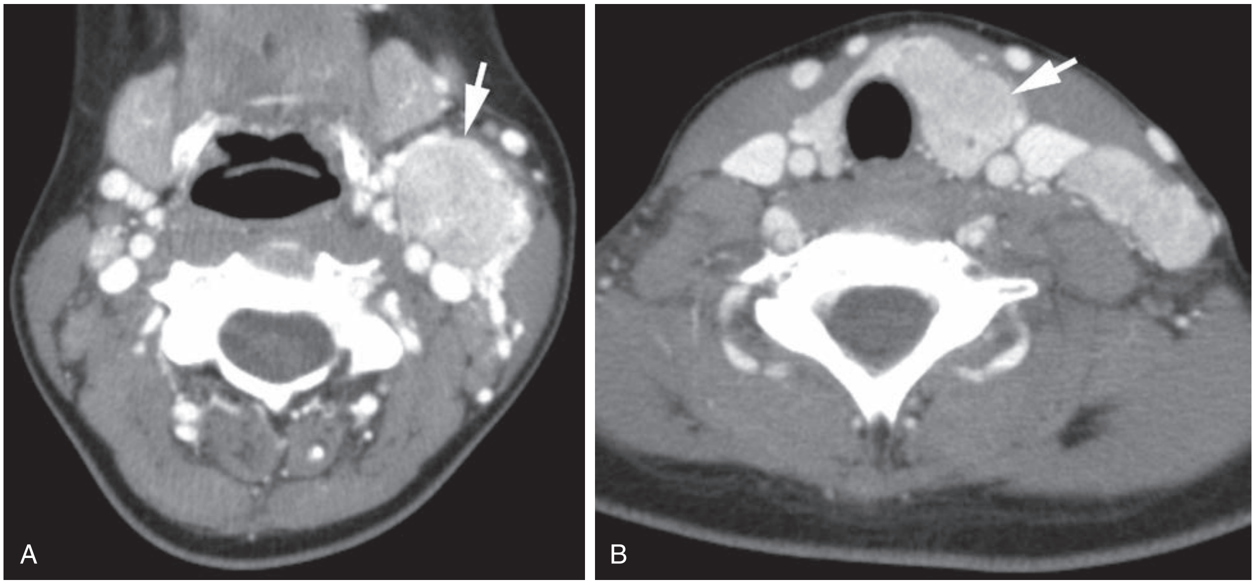

**Figure 16.5. Papillary thyroid carcinoma with nodal metastases in a 13-year-old girl.** (A) Axial contrast-enhanced CT image at the site of the palpable abnormality shows a hyperdense mass *(arrow)* situated between the submandibular gland and the sternocleidomastoid muscle. (B) More inferiorly, there is abnormal enlargement of the left thyroid lobe *(arrow)* and additional hyperdense cervical lymphadenopathy.

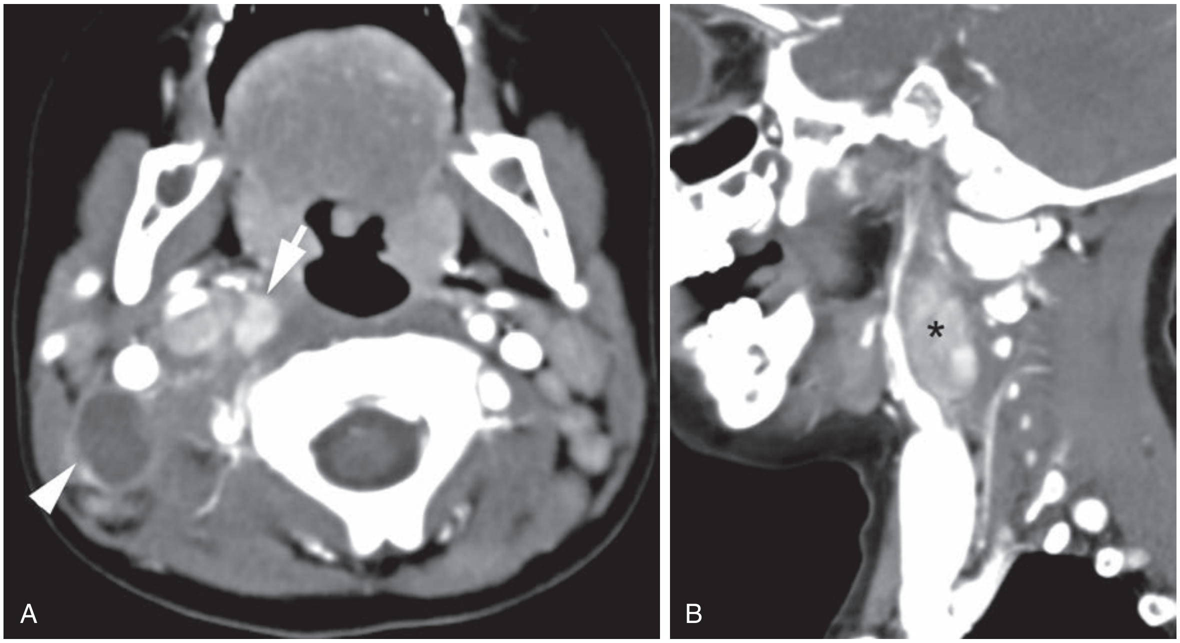

**Figure 16.6. Primary cervical neuroblastoma and metastatic node in a 3-year-old girl.** (A) Axial contrast-enhanced CT image shows a cystic level II node *(arrowhead)*. More anteriorly, there is a solid mass medial to the vessels of the carotid space *(arrow)*. (B) Sagittal reformatted CT image shows anterior displacement of the common and internal carotid artery by the lesion *(asterisk)*.

(ICA) branches. Treatment includes preoperative embolization followed by surgical resection. Residual tumor supply from ICA branches after embolization upstages these tumors and predicts a more difficult surgical resection.[13]

## Nerve Sheath Tumors

Neurofibromas are benign peripheral nerve sheath tumors that are rare in children in the absence of NF-1. In the setting of NF-1, neurofibromas can be located in the skin, along peripheral nerves subjacent to the skin, or along spinal nerve roots. Plexiform neurofibromas, a major cause of disfigurement and morbidity in patients with NF-1, extend longitudinally along a nerve and involve multiple nerve fascicles. Both lesions comprise a mixture of Schwann cells, fibroblasts, perineural cells, and mast cells. The Schwann cells may be abnormal in NF-1 patients, and they can have angiogenic and invasive properties in plexiform neurofibromas.[14] At imaging, these lesions are hypodense on CT. Neurofibromas

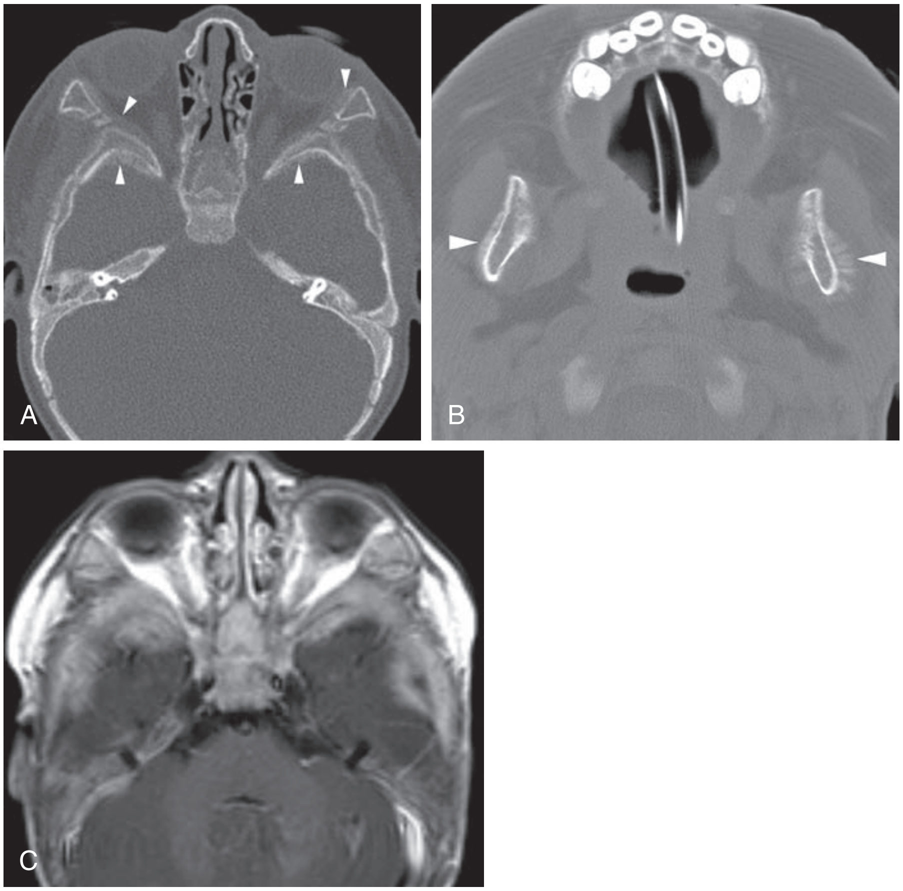

**Figure 16.7. Metastatic neuroblastoma in an 8-month-old boy.** (A and B) Axial noncontrast CT images depict abnormal aggressive appearing periosteal reaction lining orbits, middle cranial fossa, and mandibular rami bilaterally *(arrowheads)*. (C) Axial contrast-enhanced T1-weighted MR image shows that these regions have abnormal thick enhancement.

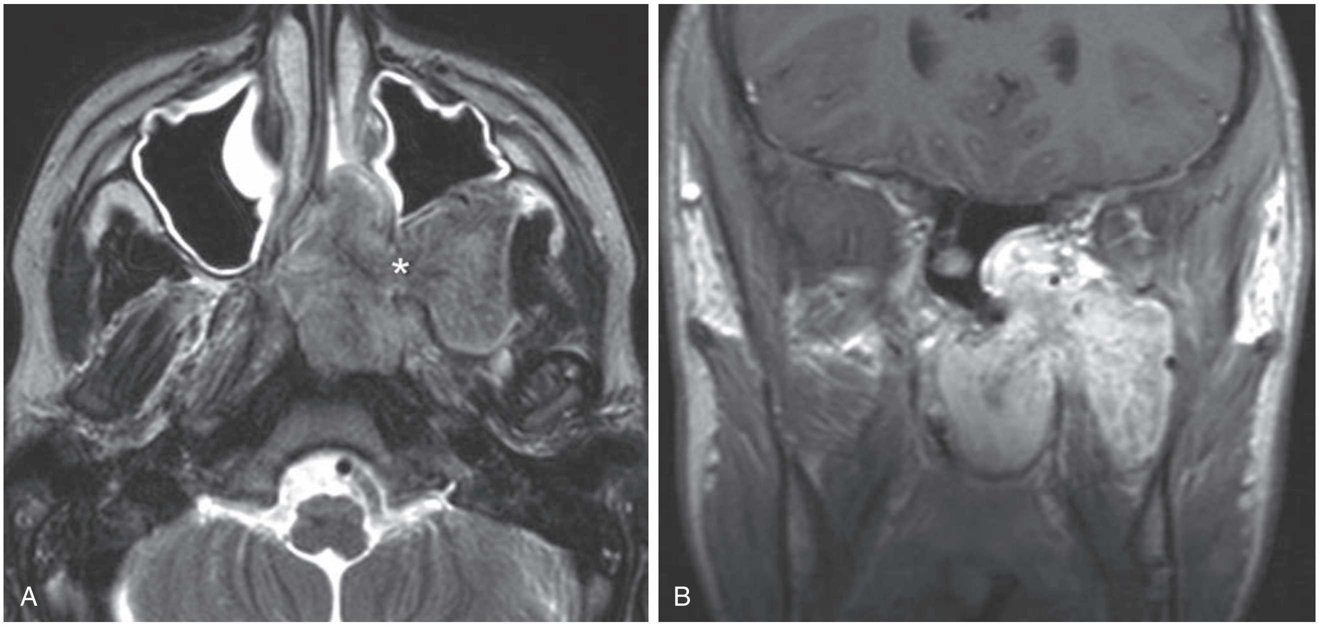

**Figure 16.8. Juvenile angiofibroma in a 14-year-old boy.** (A) Axial fat-saturated T2-weighted MR image shows a hypointense mass in the left posterior nasal cavity and nasopharynx. (B) Coronal contrast-enhanced fat-saturated T1-weighted MR image shows intense enhancement of the mass. There is involvement of the left pterygopalatine fossa and extension to the masticator space via the pterygomaxillary fissure (*asterisk* in A).

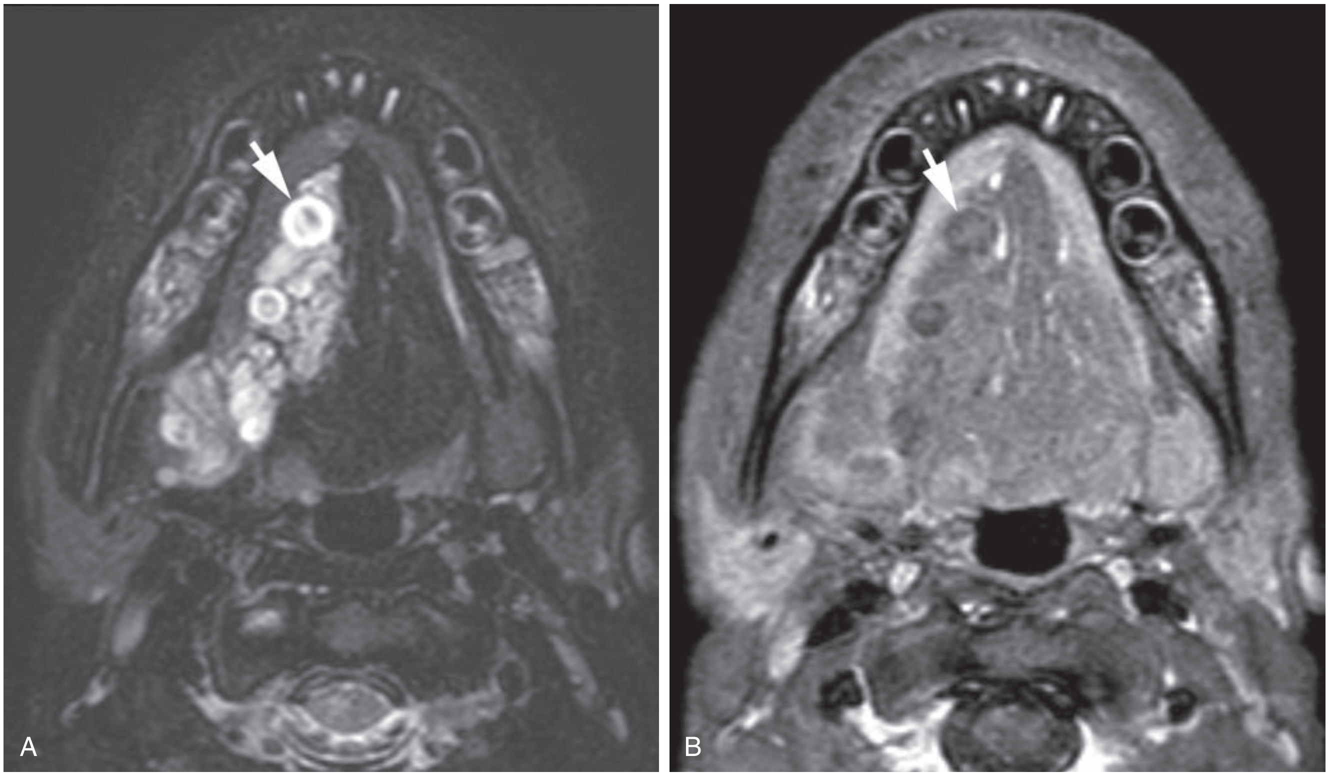

**Figure 16.9. Plexiform neurofibroma in a 7-year-old boy with NF-1.** (A) Axial fat-saturated T2-weighted and (B) axial contrast-enhanced fat-saturated T1-weighted MR images demonstrate a heterogeneous elongated lesion of the right sublingual and submandibular space. Note the "target sign" with central T2 hypointensity and enhancement *(arrows)*.

are well-circumscribed enhancing lesions. Plexiform neurofibromas are more extensive and can appear infiltrative. At MRI, the target sign is frequently seen in plexiform neurofibromas, in which central portions of the lesion have T2 hypointensity and postcontrast enhancement (Fig. 16.9). Malignant peripheral nerve sheath tumors (MPNST) are highly malignant lesions that usually arise from a preexisting plexiform or nodular fibroma in patients with NF-1. These tumors can also arise in patients who are otherwise healthy with up to 50% of MPNST occurring in children without NF-1.[15] MPNST are rapidly enlarging lesions that demonstrate enhancement and FDG avidity.

Schwannomas are rare in pediatrics, even in the setting of neurofibromatosis type 2, where they tend to arise after the second decade. These lesions demonstrate contrast enhancement and may have cystic components.

## Teratoma

Teratomas, although rare, are the most common congenital tumor of the head and neck. This tumor is composed of tissue foreign to the site of origin that histologically contains all three germ cell layers.[16] The World Health Organization classification designates these tumors as mature teratomas, immature teratomas, and teratomas with malignant transformation.[10,17] Compared with adults, pediatric teratomas are less often malignant. In the head and neck, these tumors can be cervical, naso/oropharyngeal, facial, or orbital in location. The term epignathus is applied to teratomas of the oropharynx and oral cavity in neonates. Teratomas may be diagnosed prenatally with ultrasound or MRI. At imaging, these tumors are typically heterogeneous, containing cystic and solid components. Calcifications and fat can be appreciated on both CT and MRI. Treatment is surgical resection. If airway compression by the lesion is demonstrated prenatally, the ex-utero intrapartum procedure is preferred, a technique in which the airway is secured during elective cesarean section while the neonate remains on placental support.

## Hemangioma

Infantile hemangioma is the most common vascular tumor of childhood and is prevalent in the head and neck region. These lesions are more commonly encountered in girls. Infantile hemangioma is not present at birth, becoming apparent in the first days to months of life and then undergoing a proliferative phase during the first year of life. This is followed by a period of involution that typically begins after 1 year and lasts a variable number of years. Glucose transporter 1 (GLUT1) and placenta-associated vascular antigens are highly expressed in the endothelial cells of infantile hemangiomas during both the proliferative and involuting phase. At imaging, these lesions have a characteristic appearance, having a lobulated contour and intense color Doppler flow on ultrasound and contrast enhancement on CT and MRI. Flow voids are typically present, visualized on both T1- and T2-weighted magnetic resonance (MR) images (Fig. 16.10). Children with PHACES association (*P*osterior fossa malformations, *H*emangioma, *A*rterial anomalies, *C*oarctation of the aorta, *E*ye abnormalities, *S*ternal malformation, and paraumbilical raphe) have hemangiomas that are large and plaquelike, or regional hemangiomas involving the face, sometimes with a beardlike distribution.[10,18] Hemangiomas are treated conservatively given the expected involution in most cases. If there is compression of vital structures or potential for disfigurement, oral propranolol is the treatment of choice.[19,20]

The much rarer congenital hemangioma proliferates in utero and then has a variable postnatal involution. They appear to be

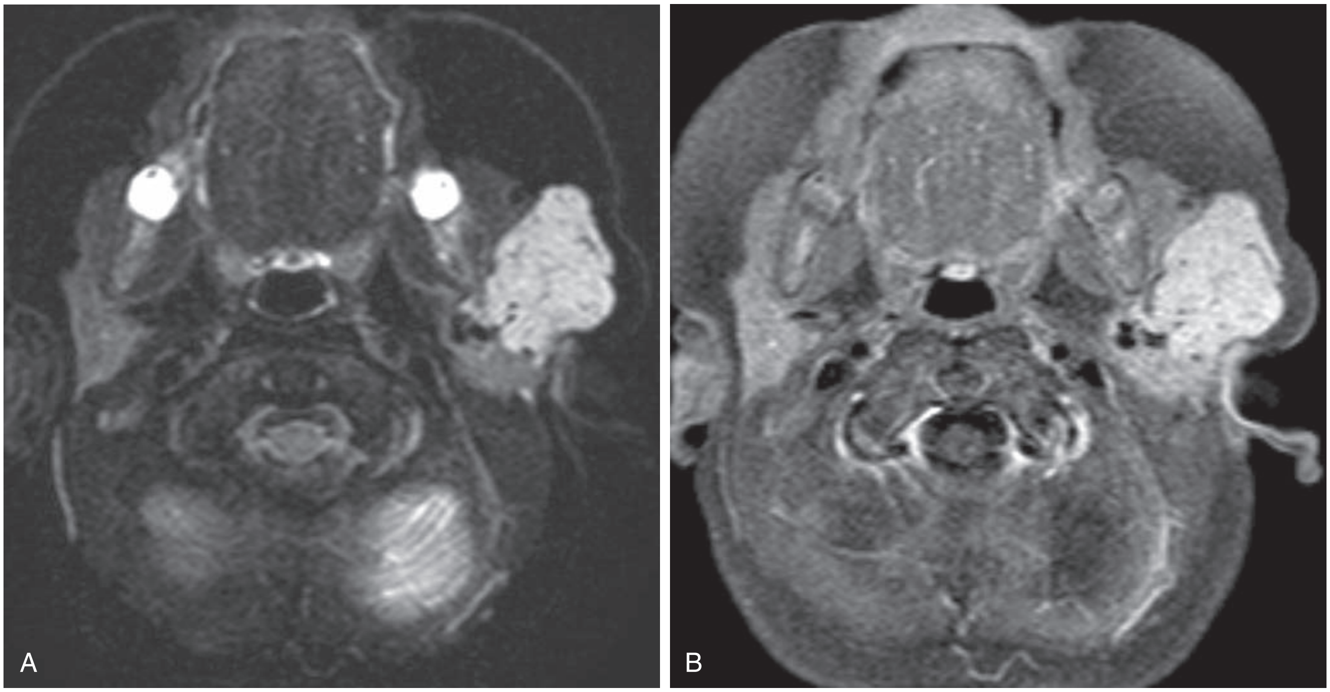

**Figure 16.10. Infantile hemangioma in a 2-month-old girl.** (A) Axial fat-saturated T2-weighted and (B) axial contrast-enhanced fat-saturated MR images show a hyperintense and enhancing lobular mass infiltrating and enlarging the left parotid gland. Flow voids are visualized within the mass.

hybrid lesions histopathologically, having features of both vascular tumor and malformation. Those that involve completely are termed *RICH* (rapidly involuting congenital hemangioma) and those that involute incompletely are termed *NICH* (noninvoluting congenital hemangioma). Cases of RICH evolving into NICH have been reported.[21] Surgical resection is the treatment of choice in NICH cases in which there is functional impairment or a cosmetic concern.

## KEY POINTS

- Lymphoma and rhabdomyosarcoma are the most common pediatric head and neck malignancies.
- Both NHL and HL present with cervical adenopathy, but HL tends to be unilateral.
- Isolated thyroid nodules in children are more likely to be malignant than those in adults.
- Neurofibromas almost always are in the setting of NF-1 and can degenerate into MPNST.
- Infantile hemangioma is the most common vascular tumor of childhood and usually involves in during the first few years of life.

# 17 Thyroid and Parathyroid

Hollie A. Lai

## THYROID GLAND

### Embryology

The name "thyroid" is derived from the Greek word for *shield* due to the gland's shape and relationship with the laryngeal thyroid cartilage. The human thyroid gland has a dual embryonic origin.[1–3] The two thyroid cell types, follicular cells (thyrocytes) and parafollicular (C-cells), are derived from all three germ cell layers.[3] The most abundant cells, the follicular cells, arise from the thyroid anlage. The development of the thyroid gland begins when a median epithelial proliferation appears in the floor of the primitive pharynx between the developing tuberculum impar and copula of the tongue anlage, which is first visible as a bud around 24 days gestation.[4] This thickening, known as the median or thyroid anlage, soon forms a ventral outgrowth known as the thyroid diverticulum. The diverticulum is initially hollow but later becomes solid. The progenitor follicular cells continue to proliferate distally and then begin to proliferate laterally, which leads to the characteristic bilobed appearance of the gland connected by an isthmus. While the thyroid cells continue to proliferate, the embryo elongates and the tongue grows. As this happens, the developing thyroid gland descends anterior to the hyoid bone and larynx forming the thyroglossal duct. Because of the close association of the developing thyroid gland and embryonic heart, it is thought that the descent of the heart results in the thyroid gland being pulled.[3,5] The thyroid gland remains connected to the tongue by the thyroglossal duct. At approximately 7 weeks gestation, the thyroid gland has reached its final site in front of the trachea and the thyroglossal duct has disappeared.[4] The original opening of the thyroglossal duct persists as a vestigial pit called the foramen cecum[6,7]. 15% to 75% of people have a pyramidal lobe,[8] which is derived from the lower part of the thyroglossal duct and extends upwards from the isthmus. At about the time the thyroid gland reaches its final position, it merges with the two lateral anlagen or ultimobranchial bodies, resulting in the incorporation of the C-cells (parafollicular cells) into the thyroid gland. The ultimobranchial bodies are a pair of transient embryonic structures derived from the endoderm of the fourth pharyngeal pouch and the ectoderm of the fifth pharyngeal pouch.[9] The C-cell precursors migrate from the neural crest[10] bilaterally to the fourth pharyngeal pouches and become localized in the ultimobranchial bodies. As the cells of the thyroid anlage and the ultimobranchial bodies migrate from their respective sites of origin and complete the merging process, they disappear as individual structures and the cells contained within them disperse in the thyroid gland. The follicular cells continue to organize the thyroid follicles, where the C-cells scatter within the interfollicular space.[4] Remnants of the ultimobranchial bodies, or solid cell nests, can be seen postnatally and are usually located in the middle third of the thyroid lateral lobes.[11]

### Physiology

The thyroid gland's primary function is to produce hormones that play a vital role in regulating many cellular and physiologic activities such as growth, development, and metabolism.

The thyroid gland synthesizes and secretes two hormones, thyroxine ($T_4$) and triiodothyronine ($T_3$). The synthesis and secretion of these hormones is closely regulated through a complex feedback mechanism known as the hypothalamic-pituitary-thyroid-axis.

The hypothalamus synthesizes and secretes thyrotropin-releasing hormone (TRH),[12–14] which is carried to the pituitary gland by the hypothalamic-pituitary portal venous system. Once in the pituitary gland, TRH stimulates the synthesis and secretion of thyrotropin (thyroid-stimulating hormone, TSH) by the thyrotrophs in the anterior pituitary gland. TSH binds to its receptor in the thyroid gland, stimulating the production and secretion of $T_4$ and $T_3$ within the thyroid follicular cells. Thyroid secretion and serum concentrations of $T_4$ and $T_3$ are maintained by a negative feedback loop involving inhibition of TSH and TRH secretion by $T_4$ and $T_3$.[15,16]

Iodide is actively transported into the follicular cells from the circulating plasma by the sodium-iodide symporter (NIS) at the basolateral membrane.[17–21] Thyroid peroxidase (TPO) oxidizes iodide into its chemically active form. Thyroglobulin in the follicular lumen serves as a matrix for the synthesis of $T_4$ and $T_3$. First, TPO catalyzes the iodination of selected tyrosyl residues in thyroglobulin in a process known as iodination and organification. This results in the formation of mono- and diiodotyrosines (MIT, DIT). TPO then catalyzes a coupling reaction in which two iodotyrosines are coupled to form $T_4$ or $T_3$. Iodinated thyroglobulin is stored as colloid in the follicular lumen. When needed, thyroglobulin is internalized into the follicular cell by micro- and macropinocytosis and digested in lysosomes. Subsequently, $T_4$ (80%) and $T_3$ (20%) are released into the bloodstream. MIT and DIT are deiodinated, and released iodide is recycled for hormone synthesis.[3]

C-cells produce thyrocalcitonin, which is important in calcium homeostatis.

### Anatomy

The thyroid gland is composed of a right and left lobe usually joined by an isthmus anteriorly. The thyroid gland extends superiorly to the level of the thyroid cartilage and inferiorly to the level of the fifth or sixth tracheal ring. Occasionally, there is an extra lobe called the pyramidal lobe. This lobe extends superiorly from the isthmus at the midline.

The thyroid gland is located in the visceral space of the infrahyoid neck, anterior and lateral to the trachea and posterior to the infrahyoid strap muscles. Anterolaterally to the thyroid gland are the sternocleidomastoid muscles. The carotid space, containing the carotid arteries and jugular veins, is located posterolaterally. Posteromedially to the thyroid gland are the tracheoesophageal grooves containing the recurrent laryngeal nerves, paratracheal lymph nodes, and parathyroid glands.

The middle layer of the deep cervical fascia surrounds the visceral space and ensheaths the thyroid gland. The fascia condenses to form the suspensory ligament of Berry, affixing the thyroid gland to the trachea and larynx, causing the thyroid gland to move with the larynx during deglutition. A thin fibrous capsule also covers the thyroid gland. From this true capsule, septae extend into the gland dividing the gland into lobes and lobules.

## Abstract:

The signs and symptoms can be similar in pediatric and adult thyroid and parathyroid disease however there are important differences. This chapter discusses the embryology, anatomy, and physiology of these glands and the specific pediatric diseases associated with them. Imaging and treatment option are explored to help the clinician better manage the pediatric patients afflicted with thyroid and parathyroid disorders.

## Keywords:

Pediatric thyroid parathyroid imaging radiology nuclear medicine

The lobules are each made up of multiple follicles. The follicles consist of an outer layer of follicular cells, which enclose a lumen that contains thyroglobulin-rich colloid. Each thyroid follicle is surrounded by a basement membrane. C-cells are found within the basement membrane and are in contact with the follicular cells, but they do not abut the lumen. Follicular cells secrete thyroid hormones and C-cells secrete thyrocalcitonin.[3,22]

The thyroid gland is highly vascular being supplied by paired superior thyroidal arteries (first anterior branches of the external carotid arteries) and inferior thyroidal arteries (branches of the thyrocervical trunks that originate from the subclavian arteries). The thyroidea ima is an inconstant single vessel that has a variable origin but usually arises directly from the aortic arch or innominate artery and helps supply the inferior thyroid gland. Venous drainage of the thyroid gland is via the superior and middle thyroid veins that drain to the internal jugular veins and the inferior thyroid veins that often join to form a single trunk draining to the left brachiocephalic vein. Lymphatic drainage is extensive and multidirectional. The thyroid gland is innervated by the vagus nerve and the cervical sympathetic neural plexus.[22]

## Normal Findings

Ultrasonography (US) is a usually one of the first choices of imaging in pediatrics because it is noninvasive, readily available, and does not utilize radiation. A normal thyroid gland will have homogenous echotexture that is slightly hyperechoic relative to adjacent neck muscles.[23,24] Colloid follicles are commonly seen as small (less than 3 mm in diameter) anechoic cystic areas. Occasionally, the follicles contain inspisated colloid, which appear as punctate echogenic foci (Fig. 17.1).[25]

Morphologic and functional information about the thyroid gland can be achieved with nuclear scintigraphy. Thyroid scintigraphy is performed using intravenous Tc-99m pertechnetate ($^{99m}$TcO4) or oral Na I-123 (I$^{123}$) (Table 17.1). Because of the large radiation dose to the thyroid gland (approximately 1–3 rads per uCi administered), I$^{131}$ is not used for routine diagnostic imaging.[26,27] The normal thyroid gland shows homogenous radiopharmaceutical uptake and distribution in both lobes. The isthmus of the thyroid gland often demonstrates slightly less activity than the right and left thyroid lobes. Normal I$^{123}$ 24-hour uptake ranges from 10% to 30%.

Computed tomography (CT) and magnetic resonance imaging (MRI) provide important adjunctive anatomic information by delineation of lesions within the thyroid gland, detection of lymph node metastases, and detection of thyroid disease extension into adjacent neck structures. The anatomic information provided by CT and MRI is also valuable in guiding the surgical approach. The normal thyroid gland (due to its iodide content) has a density of approximately 80 to 100 HU on CT. In fact, a well-visualized gland usually indicates a normally functioning thyroid. Conversely, a poorly seen gland correlates with poor thyroid function. The injection of iodinated contrast material diffusely and homogenously enhances the gland.[22] Remember that the use of iodinated contrast agents will alter radioactive iodine uptake, whereas gadolinium contrast material used for MRI will not. The normal thyroid gland shows homogenous signal intensity slightly greater than muscle on precontrast T1-weighted images. On T2-weighted images, the thyroid gland is relatively hyperintense to muscle. Following contrast administration, the gland enhances diffusely and homogenously.

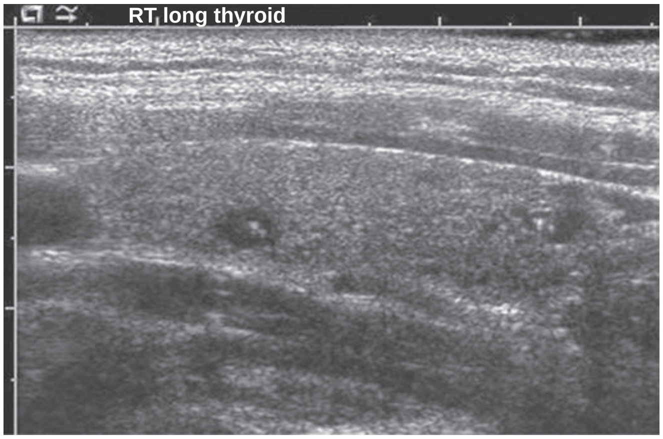

**Figure 17.1. Normal thyroid ultrasound.** Small anechoic foci with a central hyperechoic focus represent colloid follicles, which are a normal finding.

## Hypothyroidism

***Overview.*** Hypothyroidism is the most common disturbance of thyroid function in children. It can be congenital (Box 17.1) or acquired in childhood or adolescence (Box 17.2). Whatever its cause, hypothyroidism can have deleterious effects. Untreated congenital hypothyroidism in early infancy results in profound retardation of growth and neurocognitive development (cretinism). Untreated hypothyroidism in older children leads to growth failure as well as slowed metabolism and impaired memory.

### Congenital Hypothyroidism

***Overview.*** Hypothyroidism in the newborn can be permanent or transient. Congenital hypothyroidism is a condition in which lower than normal thyroxin (T$_4$) causes retardation of growth and neurocognitive development if left untreated. The incidence of congenital hypothyroidism in the United States has dramatically increased over the last 2 decades,[28] from 2.9 cases per 10,000 births in 1991 to nearly 4 cases per 10,000 births in 2000.[29]

***Etiologies, Pathophysiology, and Clinical Presentation.*** The majority of cases of primary congenital hypothyroidism are caused by thyroid gland dysgenesis (see Table 17.2). Thyroid dysgenesis refers to a developmental defect of thyroid morphogenesis. There are three types: ectopia, aplasia (athyrosis), and hypoplasia.

Dyshormonogenesis is the second largest cause of primary congenital hypothyroidism which is often inherited as an autosomal recessive trait. Dyshormonogenesis is an abnormality of one or more of the enzymes involved in the pathway of thyroid hormone synthesis and secretion. Most inborn errors of thyroid hormone synthesis are caused by defects in iodide organification with the most common defect being TPO deficiency. This results in a failure of iodide oxidation which is necessary for organification. A small percentage of infants with congenital hypothyroidism will have hypothalamic-pituitary hypothyroidism or thyroid-stimulating hormone resistance, whereas the remainder will have a transient form of congenital hypothyroidism.

Less than 5% of congenital hypothyroidism patients are diagnosed clinically at birth; most are identified by newborn screening. Newborn screening involves measuring TSH and T$_4$ concentrations. T$_4$ concentrations are decreased and TSH concentrations are elevated in patients with congenital hypothyroidism, except in central hypothyroidism where the TSH is not elevated. The laboratory abnormalities tend to be more marked in cases of thyroid aplasia than in thyroid ectopia. Patients with transient hypothyroidism will also have elevated TSH concentrations and low or normal T$_4$ concentrations that subsequently normalize.

***Imaging.*** Imaging is not routinely used to diagnose congenital hypothyroidism. The most recent recommendations discuss thyroid imaging in congenital hypothyroidism as optional because of controversy regarding the risk-benefit ratio of early thyroid scanning

**TABLE 17.1** Thyroid Scintigraphy

| | Sodium Iodide (Capsule or Liquid) (1-23I) | Tc99m-Pertechnatate (99mTcO4) | Perchlorate Discharge or Washout |
|---|---|---|---|
| Advantages | Better visualization of retrosternal thyroid tissue<br>Yields better images when uptake is low | Less expensive<br>More readily available<br>More rapid examination<br>Can be performed while the patient is on thionamides | Can determine organification defects |
| Disadvantages | Higher cost<br>Longer imaging times<br>Patient must be off thionamides | Trapped, but not organified<br>Activity in esophagus or vascular structures may be misleading<br>Poor image quality when uptake is low | Cannot detect enzymatic defects beyond the point of organification |
| Dose | 1.5 μCi/kg<br>Minimum dose = 25 μCi<br>Maximum dose = 100 μCi | 0.1 mg/kg<br>Minimum dose = 0.5 mCi<br>Maximum dose = 1.0 mCi | Same dosing as I-123<br>Potassium perchlorate:<br>Infant = 10 mg/kg<br>Child = 400 mg<br>Adult = 1000 mg |
| Route of administration | Oral | Intravenous | Oral |
| Time until imaging | 4–6 hours<br>24 hours (for uptake determination) | 20–30 minutes | Do I-123 thyroid uptake at 3 hours. If thyroid appears normal and uptake >10% give perchlorate<br>Do second thyroid uptake 60–90 minutes after perchlorate administration |
| Radiation dosimetry (5 year old)[27]<br>Administered activity<br>Critical organ<br>Effective dose equivalent | Assuming 25% uptake<br>0.1–0.3 MBq<br>0.003–0.01 mCi/kg<br>Thyroid<br>16 mGy/MBq<br>59 rad/mCi<br>0.54 mSv/MBq<br>2.0 rem/mCi | 1.8–9.2 MBq/kg<br>0.05–0.25 mCi/kg<br>Upper large intestine<br>0.21 mGy/MBq<br>0.78 rad/mCi<br>0.04 mSv/MBq<br>0.15 rem/mCi | Same as I-123 |

## BOX 17.1 Causes of Congenital Hypothyroidism

**PRIMARY (THYROID GLAND)**

Thyroid dysgenesis (80%)
- Ectopia (75%)
- Aplasia or athyrosis (25%)
- Hypoplasia (rare)

Dyshormonogenesis (15%–20%)
- Peroxidase deficiency (most common)
- Other deficiencies (less common)
- Iodide transport defect
- Iodotyrosine deiodinase defect

**SECONDARY (PITUITARY) AND TERTIARY (HYPOTHALAMUS)**

Pituitary and hypothalamic defects (uncommon)

**MISCELLANEOUS**

Thyroid-stimulating hormone resistance

Transient congenital hypothyroidism
- Functional immaturity-common in premature infants
- Transplacental transfer of maternal medication
- Transplacental transfer of maternal thyroid-blocking antibodies
- Maternal antithyroid medications
- Iodine deficiency
- Iodine excess

of infants with suspected hypothyroidism.[30] There are also clinicians who do not order imaging studies because they believe the results would not alter their management of congenital hypothyroidism.

Diagnostic studies for a patient with congenital hypothyroidism can include US and thyroid scintigraphy with $^{123}$I or $^{99m}$TcO4. Use of both US and thyroid scintigraphy has been shown to provide a more complete depiction of congenital hypothyroidism in the newborn than either study performed alone.[31]

The role of US is to identify the presence or absence of thyroid tissue, distinguish rudimentary glands from anatomically normal thyroid glands, and identify an enlarged gland or goiter.

$^{99m}$TcO4 or $^{123}$I can be used to help determine if the cause of hypothyroidism may be due to thyroid dysgenesis (see Table 17.1). In patients with thyroid agenesis, the examination fails to demonstrate functional thyroid tissue. It is important that the images include the oropharynx and upper neck as well as the upper portion of the chest so that an ectopic location of the thyroid gland can be excluded.

$^{99m}$TcO4 scintigraphy demonstrates a round or oval area of uptake in the midline of the upper neck in most cases of ectopia (Fig. 17.2). The ectopic gland may occupy a lingual (most common), sublingual, or prelaryngeal location. Mediastinal and lateral locations are rare. Functional thyroid tissue may be identified in more than one location, most commonly in the lingual and sublingual regions. It is unusual to identify thyroid tissue in its normal location at the base of the neck in the presence of an ectopic gland. Usually patients with an ectopic thyroid gland will have hypothyroidism. Unusual cases do occur in which the ectopic gland is capable of secreting sufficient thyroid hormone such that hypothyroidism is not apparent on neonatal screening. These patients often present with signs of ectopia later in life when the hyperstimulated gland enlarges and causes local symptoms.

$^{99m}$TcO4 scintigraphy in cases of dyshormonogenesis will demonstrate a normally positioned thyroid gland that may or may not be enlarged (e-Fig. 17.3). If dyshormonogenesis is suspected, a perchlorate washout test may be performed. Perchlorate is actively transported into the thyroid gland similar to iodide but with a greater affinity for the transporter and is therefore a competitive inhibitor of the thyroid iodide trap. During unimpaired thyroid hormonogenesis, iodide entering the thyroid gland is rapidly oxidized and iodinates tyrosine, forming MIT and DIT, with subsequent coupling of MIT and DIT to generate $T_4$ and $T_3$. Intrathyroid deiodination of the iodinated tyrosines and thyronines results in a very small pool of thyroidal inorganic iodide. Any congenital or acquired condition associated with a defect in iodide organification may yield a higher intrathyroidal inorganic iodide concentration. The perchlorate discharge/washout test is a means of estimating the size of this intrathyroidal "free" iodide pool, thereby detecting and roughly quantifying disturbances in iodide organification. The perchlorate discharge/washout test is performed by giving the patient an oral dose of $^{123}$I followed by a dose of perchlorate and measuring the "washout" (see Table 17.1). The perchlorate test will be negative in patients who do not have an organification defect, but also when enzymatic defects are present in the synthetic pathway beyond the point of organification.[32–34]

***Treatment.*** Levothyroxine ($T_4$) is the treatment of choice for children with hypothyroidism. The goals of the treatment are to restore normal growth and development.

## Hypothyroidism in Children and Adolescents

### Chronic Autoimmune (Hashimoto) Thyroiditis

***Overview.*** There are many causes of acquired hypothyroidism in the pediatric population (see Table 17.2) Chronic autoimmune (Hashimoto) thyroiditis is by far the most common cause of acquired

**BOX 17.2** Causes of Hypothyroidism in Children and Adolescents

**PRIMARY (THYROID GLAND)**

Chronic autoimmune (Hashimoto) thyroiditis (most common cause in the United States, increased incidence in some chromosomal abnormalities and syndromes)
Iodine deficiency (most common cause worldwide)
Iodine excess
External radiation therapy
Radioactive iodine therapy
Thyroidectomy
Goitrogen foods
Medications (e.g., thionamides, lithium, anticonvulsants)
Late-onset congenital hypothyroidism
- Thyroid dysgenesis
- Inborn errors of thyroid metabolism

**SECONDARY (PITUITARY) AND TERTIARY (HYPOTHALAMUS)**

Central hypothyroidism caused by:
- Craniopharyngioma and other tumors pressing on hypothalamus or pituitary
- Septo-optic dysplasia
- Infiltrative processes
- Langerhans cell histiocytosis
- Neurosurgery
- Cranial irradiation
- Head trauma

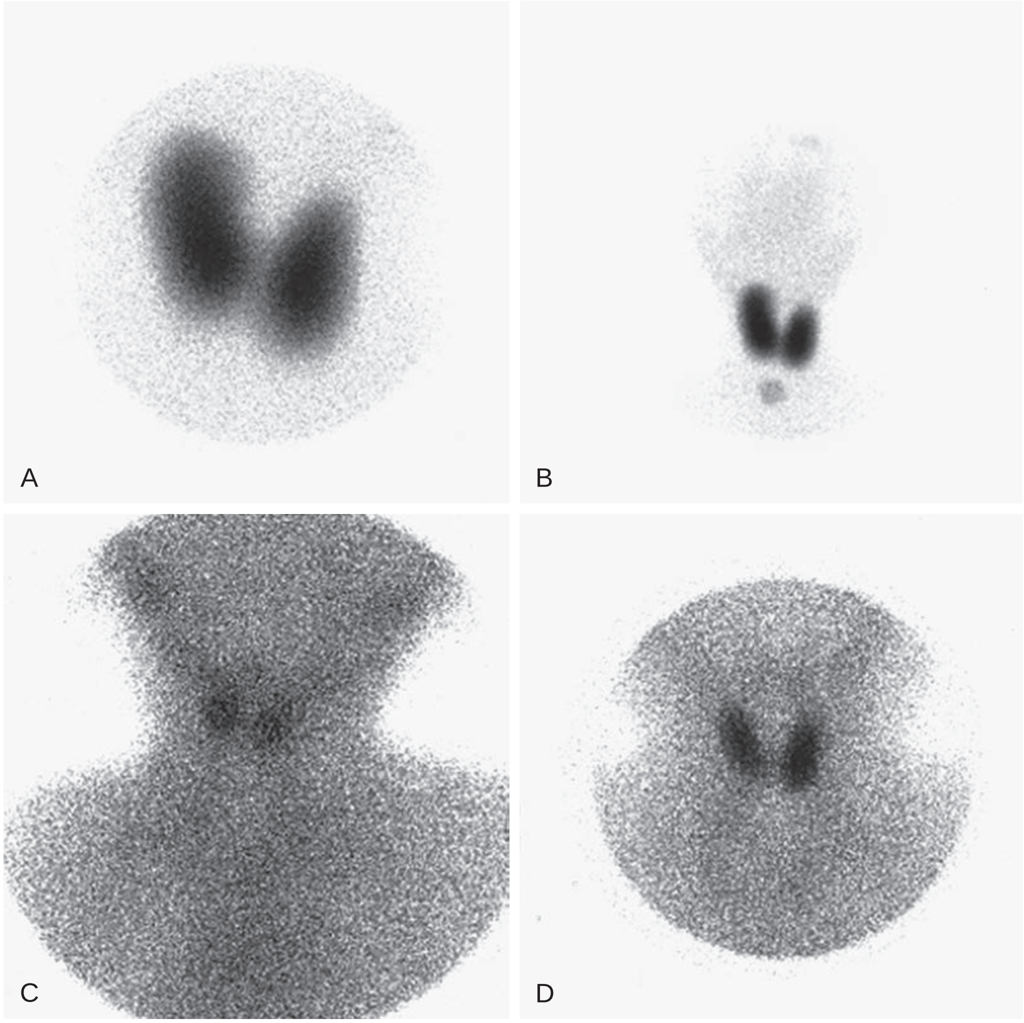
**MISCELLANEOUS**

Thyroid hormone resistance
Infection (usually not permanent)
Hemangiomas of the liver

**TABLE 17.2** Causes of Hyperthyroidism and Thyrotoxicosis in Children and Adolescents

| Name | Synonyms | Mechanism of Hyperthyroidism/ Thyrotoxicosis | Laboratory Tests | RAIU Appearance on Scintigraphy | Imaging Appearance of Thyroid Gland |
|---|---|---|---|---|---|
| **HYPERTHYROIDISM, THYROID GLAND HYPERFUNCTION (INCREASED SYNTHESIS OF THYROID HORMONE)** | | | | | |
| Graves disease | Hyperthyroid goiter<br>von Basedow disease | TRS-Ab | Low TSH<br>Elevated free $T_4$<br>Elevated $T_3$<br>High thyroglobulin<br>TSI positive<br>TRS-Ab positive<br>TPO-Ab positive or negative<br>TBII positive | Elevated, often >80%<br>Diffuse increased uptake | Ultrasonography: Enlarged gland; hypoechoic but may be normal; may be nodular; increased vascularity, "thyroid inferno"[51]<br>CT and MRI: Nonspecific findings; enlarged gland; avid, diffuse enhancement<br>Decreased attenuation on noncontrast CT reflecting decrease in iodine concentration |
| Multinodular goiter | Toxic multinodular goiter<br>Adenomatous goiter<br>Nodular hyperplasia<br>Adenomatous hyperplasia | Autonomous overproduction of thyroid hormones by nodules | Low TSH<br>Elevated free $T_4$<br>Elevated $T_3$<br>High thyroglobulin<br>All thyroid antibodies negative | Normal or elevated<br>Heterogeneous uptake; multiple foci increased uptake | Ultrasonography: Enlarged gland; multiple heterogeneous nodules; cystic changes |

*Continued*



**e-Figure 17.3. Abnormal thyroid scans.** (A and B) Organification defect. (A) Anterior pinhole view. A bilobed thyroid is present in the neck and shows diffusely increased uptake. (B) Anterior prominently sized thyroid compared with the neck and the head. (C and D) Anterior pinhole views of poorly functioning thyroid from two patients. A bilobed thyroid is normally located within the neck. Trapping by the thyroid is poor with high body background. The thyroid may appear small (C) or normal (D). This pattern can be seen in patients with thyroid gland hypoplasia or a transient insult, such as maternal antibodies. Scintigraphically, these entities cannot be distinguished.

**TABLE 17.2** Causes of Hyperthyroidism and Thyrotoxicosis in Children and Adolescents—cont'd

| Name | Synonyms | Mechanism of Hyperthyroidism/ Thyrotoxicosis | Laboratory Tests | RAIU Appearance on Scintigraphy | Imaging Appearance of Thyroid Gland |
|---|---|---|---|---|---|
| Autonomous nodule | Plummer disease<br>Toxic nodule | Uncommon in children; autonomous overproduction of thyroid hormones by solitary nodule; usually produce $T_3$ | Low TSH<br>Normal or elevated free $T_4$<br>Elevated $T_3$<br>High thyroglobulin<br>All thyroid antibodies negative | Elevated<br>Single hot focus; rest of gland suppressed | |
| TSH-producing pituitary adenoma | | Autonomous overproduction of TSH | Normal TSH<br>Elevated free $T_4$<br>High serum TSH alpha subunit concentration<br>All thyroid antibodies negative | High | Pituitary adenoma on MRI |
| Pituitary resistance to thyroid hormone | | Autosomal-dominant; thyroid beta-receptor gene mutation[52]; overproduction of TSH | Normal or slightly elevated TSH<br>Elevated free $T_4$<br>Elevated $T_3$ (less than $T_4$)<br>All thyroid antibodies negative | High<br>Diffuse uptake | |
| **THYROTOXICOSIS-EXCESS SECRETION OF PREFORMED THYROID HORMONES** | | | | | |
| Thyrotoxic phase of chronic lymphocytic (Hashimoto) thyroiditis | Hashitoxicosis<br>Lymphadenoid goiter | Autoimmune; release of preformed hormones | Low TSH<br>Elevated free $T_4$<br>Elevated $T_3$<br>High thyroglobulin<br>TPO-Ab positive; Thyroglobulin positive; TRS-Ab positive or negative | Elevated<br>Diffuse increased uptake | Ultrasonography: Findings are nonspecific; enlarged gland; hypoechoic, heterogeneous echotexture |
| Subacute lymphocytic thyroiditis | Painless sporadic thyroiditis<br>Silent thyroiditis | Autoimmune; release of preformed hormones<br>May be associated with drugs (interferon-alpha, interleukin-2, lithium) | Low TSH<br>Elevated free $T_4$<br>Elevated $T_3$<br>High thyroglobulin<br>TPO-Ab positive | Very low<br>Diffuse decreased uptake | Ultrasonography: Findings are nonspecific; enlarged gland; hypoechoic, heterogeneous echotexture |
| Thyrotoxic phase of subacute granulomatous thyroiditis | Subacute thyroiditis<br>Painful subacute thyroiditis<br>de Quervain thyroiditis<br>Granulomatous giant cell thyroiditis | Viral; release of preformed hormone | Low TSH<br>Elevated free $T_4$<br>Elevated $T_3$<br>High thyroglobulin<br>TPO-Ab negative; elevated ESR | Low<br>Diffuse decreased uptake | Ultrasonography: Findings are nonspecific; enlarged gland; hypoechoic, heterogeneous echotexture |
| Factitious thyroiditis | Thyrotoxicosis factitia | Intentional ingestion of too much thyroxine | Low TSH<br>Elevated free $T_4$<br>Elevated $T_3$<br>Low thyroglobulin | Low | |
| Iodine-induced hyperthyroidism | | Underlying multinodular goiter; thyroid hormone release triggered by exposure to iodine (contrast agents), amiodarone | Low TSH<br>Elevated free $T_4$<br>Elevated $T_3$ | Increased | |

*CT*, Computed tomography; *ESR*, erythrocyte sedimentation rate; *MRI*, magnetic resonance imaging; *RAIU*, radioactive iodine uptake; *$T_3$*, triiodothyronine; *$T_4$*, thyroxine; *TBII*, thyrotropin-binding inhibitor immunoglobulin; *TPO-Ab*, thyroid peroxidase antibodies; *TRS-Ab*, thyrotropin-receptor stimulating antibodies; *TSH*, thyroid-stimulating hormone; *TSI*, thyroid stimulating immunoglobulin.

primary hypothyroidism in children and adolescents in iodine sufficient areas. It is more common in girls than boys and increases in frequency with age during childhood and adolescence. Euthyroid goiter is more common than hypothyroidism.[35–37]

***Etiologies, Pathophysiology, and Clinical Presentation.*** Chronic autoimmune thyroiditis is a complex, thyroid-specific T-cell mediated disease with a strong genetic component.[38–40] It often coexists with other autoimmune diseases[41] and can also be expressed as part of an autoimmune polyendocrine syndrome type 2 (APS-2).[42] The two major forms of the disorder are goitrous autoimmune thyroiditis and atrophic autoimmune thyroiditis, with the common pathologic feature being lymphocytic infiltration and the common serologic feature being the presence of high serum concentrations of antibodies to TPO and thyroglobulin.

The National Health and Nutrition Examination Survey (NHANES III) from 1988 to 1994, demonstrated 7.4% of adolescents (ages 12–19) had positive antithyroglobulin antibodies (Tg Ab) and 4.8% had positive antithyroid peroxidase antibodies (TPO Ab). Approximately 2% of all surveyed adolescents had serum TSH levels indicting hypothyroidism.[43]

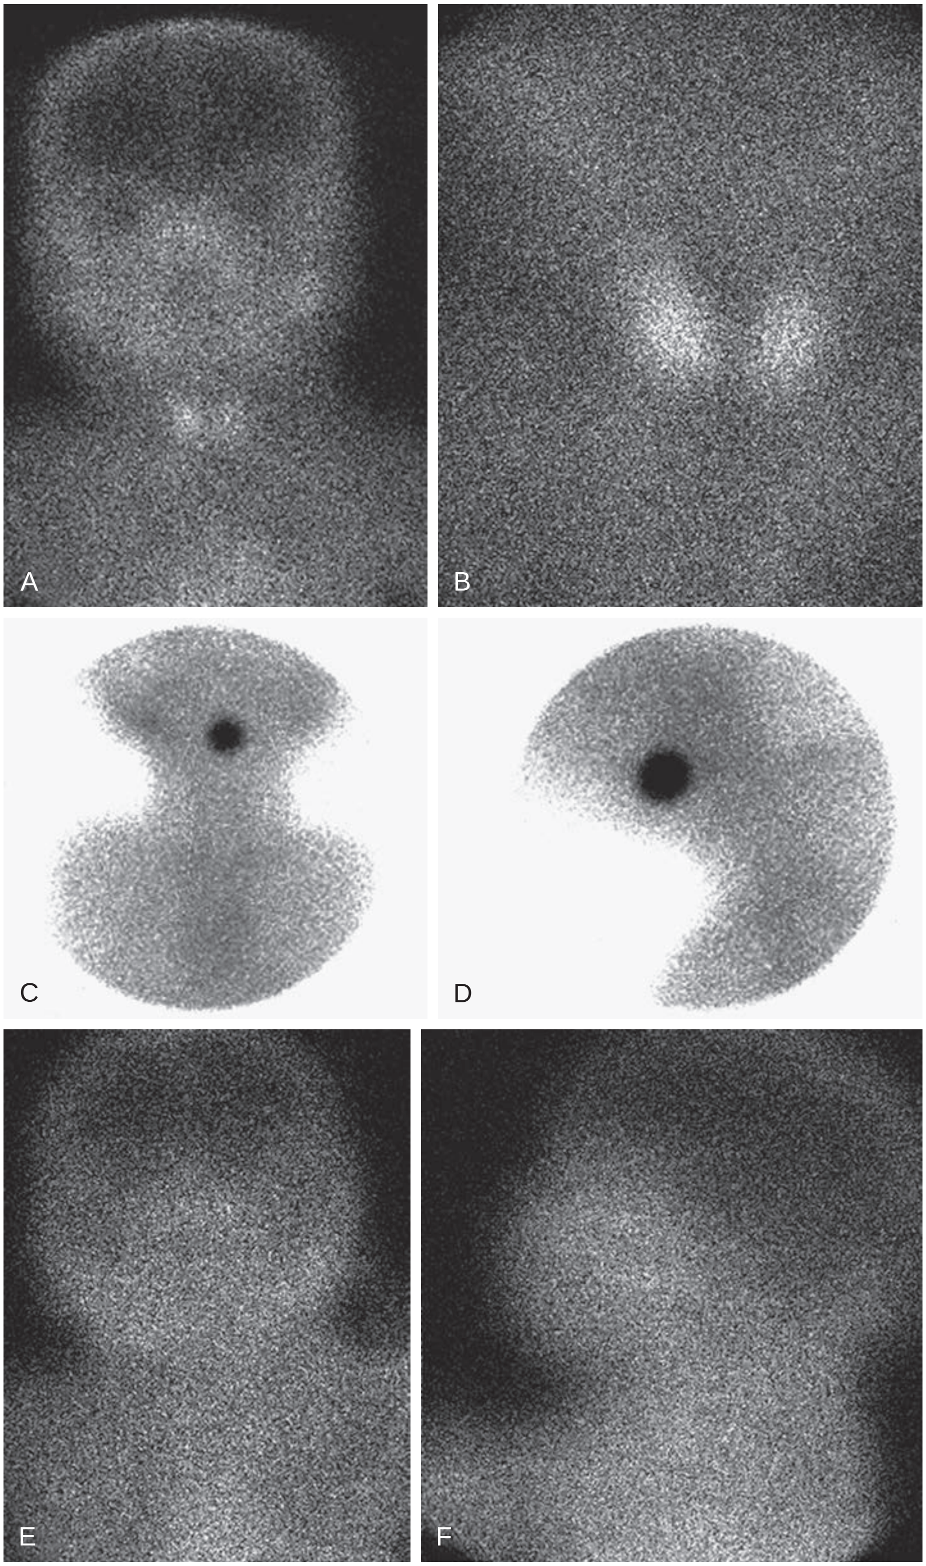


**Figure 17.2. Normal and abnormal thyroid scintigraphy.** (A and B) Normal thyroid anatomy. Anterior and pinhole views show normal bilobe architecture and normal position. Thyroid function cannot be meaningfully estimated from these images in an infant with known thyroid insufficiency. (C and D) Thyroid ectopia. Anterior and lateral views of the neck show a solitary rounded focus of radiopharmaceutical trapping at the base of the tongue. No clinical difference exists between the terms *lingual* and *sublingual*, and they are used interchangeably. (E and F) No thyroid is identified. Anterior and lateral views show no functioning thyroid tissue. Although this finding suggests thyroid agenesis, it is nonspecific because severely decreased thyroid function, particularly resulting from maternal thyrotropin receptor–blocking antibody, also may have this appearance.

The most common physical finding at presentation is a goiter.[35] The most common manifestation of hypothyroidism in children is stunted growth, often resulting in short stature. The growth delay is usually insidious in onset and may be present for several years before other, if any, symptoms occur.[44] Other common symptoms that may occur include altered school performance, sluggishness, lethargy, cold intolerance, constipation, dry skin, brittle hair, facial puffiness, and muscle aches. If the cause is from hypothalamic or pituitary disease, the patients may have headaches, visual symptoms, or pituitary disease manifestations.

***Imaging.*** Most physicians consider the presence of serum antithyroid antibodies as sufficient evidence for chronic autoimmune thyroiditis and that thyroid US or radionuclide scanning are rarely indicated. Children with central hypothyroidism however should undergo cranial MRI (with contrast) and tests for other pituitary hormone deficiencies.

Ultrasound findings are nonspecific but include an enlarged relatively hypoechoic gland with coarse heterogeneous echotexture. Less commonly, the echogenicity of the gland is increased relative to adjacent muscle. Fibrotic septations in the chronic form may produce a pseudolobulated appearance of the parenchyma. Multiple discrete hypoechoic, 1 to 6 mm, micronodules may also be seen (Fig. 17.4A–C).

In the early (preclinical) stage of Hashimoto thyroiditis, elevated $^{123}$I uptake values with diffusely increased radionuclide activity throughout the thyroid may be seen. This happens because there is an initial mild decline in circulating thyroid hormones sensed by the pituitary gland causing a compensatory rise in TSH secretion, which stimulates the gland to synthesize more thyroid hormone so that $T_3$ and $T_4$ levels return to normal. In some instances, thyroid follicles demonstrate a variable response to the chronic TSH stimulation, leading to patchy proliferation of these follicles. On a thyroid scan, this phenomenon manifests as areas of increased activity (follicles that respond to TSH) and of decreased activity (those that do not respond). As more thyroid parenchyma is replaced by fibrous tissue and the $T_3$ and $T_4$ levels decrease as the gland fails to respond to the elevated TSH level, the radionuclide uptake becomes nonuniformly decreased (Fig. 17.4D).[45]

***Treatment.*** Levothyroxine ($T_4$) is the treatment of choice for children with hypothyroidism. The goals of the treatment are to restore normal growth and development. Patients with autoimmune thyroiditis who have a suspicious thyroid examination such as a suspected nodule or significant gland asymmetry, especially if associated with palpable cervical lymphadenopathy, should be evaluated by an experienced thyroid sonologist with consideration of fine needle aspiration (FNA) for any suspicious sonographic features.[46]

## Hypertyhroidism and Thyrotoxicosis

***Overview.*** Hyperthyroidism refers to overproduction of thyroid hormone by the thyroid gland. Thyrotoxicosis refers to the clinical and biochemical manifestations of excess thyroid hormones. There are multiple causes of hyperthyroidism and thyrotoxicosis in children (Box 17.2). Most cases of thyrotoxicosis in children are associated with hyperthyroidism. Graves disease is the most common cause of the hyperthyroidism in the pediatric population.

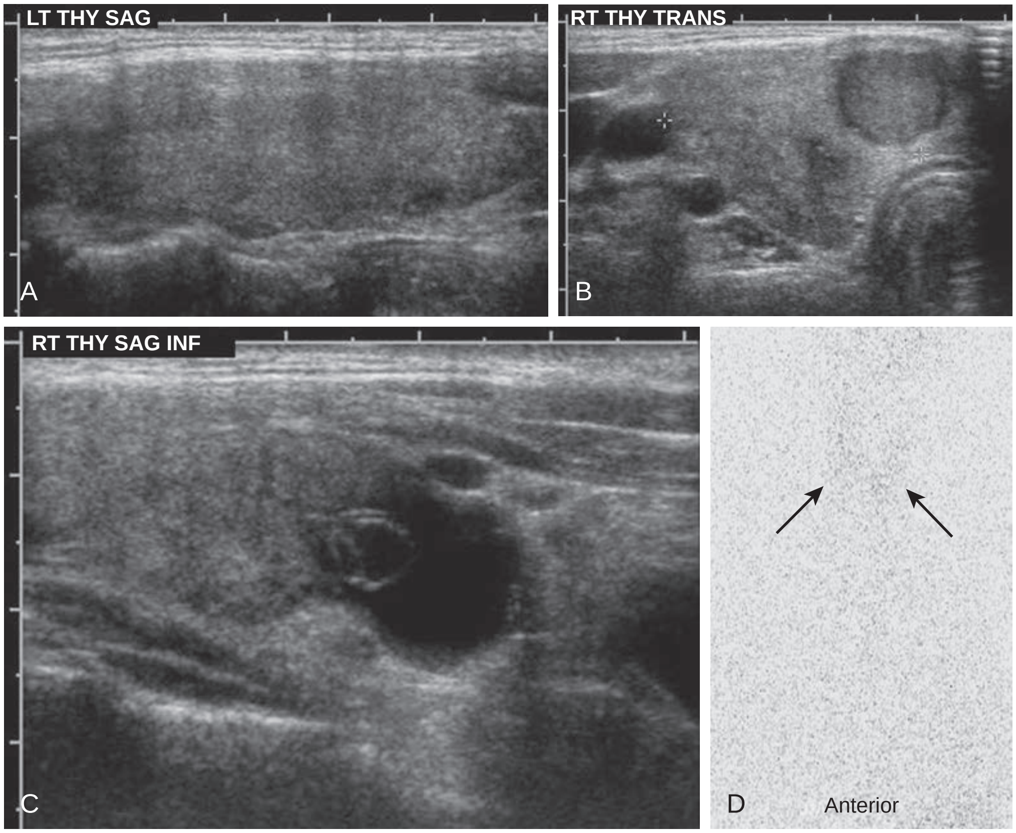

**Figure 17.4. Chronic autoimmune (hashimoto) thyroiditis.** (A) Ultrasonography demonstrates an enlarged gland that is relatively hypoechoic with heterogeneous echotexture. (B and C) The right lobe of the same patient has a hypoechoic nodule and cystic changes. (D) The $^{123}$I scan shows diffuse decreased uptake *(arrows)*. The 24-hour uptake was only 0.5%.

A 2008 study estimating the incidence of hyperthyroidism using the number of new prescriptions of thionamides and data from the 2008 U.S. census concluded that the incidence among individuals aged 0 to 11 years was 0.44 cases per 1000 population; the incidence among individuals aged 12 to 17 years was 0.26 cases per 1000 population; and the incidence among individuals aged 12 to 17 years was 0.59 cases per 1000 population.[47]

### Graves Hyperthyroidism

***Etiologies, Pathophysiology, and Clinical Presentation.*** Graves disease is the most common cause of hyperthyroidism in children and adolescents. The general cause TSH is receptor-stimulating antibodies (TRS-Ab), which activate the TSH receptor.

Many of the clinical features of hyperthyroidism are similar in children, adolescents, and adults. Most children with Graves disease have a diffuse goiter.[48] Hyperthyroidism also affects growth and pubertal development in children. Acceleration of growth with advanced epiphyseal maturation can be seen in untreated hyperthyroidism. The acceleration of growth is usually subtle and the degree depends on the duration of hyperthyroidism before diagnosis. Pubertal development, on the other hand, tends to be delayed in children with untreated hyperthyroidism. In those children who have already begun puberty, it slows until the hyperthyroidism is treated.

Graves disease causes other unique problems not associated to the high serum thyroid hormone concentrations, including ophthalmopathy and pretibial myxedema. Graves ophthalmopathy is common in children but is generally less severe than in adults. The clinical manifestations stem from a combination of increased orbital fat and extraocular muscle volume. The exact etiology is unknown, however, it may result from antibodies against a TSH receptor-like protein in retro-orbital connective tissue. Thyrotropin receptor (TSHr) mRNA and functional protein have been demonstrated in orbital fibroblasts. Studies have suggested TSHr autoantibodies (TRAbs) are potent stimulators of adipogenesis in Graves ophthalmopathic orbital cells. Therefore it is possible that circulating TRAbs in Graves patients that stimulate overproduction of thyroid hormones also increase orbital adipose tissue volume. Although originally thought to represent another causative agent, antibodies to extraocular muscles are now generally thought to be secondary to extraocular muscle inflammation and damage.[49,50]

***Imaging.*** In the majority of patients no imaging is needed. The diagnosis can be made by physical exam, laboratory tests, and onset or chronicity of symptoms. Onset of symptoms may be documented by prior laboratory studies or inferred from the review of symptoms. If thyrotoxicosis has been present for less than 8 weeks, transient thyrotoxicosis secondary to subacute thyroiditis or the thyrotoxic phase of autoimmune/silent thyroiditis should be considered. These are self-limited and refractory to therapy with thionamides. Thyrotoxicosis that has been present for more than 8 weeks suggests true hyperthyroidism thyrotoxicosis. However, if the diagnosis cannot be made clinically, an $^{123}$I uptake, with or without a scan, should be performed.[51]

***Treatment.*** Graves disease can be treated pharmacologically, surgically, or with radioiodine ablation. The thionamide antithyroid drugs propylthiouracil (PTU) and methimazole (MMI) continue to be the most commonly used treatment medications in the United States.[52,53] Thionamides exert their antithyroid effects primarily by inhibiting thyroid hormone synthesis through interference with the oxidation and organic binding of iodide into thyroglobulin.[53] In addition, PTU, but not MMI, inhibits the peripheral conversion of $T_4$ to $T_3$ by type 1 deiodinase.[54,55] Some patients are unable to take these medications or become noncompliant. In these patients, their disease may be treated by radioiodine ablation or thyroidectomy. Concerns over the potential long-term complications of pediatric radiation exposure have traditionally made endocrinologists hesitant about using radioiodine in the treatment of Graves disease. The use of radioactive iodine has now been detailed for more than 1000 children, which found remission rates that top 95% with very few complications.[56] Despite reassurances found in the literature regarding the safety of $^{131}$I in children, it has been shown total-body radiation doses after $^{131}$I therapy vary with age, and the same absolute dose of $^{131}$I will result in more radiation exposure to a young child than to an adolescent or adult.[57–61] Children are also more sensitive to the effects of radiation than adults. Therefore when treating children with radioactive iodine, in addition to selecting a dose that will achieve adequate thyroid tissue destruction, the age of the patient and the total $I^{131}$ dose need to be considered.

### Infection

***Overview.*** Acute suppurative thyroiditis is an infection of the thyroid gland that is rarely seen during childhood but is potentially life-threatening.[62,63]

***Etiologies, Pathophysiology, and Clinical Presentation.*** Acute suppurative thyroiditis is usually caused by a bacterial infection. *Staphylococcus aureus*, *Streptococcus pyogenes*, *Streptococcus epidermidis*, and *Streptococcus pneumoniae* are the most common aerobic bacteria. The predominant anaerobic bacteria are Gram-negative bacilli and *Peptostreptococcus* spp.[64]

Suppurative thyroiditis can be related to a pyriform sinus fistula or thyroglossal duct remnant, especially when recurrent infections occur.[62,65–67]

The classic clinical features of this illness include fever; neck pain; and a swollen, tender mass over the thyroid gland.

***Imaging.*** US is the modality of choice, often demonstrating unilobar or diffuse swelling and/or abscess formation. CT or MRI is not usually necessary. On MRI, the thyroid gland will demonstrate focal or diffuse swelling with decreased signal on T1-weighted and increased signal on T2-weighted images. MRI is superior to ultrasound in detecting capsule rupture into the adjacent soft tissues.

***Treatment.*** The primary treatment is antimicrobial therapy, directed against the likely bacterial pathogens. Surgery may be needed to drain abscesses and repair any developmental anomaly that led to the infection.

## Benign Masses

***Overview.*** Thyroid nodules and cysts are uncommon in healthy children before puberty.[67–71] Most thyroid nodules are benign, but multiple studies have demonstrated an increased risk of malignancy in pediatric thyroid nodules with an overall 26.4% risk of cancer[69] Risk factors associated with the development of thyroid nodules in children include iodine deficiency, prior radiation exposure, history of antecedent thyroid disease, and several genetic syndromes.[46]

### Benign Nodules

***Overview.*** The most common type of benign solitary thyroid nodules is follicular adenomas (hyperplastic nodules).[71]

***Etiologies, Pathophysiology, and Clinical Presentation.*** Follicular adenomas are thought to be the result of cycles of hyperplasia and colloid involution of thyroid nodules.[22,25] They are encapsulated lesions that are usually solitary and nonfunctioning. They are usually asymptomatic or may present as a palpable nodule. Sudden enlargement and pain is usually caused by spontaneous hemorrhage within the lesion. With the increasing performance of cross-sectional studies, thyroid nodules are often found incidentally.[72]

***Imaging.*** The findings of ultrasound, CT, and MRI are nonspecific and can be seen in both benign and malignant nodules.

On US, follicular adenomas are usually hypoechoic relative to normal thyroid tissue, although some are hyperechoic and a few isoechoic. A thin hypoechoic "halo" or rim around the lesion can often be seen. The cause of the "halo" is unknown but may be due to the fibrous capsule, compressed thyroid parenchyma, or pericapsular inflammatory infiltration.[25,73] Adenomas may also contain hypoechoic or anechoic areas from internal hemorrhage and necrosis. Calcifications may also be present (e-Fig. 17.5). Thyroid scintigraphy may be used in the evaluation of a thyroid nodule. Increased uptake in a nodule almost always indicates that the nodule is benign.

***Treatment.*** In 2015 the American Thyroid Association (ATA) published management guidelines for children and adolescents with thyroid nodules and differentiated thyroid cancer (DTC) based on scientific evidence and expert opinion. Biopsy or excision may be performed to exclude malignancy.[74] The ATA recommends "the evaluation and treatment of thyroid nodules in children should be the same as in adults with the following exceptions that: 1. Ultrasound characteristics and clinical context should be used rather than size alone to identify nodules that warrant fine needle aspiration (FNA), 2. All FNA in children should be performed under US-guidance, 3. Preoperative FNA of a hyperfunctioning nodule in a child is not warranted as long as the lesion is removed, 4. A diffusely infiltrative form of PTC [papillary thyroid carcinoma] may occur in children and should be considered in a clinically suspicious gland, and 5. Surgery (lobectomy + isthmusectomy) is favored over repeat FNA for most nodules with indeterminate cytology."[46]

Lesions with benign cytology should be followed by serial US and undergo repeat FNA if suspicious features develop or if the lesion continues to grow. A lobectomy may be performed in patients with compressive symptoms, cosmetic concerns, or patient/parent preference. Lobectomy should be also be considered in all apparently benign solid thyroid nodules >4 cm, those lesions demonstrating significant growth, or other clinical concerns for malignancy.[46]

For pediatric patients with a thyroid nodule and suppressed TSH, thyroid scintigraphy should be performed. Increased uptake within the nodule is consistent with autonomous nodular function. Surgical resection, most commonly lobectomy, is the recommended approach for most autonomous nodules in children and adolescents.[46]

## Cysts

***Overview.*** Cysts are often thought to be due to benign degenerative thyroid diseases. However, as with thyroid nodules, there is a great heterogeneity in these disease processes in children ranging from benign pure cysts to malignant lesions.[70]

***Etiologies, Pathophysiology, and Clinical Presentation.*** True simple cysts lined by epithelium are rare. The majority of benign thyroid cysts are felt to be the result of cystic degeneration of a follicular adenoma, rather than a true cyst.[70] Hemorrhagic cysts are usually the result of bleeding into a follicular adenoma.

Thyroglossal duct cysts are the result of incomplete degeneration of the thyroglossal duct. The duct remnant, which is an epithelium-lined tract, has the potential for obstruction and forming a cyst because of retained secretions. They can occur anywhere along the path of migration of the thyroid gland from the foramen cecum at the tongue base to the anterior lower neck. Most thyroglossal duct cysts are asymptomatic until they become infected. Large cysts can be clinically detected as a palpable midline or near-midline neck mass that moves with swallowing or tongue protrusion.

***Imaging.*** Simple benign cysts are anechoic on US and hypodense on CT. On MRI, they will follow the signal characteristics of water, with low signal on T1-weighted and high signal on T2-weighted images. Hemorrhagic cysts will have high signal on T1-weighted images and will be hyperdense on CT.

Thyroglossal duct cysts are usually anechoic or hypoechoic on US. The cyst may have a high protein content that can result in some internal echoes, or may appear complex with septations and solid appearing areas during or after hemorrhage or infection. On CT, a noninfected thyroglossal duct cyst will be well circumscribed with a thin rim of enhancement. Thick peripheral enhancement suggests the cyst is infected. The attenuation of the cystic component varies on CT from hypodense (low protein content) to hyperdense (high protein content or hemorrhage). On MRI, thyroglossal duct cysts usually have low T1-weighted signal and high T2-weighted signal intensities. However, when the cyst is proteinaceous, it may be hyperintense on T1-weighted images. Thyroid scintigraphy is not necessary in the evaluation of thyroglossal duct cysts except when a thyroid gland cannot be identified. In this case, scintigraphy may be necessary to determine if the cyst contains the patient's only functional thyroid tissue.

***Treatment.*** Thyroid cysts and thyroglossal duct cysts may be excised for diagnosis or if they become secondarily infected, cause mass effect resulting in pain or dysphagia, or for cosmesis.

## Malignant Masses

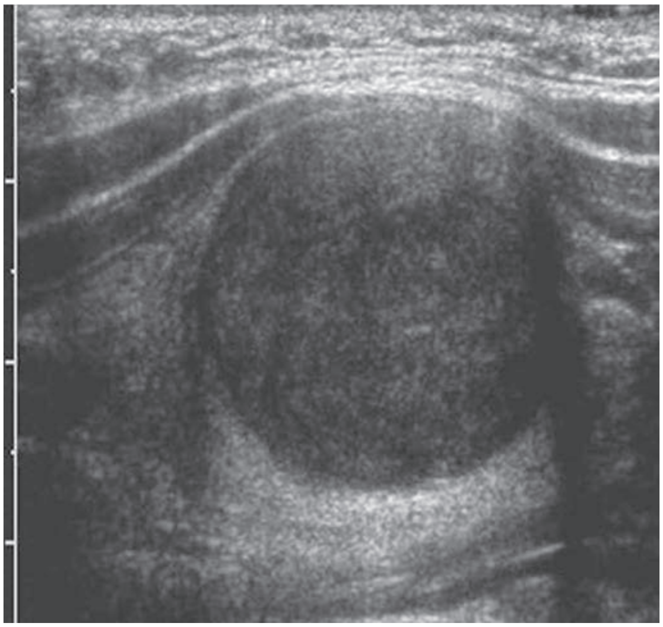
***Overview.*** According to the Surveillance, Epidemiology, and End Results (SEER) program, 2.8% of all new cases of thyroid cancer in the United States are in people between the ages of 15 to 19,[75] and the incidence appears to be increasing.[76] Papillary thyroid carcinoma accounts for the majority all pediatric cases. Follicular thyroid carcinomas are uncommon, whereas medullary, anaplastic, and poorly differentiated carcinomas are almost unheard of in young children.[77] Other rare thyroid neoplasms include teratomas[78] and non-Hodgkin lymphoma.[79] Because most childhood thyroid malignancies are of the papillary type, the discussion in this section will mainly pertain to papillary carcinomas.

***Etiologies, Pathophysiology, and Clinical Presentation.*** Exposure to head and neck irradiation is associated with an increased risk for the development of thyroid carcinoma. Prior studies have shown a high rate of thyroid cancers in children who have received previous irradiation for treatment of benign conditions.[80] Children are more sensitive than adults to the carcinogenic effect of irradiation, perhaps because of their higher proliferative index of thyroid cells.[81]

Some thyroid cancers have a genetic predisposition and can be associated with certain syndromes. A positive family history is seen in medullary carcinoma[82] and in 3% of papillary carcinomas (chromosome 19p13.2).[83] A high incidence of papillary thyroid carcinomas is seen in familial adenomatosis polyposis coli[84] and Cowden disease.[85] Inherited medullary carcinoma is seen in multiple endocrine neoplasia type 2a and 2b (MEN 2a and 2b) or as part of familial medullary carcinoma.[86]

Thyroid carcinoma in children is biologically and clinically different from that seen in adults. The most common clinical presentation is a solitary thyroid nodule.[87] Other presenting manifestations such as dysphonia or dysphagia due to local invasion of surrounding structures are rare in children. Children present with cervical node involvement (60%) and pulmonary metastases (13%)[88] more often than adults.[89] They have more advanced disease and a higher rate of recurrence.[89] The pulmonary metastases are almost always functional and tend to be miliary.[90] Lymph nodes are the most common site of dissemination followed by the lungs. Bone metastases are rare.[90]

***Imaging.*** The imaging appearance of papillary carcinoma is variable. US is often used in the evaluation a thyroid nodule. The presence of indistinct margins, hypoechogenicity, predominantly solid composition, vascularity, absence of a hypoechoic halo, and calcifications on ultrasound are more suggestive of malignancy.[91] Ultrasound can also help guide the clinician while performing a FNA.[92] Although a solitary nodule is most common in



**e-Figure 17.5. Follicular adenoma.** Ultrasound demonstrates a well-circumscribed hypoechoic lesion.

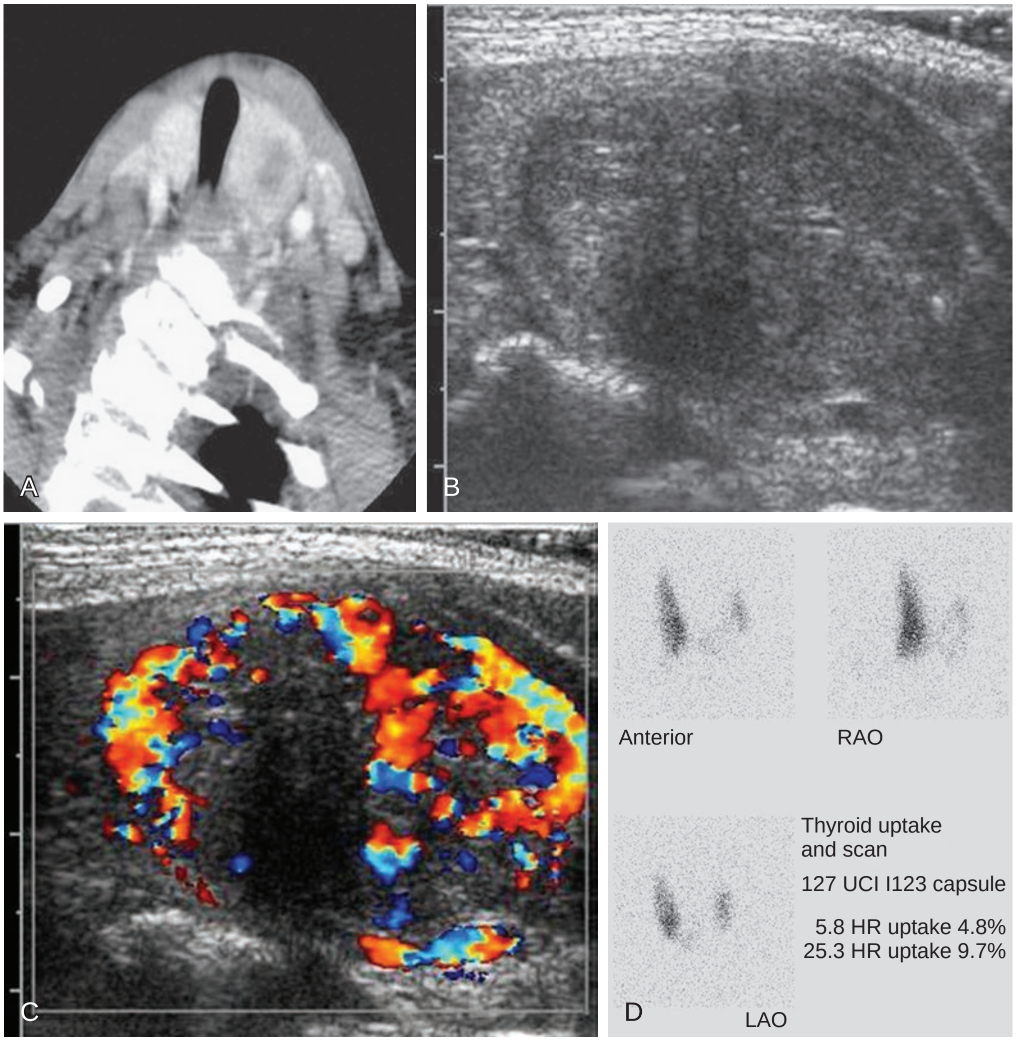


**Figure 17.6. Papillary carcinoma.** (A) Contrast-enhanced CT performed to assess for infection shows a low attenuation lesion in the left lobe of the thyroid gland. (B and C) Ultrasound images demonstrate a relatively heterogeneous nodule with punctate echogenicities and an eccentric round region of hypoechogenicity. Peripherally the lesion has increased vascularity. (D) The $^{123}$I uptake and scan demonstrates decreased uptake in the left gland and a focal "cold" lesion.

children, multifocal nodules, diffuse infiltration with heterogeneous hypodensity, or a normal appearing thyroid gland may be found.[22] Metastatic lymph nodes are usually enlarged, may be calcified, cystic, hemorrhagic, or contain colloid (Fig. 17.6).[93]

Thyroid scintigraphy is often used in the evaluation of a thyroid nodule. Cold nodules are suggestive of malignancy but can also be seen in benign lesions. Some very rare thyroid carcinomas can demonstrate increased radioisotope uptake on thyroid scintigraphy. There are also rare cases of a benign adenoma or carcinoma that have the ability to trap the radioisotope but do not organify the iodide resulting in a discordant nodule that is hot on $^{99m}$TcO4 studies but cold on radioiodine ($^{123}$I) studies.

A comprehensive neck ultrasound of all neck regions is required to optimize the preoperative surgical plan. FNA of suspicious lateral neck lymph nodes is recommended. Anatomic imaging by MRI or CT should be considered in patients with large or fixed thyroid masses, vocal cord paralysis, or bulky metastatic lymphadenopathy to optimize surgical planning.[46] MRI can be helpful in evaluating and delineating the extent of local invasion and lymph node metastases. Chest CT is more sensitive than radiography and can detect micronodular and interstitial patterns of metastases[94] much better than conventional chest radiographs (Fig. 17.7).

As with adults, cytopathology findings on pediatric thyroid FNA are categorized according to The Bethesda System for Reporting Thyroid Cytopathology.[95]

***Treatment.*** The ATA recommends a total thyroidectomy for the majority of pediatric patients. The rationale for this approach is based on multiple studies showing an increased incidence of bilateral and multi-focal disease. Bilateral lobar resection compared with lobectomy has been shown to decrease the long-term risk for persistent or recurrent disease.[46,96–98] Thyroidectomy also enables the use of thyroglobulin levels and whole body radioiodine scans for monitoring disease persistence and recurrence.

Central neck dissection is recommended for children with malignant cytology and evidence of gross extrathyroidal invasion and/or locoregional metastasis on preoperative staging or intraoperative findings. For patients with no clinical evidence of gross extrathyroidal invasion and/or locoregional metastasis, prophylactic central neck dissection may be selectively considered based upon tumor focality and size and the experience of the surgeon. For patients with unifocal disease, ipsilateral central neck dissection,

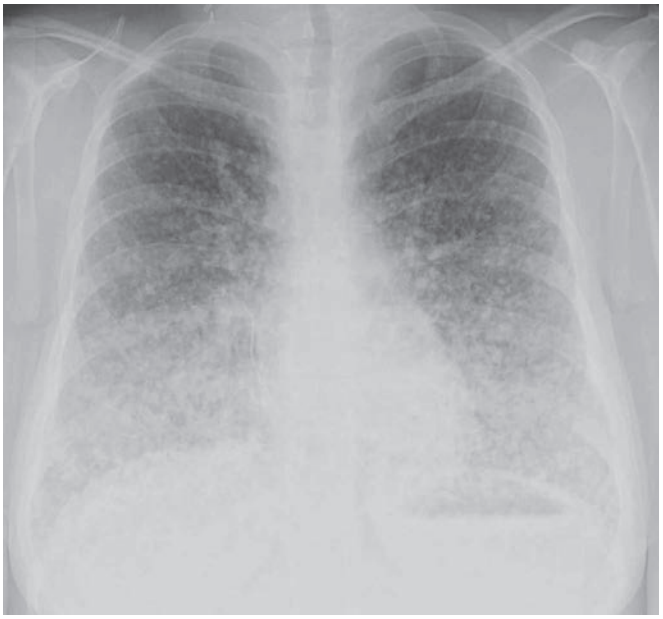

**Figure 17.7. Pulmonary metastases from papillary thyroid carcinoma.** Chest radiograph shows innumerable diffuse small pulmonary nodules (miliary disease).

with pursuit of contralateral central neck dissection based on intraoperative findings, may help balance the risks and benefits. The ATA also recommends compartment-oriented lymph node resection. "Berry picking" and attempting to use palpation to determine if metastatic disease is present in a lymph node are not recommended.[46]

The ATA recommends pediatric thyroid surgery to be performed in a hospital with the full spectrum of pediatric specialty care, to include, but not be limited to: endocrinology, radiology (ultrasound and anatomic imaging), nuclear medicine, anesthesia, a high volume thyroid surgeon, and intensive care. The surgery should ideally be performed by an experienced surgeon who performs at least 30 or more cervical endocrine procedures annually.[46]

Postoperative staging is usually performed within 12 weeks after surgery. ATA Pediatric classified Low-Risk patients may be initially assessed and followed with a TSH-suppressed thyroglobulin (Tg) alone. In contrast, a TSH-stimulated Tg and a diagnostic whole body $^{123}$I scan is typically recommended to assess for evidence of persistent disease in ATA classified Pediatric Intermediate- and High-Risk patients. Additional imaging, to include neck ultrasound and/or hybrid imaging using SPECT/CT, may be used conjunctively to more accurately define the anatomic location of radioactive iodine uptake noted on a whole body scan.[46] Although $^{131}$I can be used, $^{123}$I should be used whenever possible for whole body scans.[99–101]

$^{131}$I is indicated for treatment of iodine-avid persistent locoregional or nodal disease that cannot be resected, as well as known or presumed iodine-avid distant metastases. For patients with persistent disease after $^{131}$I administration, the decision to pursue additional $^{131}$I therapy should be individualized according to clinical data and previous response. The potential risks and benefits must be weighed on an individual basis.[46]

The uptake of radioiodine is dependent on TSH stimulation of thyroid tissue and carcinoma tissue. The TSH level should be greater than 30 uU/mL for optimum radioiodine uptake. A diagnostic scan followed by ablation is performed 6 weeks after thyroidectomy. Thyroid hormone medications must be withheld for a sufficient time to permit an adequate rise in the TSH level. Additionally, the patient should be placed on a low iodine diet for 2 weeks before the scan, to increase tissue avidity for iodine.[46,90] $T_3$ has a short half-life and can be given until 2 weeks before the scan.[94]

The normal thyroid remnant tissue is more efficient than the carcinoma tissue at concentrating radioiodine. As a result, the first diagnostic whole body radioiodine scan done after thyroidectomy might not detect residual tumor or metastases. These may show up on the scan obtained after radioablation, as much higher doses of radioiodine are used for ablation.

The maximally safe radioiodine dose in children can be calculated based on quantitative blood and whole body dosimetry, and the minimally effective dose can be calculated based on lesion dosimetry.[102] Because this is complicated, most centers use a fixed dose of 30 mCi.[103] Rarely, a second treatment may be needed to completely ablate the remnant. A much higher dose of up to 175 to 200 mCi is required to ablate pulmonary metastases.[104] It is customary to obtain a scan 4 to 7 days after radioablation, which will demonstrate avid uptake in the thyroid remnant and may show metastases not apparent on the previous diagnostic radioiodine scan.[94]

Based on the belief that thyroid carcinoma cells are dependent on TSH stimulation for growth, TSH suppressive therapy with thyroxine is also used to suppress tumor growth. The optimum TSH level that needs to be maintained is not known. Initially, TSH levels of less than 0.1 uU/mL are recommended, but once remission has been achieved, levels of less than 0.5 uU/mL may be acceptable.[96]

## PARATHYROID GLANDS

### Embryology

The parathyroid glands are endodermal in origin and develop from the third and fourth pharyngeal pouches. There are usually four glands (two superior and two inferior); however, supernumerary and less than four glands may occur.

The third pharyngeal pouches expand into solid dorsal bulbar portions and hollow ventral elongate portions. During the fifth week, each cranial dorsal portion begins to differentiate into the inferior parathyroid glands. The caudal ventral portions migrate medially and eventually meet and fuse to form the thymus. As both primitive parathyroid glands lose their connection with the pharyngeal wall, they descend with the thymus. This migration of the inferior parathyroid glands with the thymus accounts for their lower position than the superior parathyroid glands that are derived from the fourth pharyngeal pouches.[105] The glands are usually distributed evenly between the lower pole of the thyroid gland and isthmus, but can be found anywhere along their course of descent.[106]

As with the third pharyngeal pouches, the fourth pharyngeal pouches also expand into solid dorsal bulbar portions and ventral elongate portions. During the fifth week each dorsal portion begins to differentiate into the superior parathyroid glands. As they lose their attachment with the pharyngeal wall, they attach to the posterior surface of the descending thyroid. They have a much shorter migration distance compared with the inferior parathyroid glands, which accounts for their more predictable location. Generally, the superior parathyroid glands are located posterior at the level of the upper two-thirds of the thyroid gland, approximately 1 cm above the crossing point of the recurrent laryngeal nerve and inferior thyroid artery.[107] The ventral portions of the fourth pharyngeal pouches develop into the ultimobranchial bodies, which fuse with the developing thyroid gland.

The epithelium of the dorsal parts of the third and fourth pouches proliferates during the fifth week and forms small nodules on the dorsal aspect of each pouch. Vascular mesenchyme soon grows into these nodules, forming a capillary network. The chief cells differentiate during the embryonic period and are believed to become functional in the fetus. The oxyphil cells do not differentiate until about 5 to 7 years after birth.[108]

## Physiology

The function of the parathyroid glands is to produce parathyroid hormone (PTH), which is one of two major hormones involved in calcium and phosphate homeostasis. Chief cells within the parathyroid glands produce PTH. Oxyphil cells may also secret PTH, but their true function is unknown. PTH regulates serum-ionized calcium by maintaining concentrations in a narrow range through stimulation of renal tubular calcium reabsorption and bone resorption.[108] PTH also stimulates the conversion of calcidiol (25-hydroxyvitamin D) to calcitriol (1,25-dihydroxyvitamin $D_3$) in renal tubular cells, thereby stimulating intestinal calcium absorption. PTH secretion is, in turn, regulated by serum-ionized calcium acting via a calcium-sensing receptor (CaSR) on the surface of parathyroid cells.[109] When the CaSR is activated by a small increase in serum-ionized calcium, PTH secretion is inhibited. Conversely, the effect of deactivation of the receptor by a small decrease in serum-ionized calcium stimulates PTH secretion.

## Anatomy

The paired superior parathyroid glands are fairly constant in their position near the upper surface of the thyroid lobes. The inferior parathyroid glands are found in close proximity to the lower pole of the thyroid gland. The glands however can be ectopic. Ectopic superior parathyroid glands can be found at the level of the upper pole of the thyroid gland (2%) and above the upper pole (0.8%). Other ectopic positions of the superior parathyroid glands such as in the posterior neck, retropharyngeal, retroesophageal, or intrathyroid regions, glands are even rarer (1% total).[106,107] Ectopic inferior parathyroid glands can be found anywhere along their area of descent up to the superior border of the pericardium.[106] Supernumerary glands, when present, are often found in the mediastinum associated with the thymus.

The parathyroid glands are encapsulated and well vascularized. The glands are composed of chief cells and oxyphil cells embedded within a fibrous capsule intermixed with adipose tissue. The vascular supply of the parathyroid glands is predominately the inferior thyroid artery,[110] although the superior parathyroid glands can also be supplied by the superior thyroid artery.[107,111] The venous drainage is predominately to the inferior thyroid veins.[112]

The parathyroids are meagerly supplied with vasomotor nerve fibers from either the superior, middle, or inferior cervical sympathetic ganglia.[113,114]

## Normal Findings

Normal glands are difficult to visualize because of their small size (less than 5 mm in length). On ultrasound, a normal parathyroid gland will have an echotexture similar to the adjacent thyroid parenchyma, which adds to the difficulty in identifying the normal glands.[25]

## Hyperparathyroidism

***Overview.*** Primary hyperparathyroidism is rare in children.[115,116] The exact incidence is unknown but is estimated to be 2 to 5 in 100,000.[115] Primary hyperparathyroidism is caused by overproduction of PTH by a pathologically changed parathyroid gland.

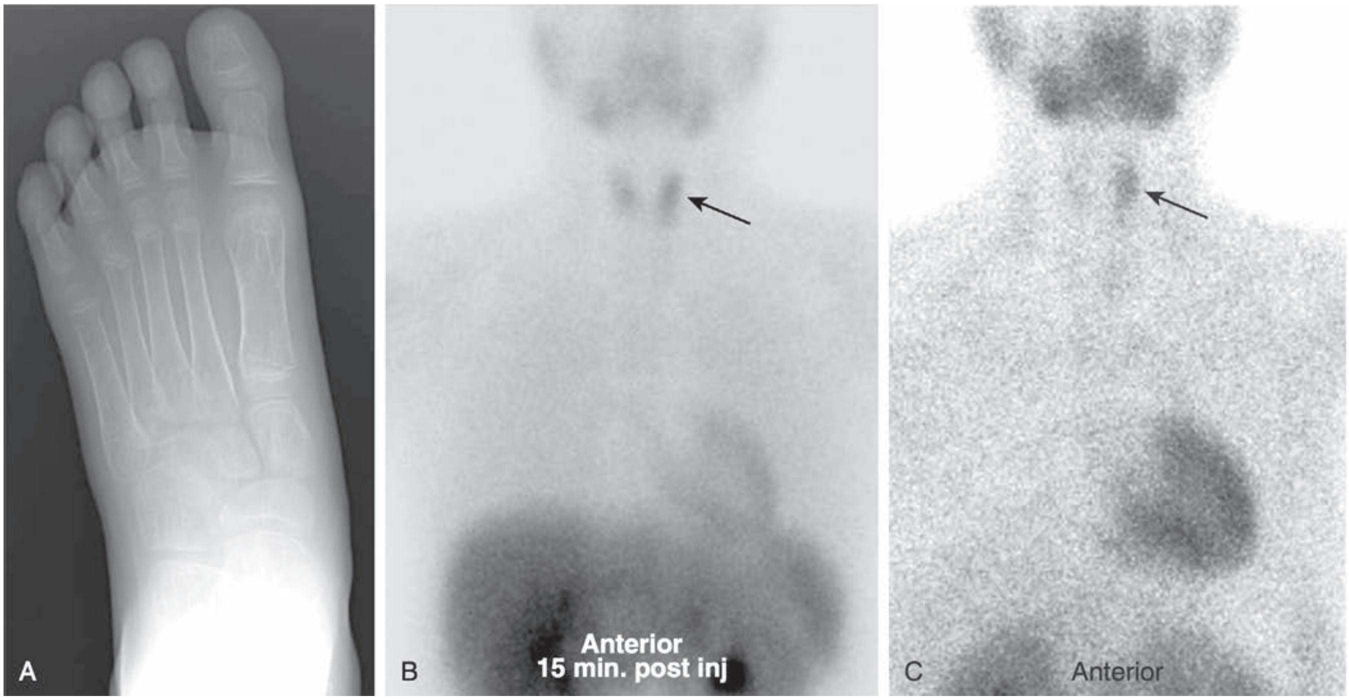

**Figure 17.8. Parathyroid adenoma in a patient presenting with foot pain.** (A) Radiograph of the foot demonstrates diffuse severe osteopenia. Laboratory studies revealed marked hypercalcemia and elevated parathyroid hormone. Initial ultrasonography failed to identify an adenoma. (B) Nuclear scintigraphy shows increased uptake is noted in the left lobe of the thyroid gland *(arrow)* on the initial 99mTc-sestamibi images. (C) Incomplete washout of the radiopharmaceutical is seen on 2-hour delayed images *(arrow)*, suggesting a parathyroid adenoma. The lesion was surgically excised, and the patient’s symptoms resolved.

***Etiologies, Pathophysiology, and Clinical Presentation.*** Primary hyperparathyroidism in children is most often caused by a parathyroid adenoma.[115–117] Multiple endocrine neoplasia (MEN)-I or -II syndromes or familial non-MEN hyperparathyroidism have also been documented and can constitute as much as 30% to 50% of pediatric hyperparathyroid disease.[117–119]

The parathyroid gland(s) becomes overactive and secretes excess amounts of PTH leading to an increase in serum calcium levels. PTH stimulates calcium and phosphate mobilization through osteoclastic bone resorption. In the kidney, PTH stimulates the synthesis of calcitriol, decreases urinary calcium excretion, and increases phosphate excretion. PTH enhances the gut absorption of minerals directly and through calcitriol.

The symptoms of hyperparathyroidism can be nonspecific and include joint aches, fatigue, weakness, loss of appetite, depression, and difficulty concentrating. The commonest clinical signs in children with primary hyperparathyroidism have been reported to be skeletal (bone resorption) and renal disease (hematuria, nephrocalcinosis, or nephrolithiasis).[118]

***Imaging.*** Imaging is rarely used to diagnose hyperparathyroidism. Evaluation of serum calcium and PTH levels is diagnostic. Occasionally, a patient may have an elevated calcium level and a normal or minimally elevated PTH level. Because PTH should normally be low when calcium is elevated, a minimally elevated PTH is considered abnormal and indicates hyperparathyroidism.

Imaging can help in localization for surgical planning. US is a reliable noninvasive method for confirming parathyroid pathology in children preoperatively. A parathyroid adenoma will appear well defined and hypoechoic on ultrasound, although differentiating an adenoma from hyperplasia or a lymph node can often be difficult.

Other reliable studies include $^{99m}$TcO4/$^{201}$Tl subtraction imaging and $^{99m}$Tc-sestamibi scans, which have been reported to have a sensitivity of 67% to 80% for localizing adenomas and a sensitivity of 45% to 60% for hyperplasia in adults; however, data in children are not well established (Fig. 17.8).[120,121]

The most specific radiographic manifestation of hyperparathyroidism is subperiosteal bone resorption. Brown tumors (osteoclastomas) are rare sequelae of hyperparathyroidism occurring in fewer than 5% of all cases.[122] The incidence in pediatric patients with hyperthyroidism is unknown. The lesions localize in areas of intense bone resorption, and the bone defect becomes filled with fibroblastic tissue.

***Treatment.*** Regardless of etiology, parathyroid resection is the treatment of choice for hyperparathyroidism in children.[118,121]

## KEY POINTS

- Ultrasound is the primary imaging modality for evaluating the thyroid and parathyroid glands, and for guiding aspiration and biopsy.
- The majority of cases of congenital hypothyroidism are caused by thyroid gland dysgenesis.
- Chronic autoimmune thyroiditis (Hashimoto thyroiditis) is the most common cause of acquired hypothyroidism in children.
- Graves disease is the most common cause of hyperthyroidism in children.
- Thyroid nodules are less common in children than in adults, but have a higher incidence of malignancy.

# SECTION 3 Neuroradiology

## PART 1 Cranium and Face

# 18 Embryology, Anatomy, Normal Findings, and Imaging Techniques

Thomas L. Slovis, Kristin A. Fickenscher, and Andrew Johansen

## ANATOMY OF THE SKULL

The skull is divided into three portions: the neurocranium, the face, and the base. The neurocranium is composed of the membranous portions of the occipital, parietal, frontal, and temporal bones, and is bounded inferiorly by the base of the skull, which includes the sphenoid and ethmoid bones. The face is between the forehead and chin.

Routine skull radiographs include the frontal projection, Towne view of the occipital bone, and the lateral view. Submentovertical, Waters, and Caldwell (posteroanterior 15 degrees) views may be added for specific indications.

The radiation dose (with the thyroid and lens being the most sensitive structures) varies with the view obtained and the age of the patient. Best practice skin doses for a lateral skull range from 0.09 mGy in the first year of life to 0.46 mGy in a 10- to 15-year-old child (see Huda in Suggested Readings).

Indications for skull radiographs are listed in Box 18.1. Computed tomography (CT) and magnetic resonance imaging (MRI) are used for evaluation of intracranial contents, facial structures, craniosynostosis, and trauma.

## NEONATAL AND INFANT SKULL

### Size and Shape

During infancy, the neurocranium is larger relative to the face. Neurocranium to face ratios in the lateral projection are roughly 3 : 1 to 4 : 1 at birth, and decrease to 2 : 1 to 2.5 : 1 by age 6 years. The calvarium is an incompletely mineralized membranous capsule with individual bones divided from one another by connective tissue sutures and fontanelles. The six major fontanelles are located at the four corners of the parietal bones—two in the skull midline and two pairs on each side (Fig. 18.1). Accessory fontanelles may occur in several locations but usually are in the sagittal suture. The sutures and the skull base synchondroses are prominent in newborns but diminish in width during the first 2 to 3 months. Obliteration of the sutures does not begin until the second to third decades. Figs. 18.1 through 18.4 and e-Fig. 18.5 illustrate sutures, fontanelles, and synchondroses.

The sphenoid bone at birth consists of a single central mass composed of the body, lesser wings, and two symmetric lateral masses, each of which includes a greater wing and a pterygoid process. The pituitary fossa is round with smooth margins; the dorsum sella is short and blunt, and the clinoid processes are rudimentary. The angle between the body of the neonatal mandible and the ramus in lateral projection is about 160 degrees; the bodies are separated by a midline cartilaginous symphysis mentalis (see Fig. 18.3). Early tooth calcification is seen in the fifth fetal month.[1]

Components of the individual ununited bones in infancy may cause confusion if they are not correctly recognized. The frontal bone is divided in half by the metopic suture (see Figs. 18.1 and 18.3). Apparent discontinuity of the sphenoid bone with the frontal bone superiorly and the occipital bone posteriorly indicates sites of the sphenoid synchondroses (see Fig. 18.2). The four components of the occipital bone (see Fig. 18.2 and e-Fig. 18.5) likewise may simulate discontinuities.

## GROWTH AND DEVELOPMENT

Most of the postnatal skull growth occurs during the first 2 years of life, after which most of the features of the adult skull are present. During the first 2 years, the bone thickness increases. The inner and outer tables, diploic space, vascular markings, and grooves for the dural sinuses develop by the end of the second year.

With increasing age, the fontanelles and sutures become smaller and narrower. The anterior fontanelle is reduced to fingertip size during the first half of the second year; the posterior fontanelle may be closed at birth (range of closure: birth to several months). Closure of the fontanelles occurs clinically before it is visible radiographically. The metopic suture is variable and may close from birth to the third year; however, it persists in about 10% of adults. In the occipital bone, the mendosal suture (see Fig. 18.4

**BOX 18.1** Indications for Plain Film Examination of the Skull

**DEFINITE**

- Trauma in possible child abuse cases (as part of a skeletal survey)
- Syndrome evaluation
- Craniosynostosis (initial test)
- Physical findings in patient without neurologic symptoms
- Cephalhematoma
- “Bump”
- Foreign body (initial test)
- Metastatic workup for small round cell tumor

**POSSIBLE**

- Initial evaluation in facial trauma

**NOT AN INDICATION**

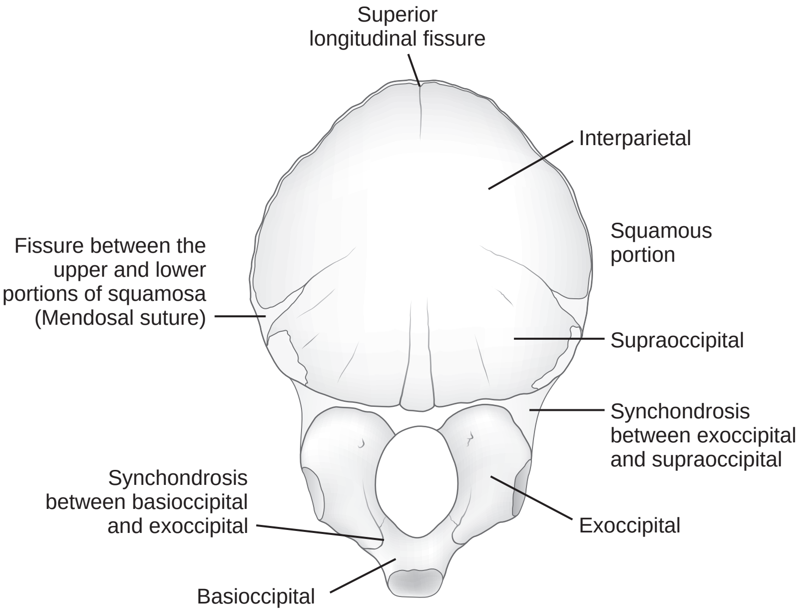
- Mild trauma
- Neurologic abnormalities (use computed tomography or magnetic resonance imaging)
- Sinusitis evaluation

## Abstract:

The pediatric skull is remarkably variable in size, shape, thickness and mineralization and undergoes significant change as a result of normal childhood development. This chapter discusses the embryology, anatomy and age related development of the pediatric calvarium and paranasal sinuses. This chapter emphasizes normal and developmental variants including Wormian bones, calvarial sutures, fontanelles, and vascular and diploic spaces, as well as the best imaging techniques for the pediatric calvarium and parnasal sinuses.

## Keywords:

pediatric skull
fontanelle
Wormian bones
sutures
paranasal sinuses



Superior longitudinal fissure
Interparietal
Squamous portion
Fissure between the upper and lower portions of squamosa (Mendosal suture)
Supraoccipital
Synchondrosis between exoccipital and supraoccipital
Synchondrosis between basioccipital and exoccipital
Exoccipital
Basioccipital

and e-Fig. 18.5) disappears during the first 2 years, but can persist. The synchondrosis between the supraoccipital and exoccipital (supracondylar) portions disappears during the second or third year. The spheno-occipital synchondrosis begins to close near puberty but may persist until the 20th year. Extensive variation makes sutures an unreliable criterion for estimation of age. Around the 20th year, the skull attains its definitive size.

## Normal Variations

Intrasutural, or wormian, bones occur most frequently along the lambdoid sutures (Fig. 18.6 and e-Fig. 18.7; Box 18.2), and less frequently in the fontanelles (see e-Fig. 18.7). The interparietal or Inca bone (Fig. 18.8) results from division of the supraoccipital portion of the occipital bone into two parts by the mendosal suture, with the superior part arising from membranous bone and the inferior part from cartilage continuous with the supracondylar basiocciput. A rare synchondrosis runs vertically through the squamous occipital bone (e-Fig. 18.9); persisting superior and inferior portions of the line are known as the *superior longitudinal fissure* (bi-interparietal suture) and the *cerebellar synchondrosis* (median cerebellar suture). Where the supraoccipital portion of the occipital bone forms the posterior border of the foramen magnum, accessory supraoccipital bones occasionally are found (e-Fig. 18.10). An outward bulge of the occipital squamosa just above the torcular Herophili in a newborn (Fig. 18.11) is called *bathrocephaly*. Rarely, a horizontal interparietal suture divides the parietal bones into superior and inferior moieties (e-Fig. 18.12).

Compression of the fetal skull, molding, during passage through the maternal pelvis produces dysmorphic findings after birth (Fig. 18.13).[2] During the first weeks and months of life, suture widths vary so much that caution is required for the diagnosis of increased intracranial pressure, particularly because superimposition of sutures can produce spurious widening (Fig. 18.14).

## JUVENILE SKULL

After 2 years of age, skull radiographs are similar to adults (Fig. 18.15). During childhood, growth continues at a reduced velocity with a slight postpubertal spurt. The skull grows until late in childhood developing adult characteristics (Figs. 18.16–18.8, e-Fig. 18.19).

### BOX 18.2 Conditions in Which Wormian Bones May Be Present

**TREATABLE**

- Hypothyroid (cretinism)

**COMMONLY FOUND**

- Normal
- Cleidocranial dysplasia
- Osteogenesis imperfecta

**OTHERS (NONINCLUSIVE)***

- Chondrodysplasia punctata
- Copper deficiency: Menkes syndrome
- Hypophosphatasia
- Progeria
- Pyknodysostosis
- Zellweger syndrome

*Many other syndromes may have incidental wormian bones.

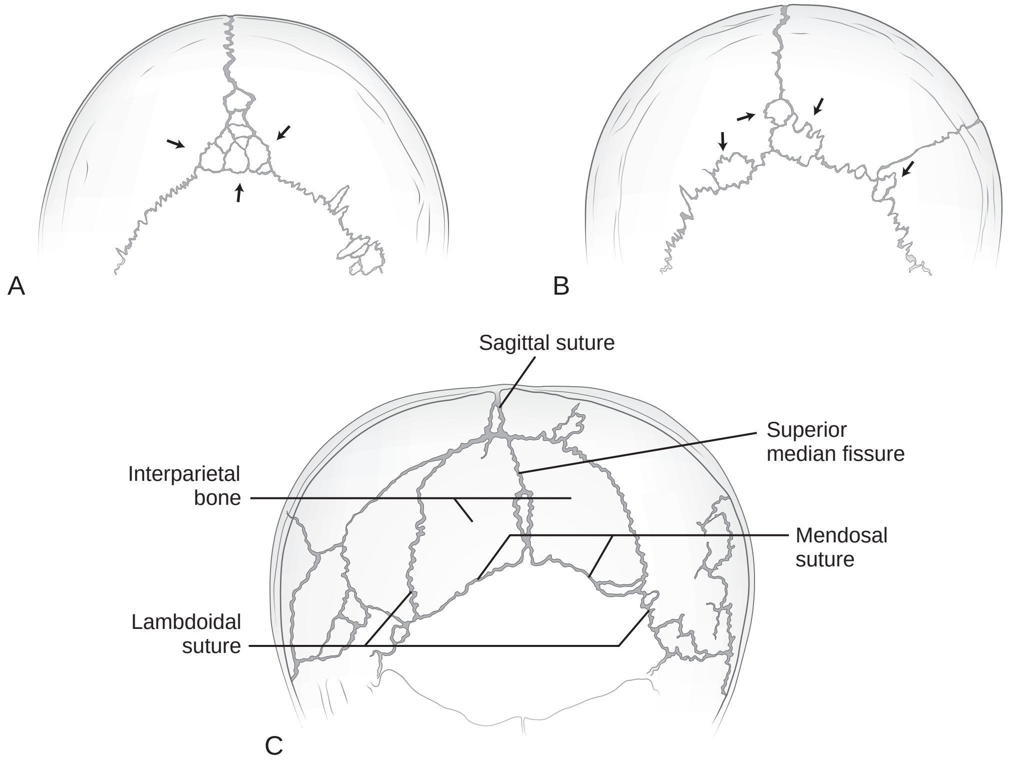

**Figure 18.6. Schematics of wormian bones.** (A) Multiple wormian bones *(arrows)* in the sagittal suture. (B) Multiple wormian bones *(arrows)* in the sagittal and lambdoid sutures. (C) Interparietal bone bounded by the lambdoid and persistent mendosal sutures. The superior median fissure also is still present and divides the interparietal bone into right and left halves.

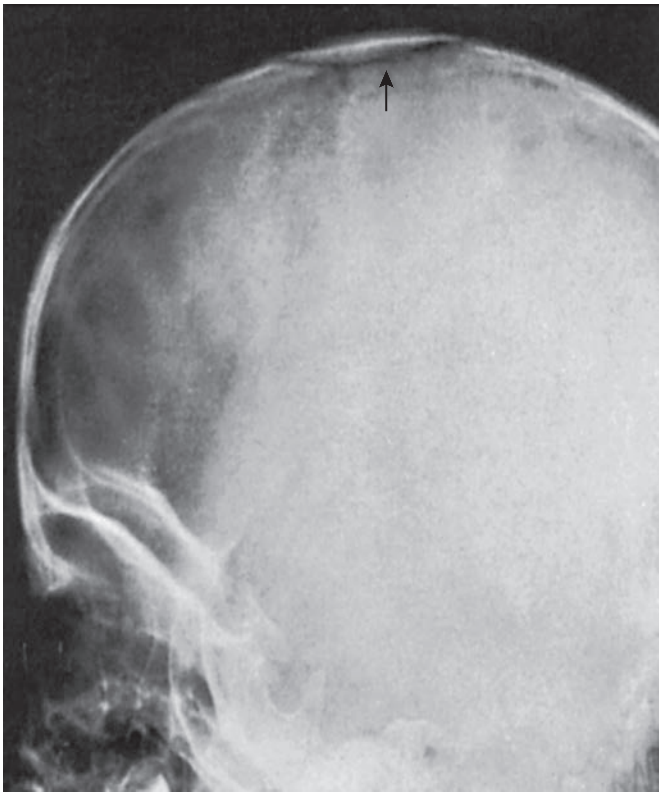
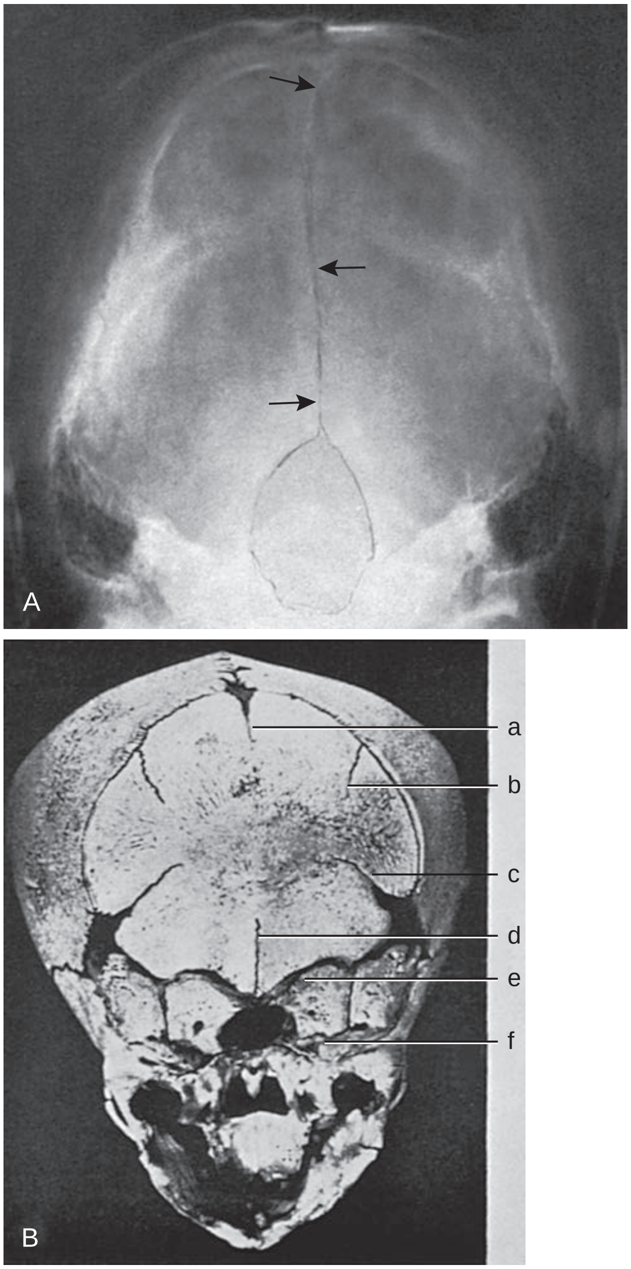
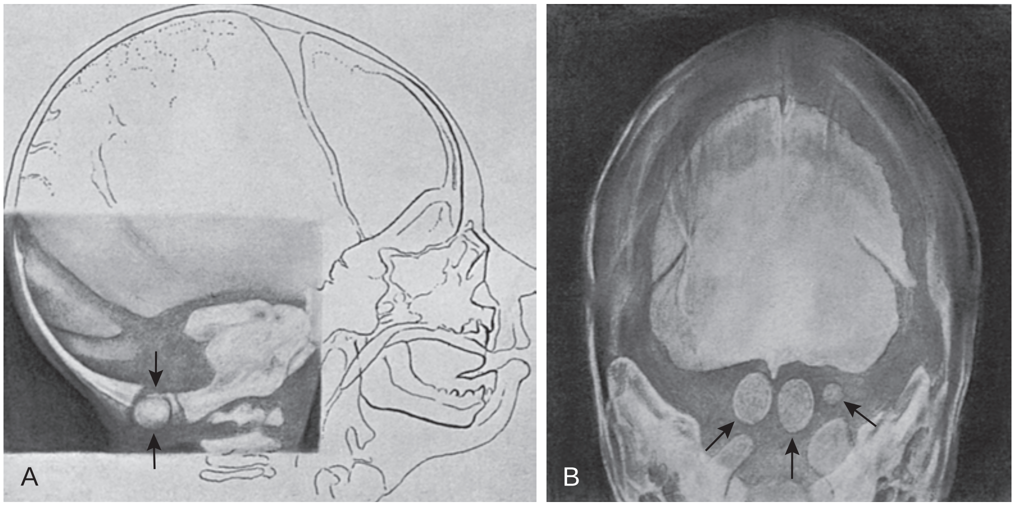


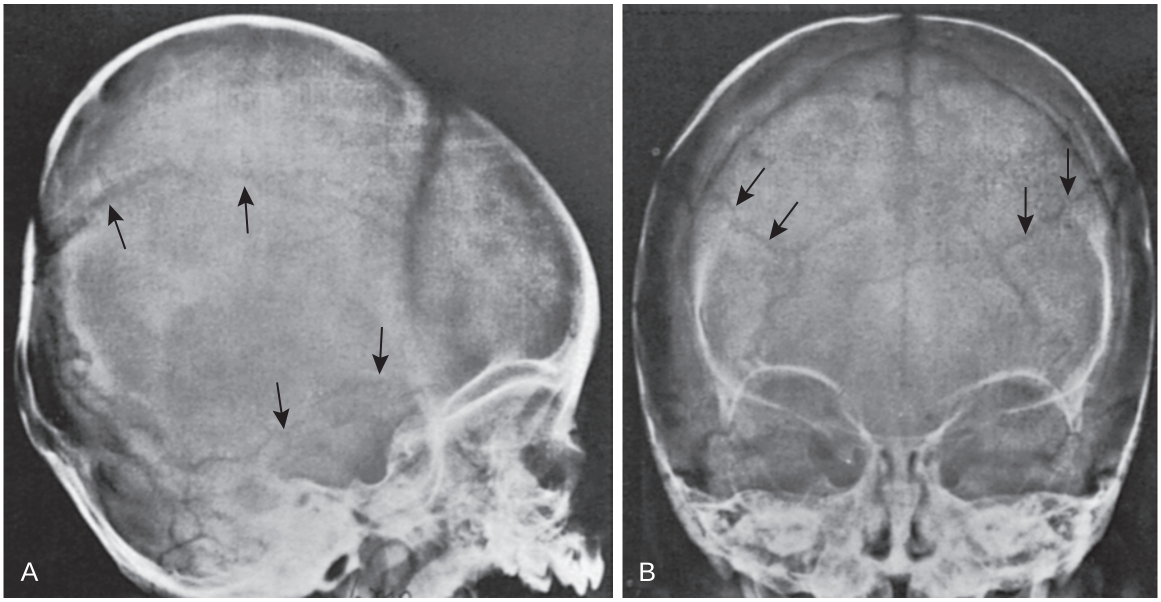
**e-Figure 18.7. A large independent bone *(arrow)* in the anterior fontanelle of a normal 2.5-year-old girl.** Normal variants of this type must be kept in mind when evaluating radiographs trauma. *(Courtesy of Dr. B.R. Girdany, Pittsburgh, PA.)*



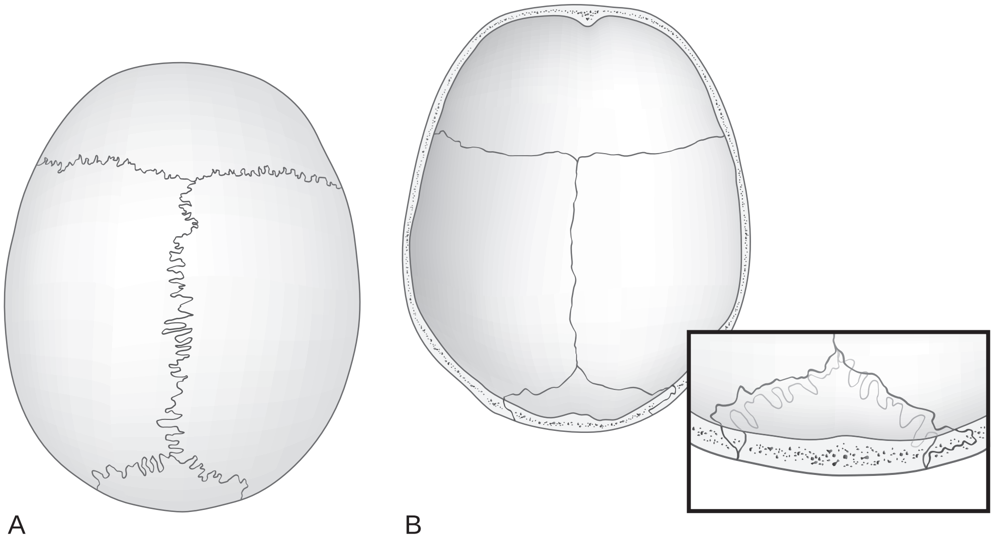
**e-Figure 18.9. Occipital bone.** (A) Towne projection showing radiolucent midline longitudinal or cerebellar synchondrosis *(arrows)* in the occipital squamosa of an 11-year-old girl, which resulted from failure of fusion mediad of its lateral paired ossification centers. This radiolucent strip can be mistaken for a fracture line. (Sutures were retouched with a pencil.) (B) Persistent longitudinal or cerebellar synchondrosis *(d)* in the occipital squamosa of a skull of a newborn; only the caudal segment of the synchondrosis is still open in this case. *a,* Superior median longitudinal fissure; *b,* superior lateral longitudinal fissure; *c,* mendosal suture; *e,* synchrondrosis between exoccipital and supraoccipital bones; *f,* synchrondrosis between basioccipital and exoccipital bones. *(From Koehler A, Zimmer EA.* Borderlands of the Normal and Early Pathologic in Skeletal Roentgenology. *3rd ed. Philadelphia: Grune & Stratton [translated from German ed 11 by S.P. Wilk]; 1968.)*



**e-Figure 18.10. Accessory bones of the supraoccipital bone.** (A) Lateral projection on the second day of life shows separate bony images *(arrows)* in the innominate synchondrosis. (A) A Towne projection of the same skull on the 20th day of life. Three ossicles *(arrows)* are present in the cartilage above the foramen magnum, along with a midline bony process on the under edge of the supraoccipital that is similar to the fetal process in this same site described by Kerckring in *Spicilegium Anatomicum* (Amsterdam, 1670).



**e-Figure 18.12. Bilateral bifid parietal bones, each of which is divided into an upper and lower segment by an extra horizontal suture.** The flattening of the occipital squamosa is postural in origin. The infant was 6 months old and had not experienced a head injury. Lateral (A) and frontal (B) projections are shown. *Upper arrows* point to the anomalous horizontal intraparietal sutures, and *lower arrows* point to the normal squamosal (parietotemporal) sutures. *(Courtesy of Dr. B.R. Girdany, Pittsburgh, PA.)*



**e-Figure 18.19. Drawings of anatomic specimens show the relationship of the outer and inner tables and diploic space of the calvaria to the great sutures.** (A) External aspect of the calvaria shows deep serrations in sutures of the outer table. (B) Internal aspect shows the straight, nonserrated sutures of the inner table. The *inset* drawing depicts the lambdoid suture near the lambda; the differences in position and course of the sutures of the outer and inner tables are shown. In the diploic space, the suture runs in a plane at approximately right angles to the course of the sutures in the tables.

## Normal Variations

The juvenile skull is remarkably variable in size, shape, thickness, mineralization, depth of dural sinus grooves, diploic space pattern, convolutional markings, degree of temporal bone and paranasal pneumatization, and pituitary fossa morphology. In children older than 2 years, the sutures extend through both tables and the diploic space. The outer table portion of the suture may be deeply serrated when the inner table portion is practically a straight line (see e-Fig. 18.19) and may be erroneously interpreted as a fracture. Persistence of the metopic suture may simulate a vertical occipital bone fracture in anteroposterior, caudally angulated radiographs. The frontal crest on the internal surface of the frontal squamosa in the midsagittal plane may be sufficiently prominent to simulate calcification of the falx cerebri (e-Fig. 18.20).

### Convolutional (Digital) Markings

Convolutional (digital) markings are areas of diminished calvarial density separated by strips of normal density (Fig. 18.21). These areas correspond closely to the cerebral convolutions.[3] Convolutional markings are formed by localized pressure of pulsating brain on the inner table of the neurocranium.

### Diploic and Vascular Markings

The diploic space is filled with cancellous osseous bone varying in volume and pattern giving the calvarial vault a fine, honeycomb texture. Radiographically, the diploic veins lie in large, irregular channels of diminished density that extend through the cranial vault in all directions (e-Fig. 18.22 and Fig. 18.23). They vary in size, course, and visibility.

Venous and atrial grooves on the internal calvarial surface are seen as strips of diminished density on radiographs (Fig. 18.24). Compared with the venous grooves, the arterial grooves tend to taper more. The most constant of these channels is the middle meningeal artery, which courses upward and backward from the pterion. The largest vascular markings manifest as osseous thinning over the dural venous sinuses. The superior sagittal sinus lies in a shallow groove on the internal surface at the median plane of the vault near the falx cerebri attachment. At the torcular Herophili, the channels for the superior sagittal and transverse sinuses meet; one transverse sinus is often larger (dominant) compared with the other (see Fig. 18.18). The torcular Herophili in lateral projections may simulate an abnormal defect when it is unusually deep (e-Fig. 18.25). At the bend of the transverse sinus near the mastoid process, superimposition of the transverse and sigmoid sinuses may produce a rounded, radiolucent focus when these sulci are especially deep (e-Fig. 18.26). Often the groove for the bregmatic vein is a conspicuous strip of hypodensity on one or both lateral calvarial walls (e-Fig. 18.27); this groove, also called the *sphenoparietal sinus*, is a misnomer because the true sinus runs underneath the lesser wing of the sphenoid bone and does not always communicate with the bregmatic vein.

### Pacchionian Bodies

The Pacchionian, or arachnoid, granulations (e-Fig. 18.28) are attached to the undersurface of the dura. Originally, they were thought to be the site of cerebrospinal fluid absorption, but this theory has been disputed.[4] These structures are irregular, sharply defined impressions located along the parasagittal inner table of skull. These normal structures appear after age 18 months of age.

### Symmetric Parietal Foramina

About 60% of skulls show small defects (parietal foramina) in the superior posterior angles of the parietal bones through which emissary veins penetrate. The veins communicate with the sagittal sinus internally and occipital vein tributaries externally. Occasionally, large defects are seen and have been termed *enlarged parietal foramina*.[5] Occasionally, they are palpable and, less frequently, they unite to form one large, single defect (Figs. 18.29 and 18.30). The defects result from a failure of mineralization of the membranous bone, and thus the term "enlarged parietal foramina" is a misnomer. The defects are not associated with other skeletal anomalies and have no clinical significance except in the differential diagnosis of cranial defects.

Large parietal foramina have been recognized as an inherited trait ever since Goldsmith found them in 56 members of the Catlin family, giving rise to the term "Catlin mark."[6] They may persist throughout life, although they tend to become smaller or disappear leaving focal sclerotic residua.

## ANATOMY OF THE PARANASAL SINUSES

## Normal Paranasal Sinuses

The paranasal sinuses are paired pneumatic cavities that communicate with the nasal fossae and are located in the maxilla, ethmoid, frontal, and sphenoid bones. Because of the air cell mucosa

continuity with the nasal cavity via the Eustachian tubes, the mastoid air cells can be considered an additional component. The size and shape of the cavities vary with age, among persons, and on the two sides of the same person.[7,8]

The sinus openings into the nasal cavity are shown in Figs. 18.31 and e-Fig. 18.32. The postnatal growth and sinus extension are shown in e-Fig. 18.33. The fully developed maxillary, frontal, and ethmoid sinuses are illustrated in e-Figs. 18.34 and 18.35. CT shows sinus extensions into the orbital roofs and apices of the petrous temporal bone that are not visible on conventional radiographs.

## Maxillary Sinuses

Changes in maxillary sinus development are shown in e-Fig. 18.35 and Fig. 18.36. The maxillary sinuses are present at birth, expand steadily, and are mature by puberty.[9] Developmental variations include unilateral hypoplasia and prominent septa that compartmentalize the sinus (Fig. 18.37). The roots of the maxillary molars occasionally impinge on the sinus walls (e-Fig. 18.38) and sometimes produce mucous membrane folds. In oblique ventrodorsal skull radiographs, the roots of the teeth may be superimposed on the sinuses and artifactually appear to project into them. A molar that fails to migrate is found in its fetal position near the superomedial angle of the maxillary sinus (Figs. 18.39 and 18.40). The height of the antral floor and morphology of the nasal cavity may influence surgical approaches.

## Frontal Sinuses

Morphologic variation in the frontal sinuses is common. The frontal sinuses are not sufficiently developed for radiographic

identification until 6 years of age. The rate of expansion varies, and they extend to the orbital roof between 6 and 12 years. By puberty, most frontal sinuses have reached adult size. Some are extensions of the anterior ethmoid cells. In some cases (especially in instances of hypoplasia of the frontal lobes of the brain), exaggerated extension into the horizontal plates of the frontal bones may occur. This phenomenon is easily recognized in lateral projections.

## Ethmoid Sinuses

The ethmoid sinuses are composed of a series of cells of variable number, forming paired bony labyrinths suspended from the horizontal plate of the ethmoid bone on each side of the vertical plate, with the lateral walls forming the medial orbits. They are separated by thin osseous septa covered with mucous membranes. They communicate with the nasal cavities directly or indirectly through cells of the same group. They are present at birth, expand rapidly during the first 5 years, expand less quickly until about 8 years, and typically are complete by age 12 years. They usually form three groups: anterior, middle, and posterior (see e-Fig. 18.32 and 18.35). The ethmoid cells often extend into the turbinates, crista galli, and neighboring frontal, maxillary, sphenoid, and palate bones. Three anatomic variants of ethmoid cells are found: Agger nasi, Haller, and Onodi cells (see Chapter 8). Extension of sinus infection to the orbit can occur easily via the lamina papyracea (see Chapter 8).

## Sphenoid Sinus

The paired cavities in the sphenoid bone are separated by an osseous partition that may be displaced to one side so that the

London: Edward Arnold & Co.; 1921.)*

two cavities vary in size and shape.[10–12] The cavities can be visualized when superimposed in lateral radiographs or side by side in submentovertical projections (e-Fig. 18.41). Ridges and septa sometimes divide each cavity into compartments. The air cells are not present at birth; by age 4 years, they are 4 to 8 mm in diameter, and become adult size between 7 and 11 years (Fig. 18.42).

## Osteomeatal Unit

The components of the osteomeatal unit (OMU; the central sinus drainage anatomy) are present at birth, albeit crowded (see Figs. 18.31, 18.43, and 18.44). This anatomy is clearly shown with CT obtained either directly coronal or reconstructed from axial images.

## IMAGING OF THE SINUSES

### Plain Radiographs

In general, radiographs are unnecessary for the diagnosis of paranasal sinus disease, particularly in children less than 6 years.[13,14] Nor are they valuable for assessing suitability for, or complications from, sinusitis or sinus surgery.[15,16] Plain radiographs have dubious value in children less than 2 years and certainly infants less than 1 year because of high false-positive rate.[17–19] In older children, a single Waters view may prove useful. See Chapter 8 for further discussion of sinus imaging.

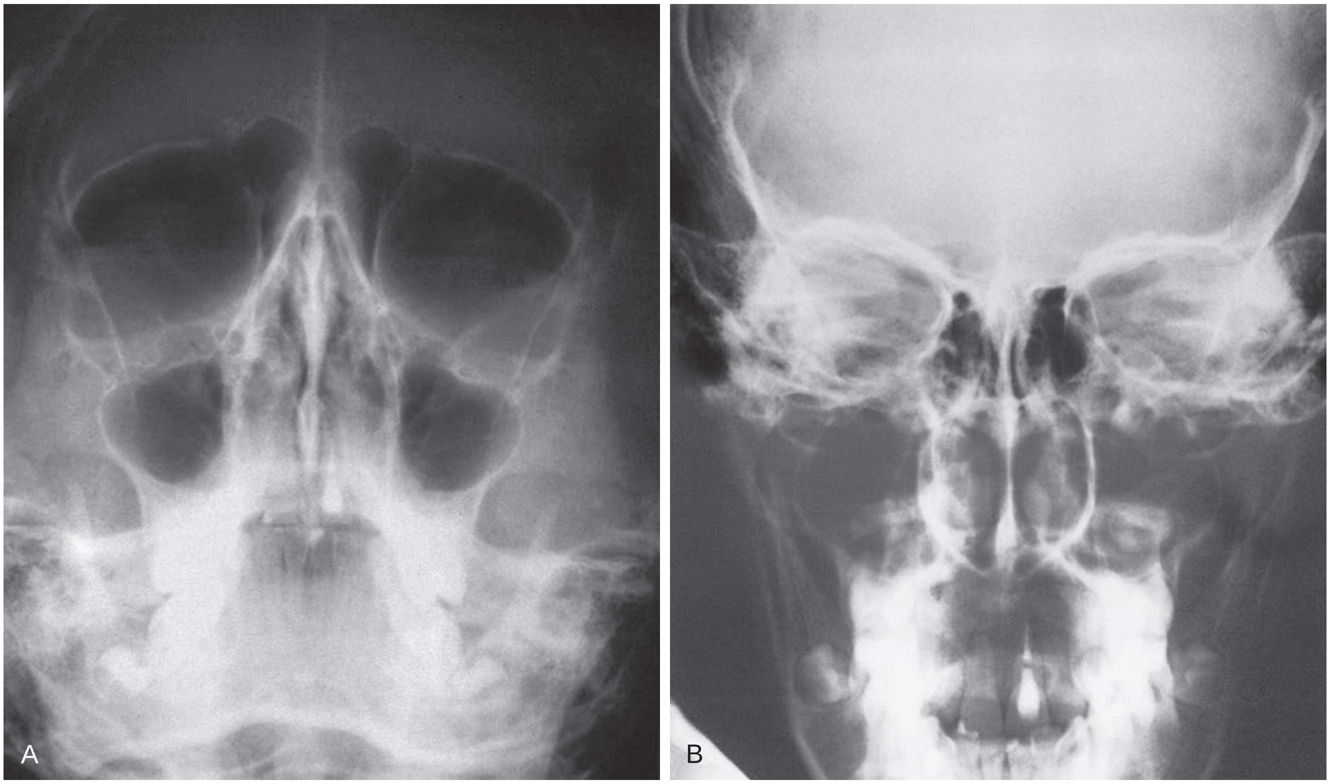

**Figure 18.42. Radiographs of the paranasal sinuses.** (A) Normal Waters (parietocanthial), (B) Posteroanterior axial, (C) Caldwell and (D) Lateral views.

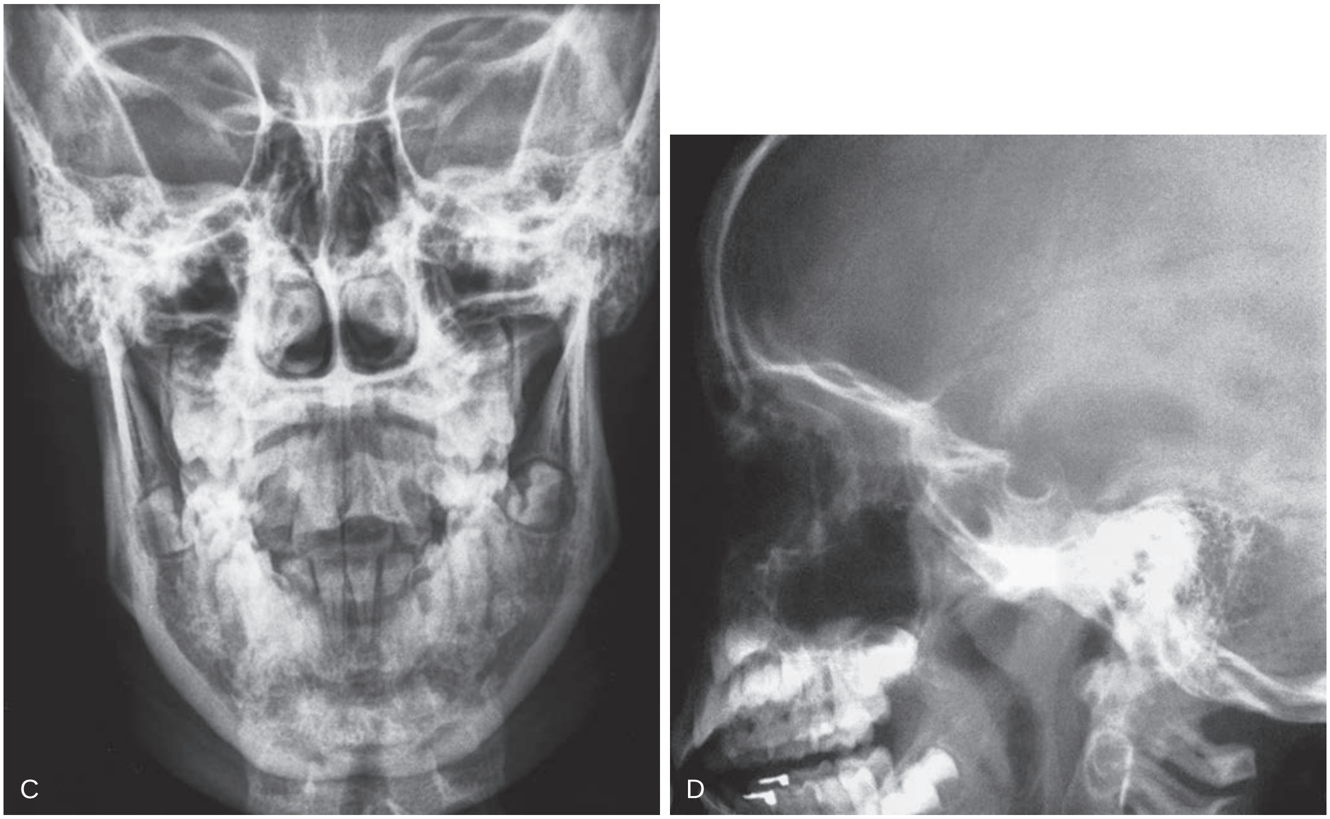

**Figure 18.42, cont'd.**

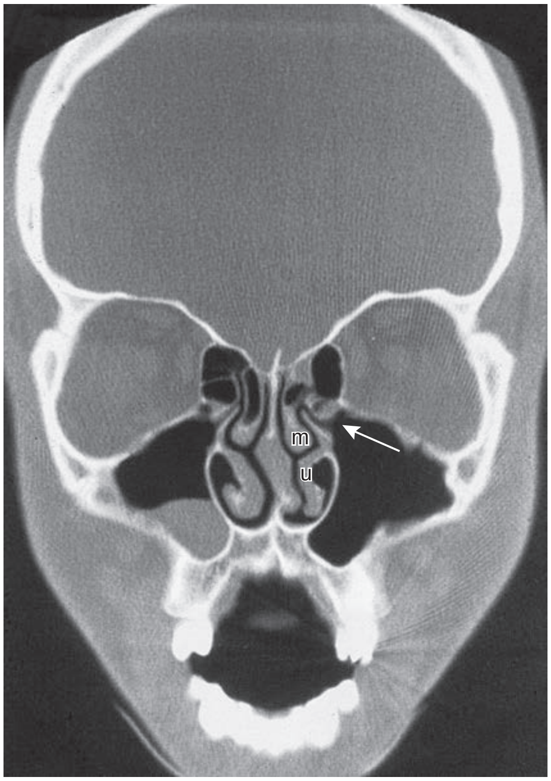

**Figure 18.43. Coronal CT through the midsinuses and nose showing the osteomeatal unit.** Note the mucous retention cyst in the right maxillary antrum and concha bullosa in the right middle turbinate. The patient has no history or evidence of sinus disease. The ostium (opening) *(arrow)*, infundibulum (airspace superior to ostia and lateral to the uncinate process of the inferior turbinate *[u]*), and middle turbinate *(m)* are shown. The circular airspace above the uncinate process is the hiatus semilunaris.

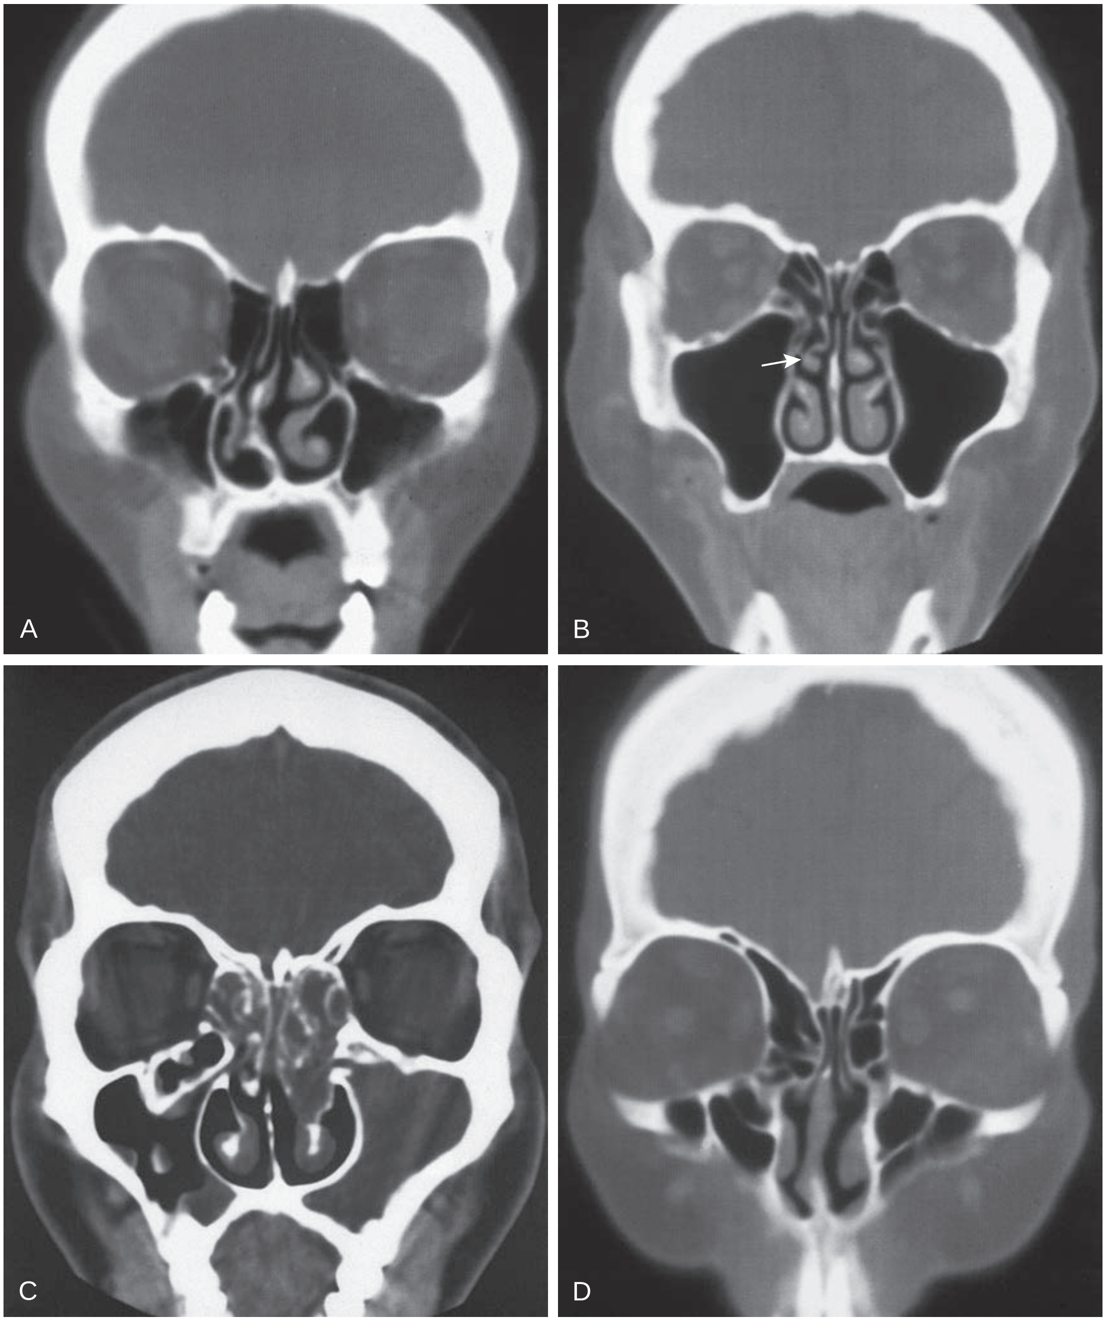

**Figure 18.44. Normal coronal CT variants of the nose.** (A) Deviated nasal septum, (B) a paradoxically bent middle turbinate *(arrow)*, (C) Haller air cell (ethmoid cells located along the rim of the ostia and protruding into the maxillary antrum), and (D) large Agger nasi air cells—the most anterior air cells.

## KEY POINTS

- The head is larger relative to the face in neonates and infants.
- Obliteration of the sutures is not complete until the second to third decade of life.
- Wormian bones, Inca bone, and bathrocephaly are normal cranial variants in children under 2 years of age.
- Cranial variants of normal children and juveniles include the paracondylar process, digital markings, and Pacchionian bodies (arachnoid granulations).
- Plain sinus radiographs have extremely limited utility, especially in children under 2 years, and are unnecessary for diagnosing sinusitis, particularly in children under 6 years old.
- Maxillary and ethmoid air cells are present at birth.
- Sphenoid air cell pneumatization begins around 2 years of age.[20]
- Frontal sinuses are seen between 6 and 12 years of age.

# 19

# Prenatal Imaging

Ashley James Robinson, Susan Blaser, and A. Michelle Fink

The fetal abnormalities described in this chapter are those most likely to be assessed by a pediatric radiologist who primarily performs fetal magnetic resonance imaging (MRI), computed tomography (CT), radiography, and ultrasound. These additional modalities are particularly useful for acquiring further characterization of fetal abnormalities, especially when a fetal autopsy will be declined but a couple needs to be counseled regarding future pregnancies.

In most of the references provided, a combination of prenatal ultrasound plus MRI and/or CT was performed. The suggested readings list includes references to several standard ultrasound texts that deal with the subject matter from the perspective of ultrasound as the primary imaging modality.

## SCALP

A scalp cyst, although infrequently encountered, is likely to require further assessment by fetal MRI. The most important differential diagnosis is between an ectodermal cyst and a meningocele or encephalocele.[1-6] A fetus with an ectodermal cyst should have no underlying skull defect or transiting vessels or membranes, and the underlying brain should be normal. Because of limitations of resolution, small defects and thus the diagnosis of meningocele can be missed when MRI is used (e-Fig. 19.1).[7]

Hemangioma is another scalp abnormality that occurs infrequently (Fig. 19.2). The main differential diagnosis is encephalocele.[8,9] Further evaluation by fetal MRI can be helpful in demonstrating the absence of a skull defect or an abnormality of the underlying brain.[1,10-14]

Other lesions that should be considered in the differential diagnosis of scalp abnormalities include lymphatic malformation, edema, nevus sebaceous, sarcoma, and a teratoma perforating the skull.[1,15,16] Rare abnormalities that have been described on antenatal imaging include gyriform thickening of the scalp in fetuses with cutis verticis gyrata associated with Noonan syndrome[17] and hamartomata of the scalp in fetuses with encephalocraniocutaneous lipomatosis.[18]

## SKULL

Skull defects are a result of errors in dorsal induction, the process whereby the neural tube forms and closes (neurulation).[19,20] A spectrum of anomalies is characterized by absent flat bones of the skull.

### Large Bony Defects

#### Acalvaria

*Acalvaria* is the term used when the bony skull vault, meninges, and scalp muscles are absent and a normal brain is covered by skin only.[21] *Acrania* is the term used when the skull vault, scalp muscles, and skin are absent and a dysplastic brain is covered by meninges only.[22]

#### Exencephaly

Exencephaly is the combination of acrania with abnormal brain tissue[22] and has been demonstrated to be the predecessor of anencephaly.[23,24] Exencephaly can be seen in association with amniotic band sequence[25-28] and limb body wall complex,[29,30] but can be distinguished from them because they generally form asymmetric skull defects (e-Fig. 19.3).[19] MRI can help to differentiate exencephaly from other cranial vault defects.[31]

#### Anencephaly

Anencephaly, which is the single most common open neural tube defect,[32] is characterized by acrania with complete absence of a normal brain above the brainstem (e-Fig. 19.3A).[19,20] It is the end result of exencephaly with mechanical and chemical attrition of the abnormal brain tissue in utero[22]; the remaining tissue constitutes a mass of exposed vascular neural tissue. The cartilaginous skull is intact. This condition invariably is fatal. When accompanied by dysraphism of the entire spine, it is known as craniorachischisis.[19] Fetal MRI findings have been described in cases associated with omphalocele,[33] gastroschisis,[34] and pentalogy of Cantrell.[35,36]

### Focal Bony Defects

#### Cephaloceles

Focal defects in the skull can allow internal structures to herniate. The terminology changes depending on whether the contents of the hernia include just meninges and cerebrospinal fluid (cephalocele), brain matter (encephalocele), or a ventricle (encephalocystocele). Most defects are in the midline, are occipital (Fig. 19.4),[19,20] and usually contain dysplastic brain tissue and venous sinuses.[20] They can be part of syndromes such as the ciliopathies (e.g., Meckel-Gruber), the congenital muscular dystrophies (e.g., Walker–Warburg), and Chiari III malformation.[19,20,37,38] The most common type of encephalocele in Southeast Asia is frontoethmoidal.[39]

Fetal MRI can be useful to differentiate a cephalocele from a scalp cyst and to determine if it contains brain tissue, with diffusion-weighted imaging being particularly helpful for detecting displaced brain, and echo-planar imaging for detecting draining veins.[1,40,41] Care must be exercised to differentiate a cephalocele from an encephalocystocele with very thin parenchyma.[42] Large encephaloceles can appear similar to anencephaly, although the calvarium typically has developed to some extent.[19] An atretic cephalocele typically presents as a midline subcutaneous nodule or cyst,[43] and underlying venous anomalies often are present that are similar to those seen with enlarged parietal foramina.[44-46]

#### Enlarged Parietal Foramina

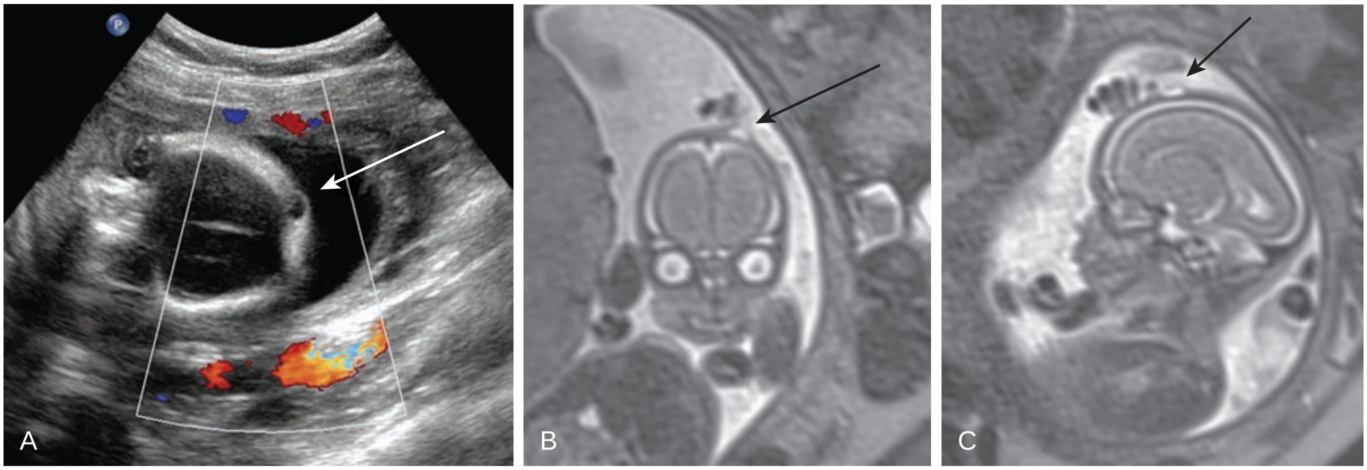
Enlarged parietal foramina are thought to be the result of defective ossification of the membranous skull. During fetal life they comprise a large central defect that, because of subsequent ossification, including midline ossification (Fig. 19.5), become bilateral symmetric defects.[47] In contradistinction, encephaloceles typically are midline or unilateral. Enlarged parietal foramina can be large defects, typically closing almost completely during childhood, leaving only small bilateral foramina.[43,48] Although typically benign, they can be associated with hypoplasia or atresia of the straight sinus with a persistent falcine sinus draining to the straight sinus at the level of the anomaly.[43,47] Associated abnormalities of occipital cortical infolding can be seen postnatally.[49] Enlarged parietal foramina can be hereditary (autosomal dominant), associated with genes *MSX2* and *ALX4*.[50,51] Enlarged parietal foramina also can be syndromic, as in Potocki–Shaffer syndrome.[52]

## Abstract:

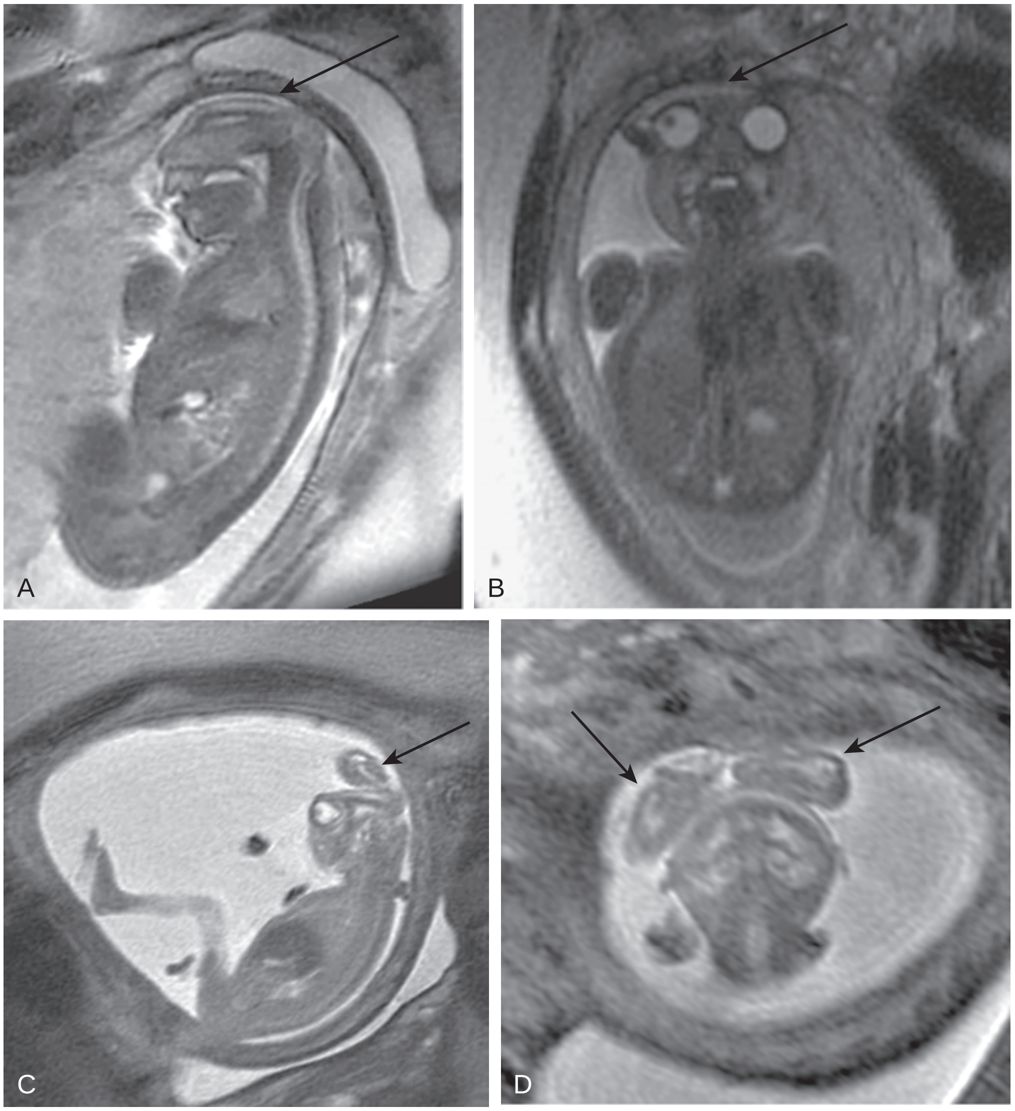
Detailed assessment of the fetus is primarily performed by ultrasound, with fetal magnetic resonance imaging used as a secondary complimentary modality for further characterisation. Increasingly computed tomography is being used in the assessment of the fetal axial and appendicular skeleton. This chapter describes the most common scalp and cranial vault abnormalities that are encountered in the fetus, including large bony defects such as acalvaria, exencephaly and anencephaly, focal bony defects such as cephaloceles and enlarged partietal foramina, mineralization defects of various skeletal dysplasia, and size and shape abnormalities typical of spina bifida aperta, skeletal dysplasia and various forms of craniosynostosis.

## Keywords:

skeletal dysplasia
abnormalities
spina bifida aperta
skeletal dysplasia
craniosynostosis



**e-Figure 19.1. Scalp cyst.** (A) Prenatal sonogram shows a parasagittal scalp cyst *(arrow).* No clear intracranial communication or intracyst contents are present. (B) Coronal fetal MRI shows a cyst *(arrow).* The subjacent brain appears normal. No skull defect is seen. (C) Sagittal fetal MRI shows a cyst *(arrow)* in the sagittal view.



**e-Figure 19.3. Anencephaly/exencephaly.** (A) Sagittal and (B) coronal fetal MRI images show anencephaly. The cranium and brain are completely absent *(arrow)* above the orbits. (C) Sagittal MRI in another fetus shows exencephaly. The cranium is absent, and persistent dysplastic brain tissue is present *(arrow).* (D) Coronal image shows bilateral dysplastic hemispheres *(arrows).*

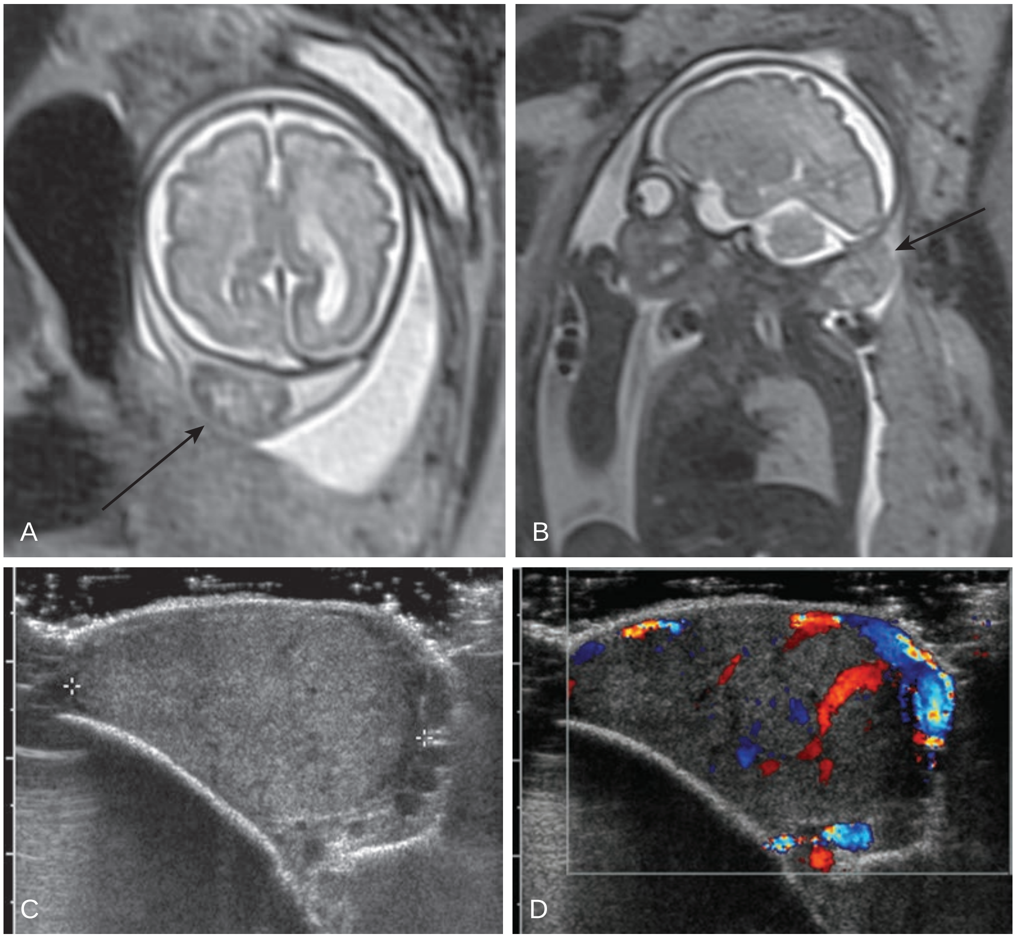


**Figure 19.2. Scalp hemangioma.** (A) Axial fetal MRI shows a heterogeneous mass in the occipital scalp *(arrow)*. The skull appears intact. (B) Sagittal fetal MRI shows a sagittal view of a mass in the occipital scalp *(arrow)*. (C) Postnatal sonogram shows a heterogeneous mass in the scalp. The skull appears to be intact. (D) Color Doppler sonogram shows vascular flow throughout.

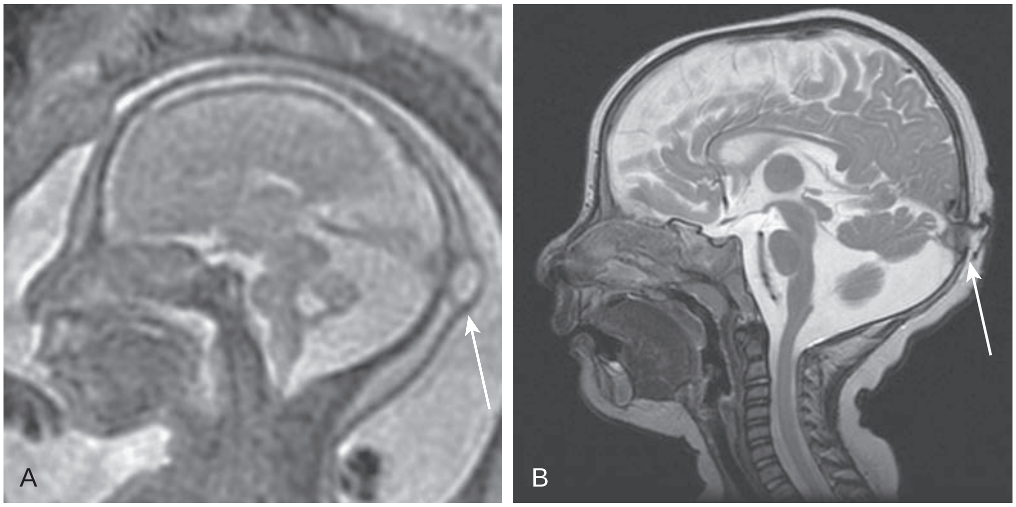

**Figure 19.4. Cephalocele.** (A) Sagittal fetal MRI shows a small occipital cyst *(arrow)* with abnormal cerebellar vermis. (B) Postnatal sagittal T2-weighted MRI shows an atretic cephalocele with a scalp abnormality *(arrow)*. *(From Robinson AJ, Blaser S, Toi A, et al. The fetal cerebellar vermis: assessment for abnormal development by ultrasonography and magnetic resonance imaging.* Ultrasound Q. *2007;23(3):211–223.)*

Enlarged parietal foramina.** (A) Sagittal fetal sonogram shows a skull defect with intact overlying scalp *(arrow).* (B) Sagittal fetal MRI shows a skull defect that does not contain brain *(arrow).* (C) Sagittal T2-weighted postnatal MRI shows a skull defect that now contains brain. An abnormal course of a straight sinus is present *(arrow). (From Fink AM, Maixner W. Enlarged parietal foramina: MR imaging features in the fetus and neonate.* AJNR Am J Neuroradiol*. 2006;27:1379–1381.)*

**TABLE 19.1** Skull Abnormalities in Common Lethal Skeletal Dysplasias

| Skull Type | Mineralization | Size | Shape | Trunk Length | Fractures |
|---|---|---|---|---|---|
| Osteogenesis imperfecta (type IIa) | Demineralized | Normal | Deformable | Short | Many |
| Hypophosphatasia | Demineralized | Normal | Deformable | Normal | Few |
| Achondrogenesis | Type I demineralized<br>Type II normal | Large | Normal | Short | Few |
| Thanatophoric dysplasia | Normal | Large (megalencephaly) | Type I normal<br>Type II cloverleaf | Normal | None |

*Modified from Glanc P, Chitayat D, Unger S. The fetal musculoskeletal system. In: Rumack CM, Wilson SR, Charboneau JW, eds.* Diagnostic Ultrasound, *3rd ed. St. Louis: Elsevier; 2005.*

## Mineralization Defects

Prenatal ultrasound may reveal defective skull mineralization in fetuses with several skeletal dysplasias, primarily osteogenesis imperfecta type IIa (e-Fig. 19.6), hypophosphatasia congenita, and achondrogenesis.[53-55] A summary of distinguishing features is provided in Table 19.1. Radiography of the pregnant patient increasingly is being used, and fetal three-dimensional CT is an emerging technique in the evaluation of fetal skeletal dysplasias.[1,20,32,53,56-66]

## Size and Shape Abnormalities

Microcrania and macrocrania are defined when the head circumference differs more than three standard deviations from the mean in either direction.[32]

### Microcrania

The birth incidence of microcrania is 1:1000.[60] Microcrania often is the result of an underlying small brain, that is, microencephaly[1] (e-Fig. 19.7). Causes include genetic syndromes,[60] chromosomal defects (typically trisomy 13),[20] hemorrhage, teratogens, infection, radiation,[60] and encephalocele.[1,20]

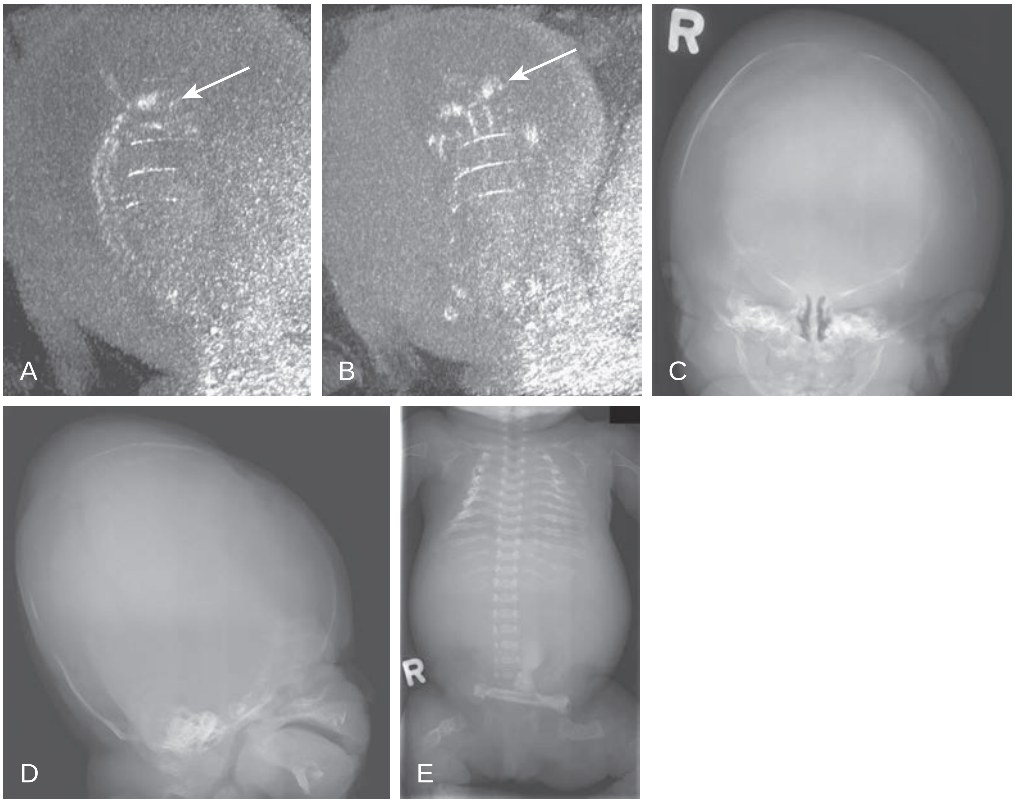
### Macrocrania

Macrocrania typically is seen as a result of fetal hydrocephalus. Other causes include hydranencephaly,[20,61] intracranial teratoma or astrocytoma, and, occasionally, rarer tumors.[1,62] Skeletal dysplasias that cause enlargement of the head include achondrogenesis (type 1)[53] and skeletal dysplasias and craniosynostosis syndromes caused by fibroblast growth factor receptors 2 and 3 (*FGFR2* and *FGFR3*) mutations, such as thanatophoric dysplasia (e-Fig. 19.8) due to an enlarged brain (megalencephaly), with preferential enlargement of the temporal lobes and coexistent cerebral malformations, in particular, abnormal premature temporal lobe sulcation, which has been demonstrated by both fetal ultrasound and MRI.[63-72] Partial callosal dysgenesis also has been reported in fetuses with this condition.[66] Table 19.1 summarizes these distinguishing features.

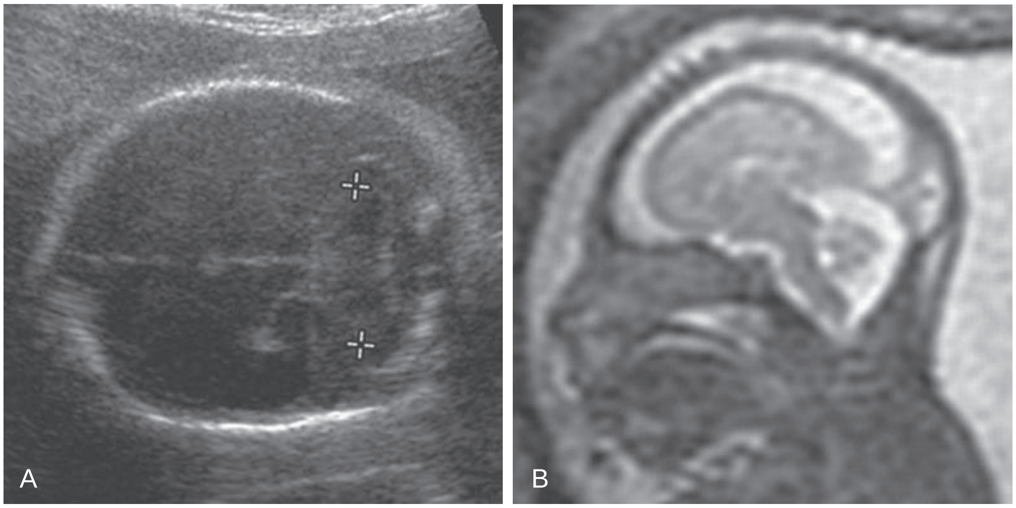
### Dysmorphism

**Lemon-Shaped Skull and Spina Bifida.** A lemon-shaped skull, characterized by a concave or linear contour at the level of the coronal sutures (the “lemon sign”), is a well-known morphologic finding that is highly sensitive for open neural tube defects (e-Fig. 19.9).[73-75] However, it has a poor positive predictive value in low-risk fetuses and is seen in fetuses with other pathologies, including encephalocele and a variety of non–neural tube structural anomalies.[32,76-78]

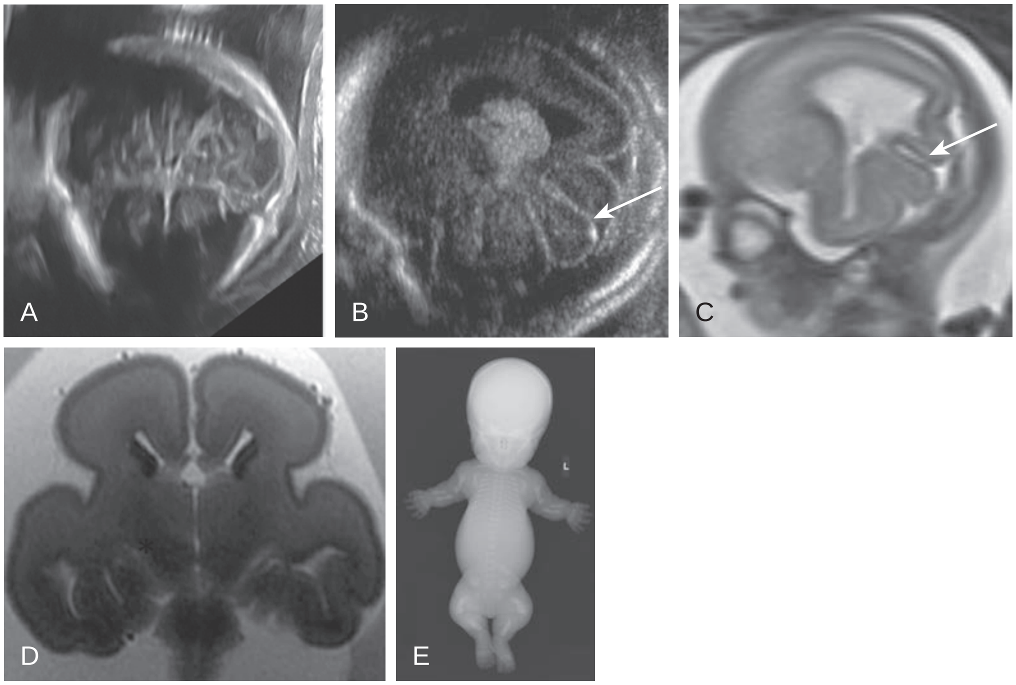
**Cloverleaf Skull (Kleeblattschädel).** A cloverleaf appearance occurs as a result of bilateral coronal and lambdoid synostosis and is found in fetuses with type II thanatophoric dysplasia (Fig. 19.10).[1,53,64] Cloverleaf skull also has been used to describe the dysmorphic appearance of the skull in fetuses with syndromic craniosynostosis,[79-81] and which in prenatal life is often associated with abnormal karyotype, as described in Chapter 20. Several case reports have described the use of fetal MRI in its antenatal diagnosis.[79,82,83]



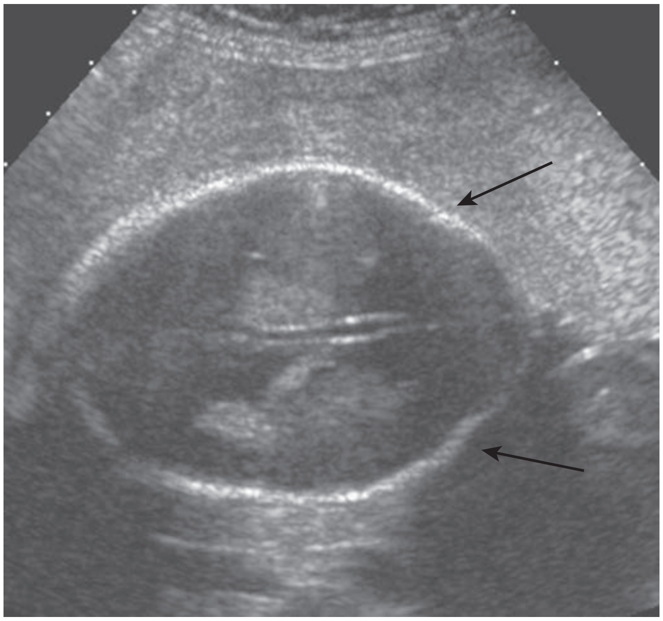
**e-Figure 19.6. Osteogenesis imperfecta.** (A) Fetal CT scan with sagittal reformatting shows that only the skull base *(arrow)* and spine are visible. The cranial vault is severely undermineralized. (B) Fetal CT scan with coronal reformatting shows that only the skull base is mineralized *(arrow).* (C) Postmortem frontal and (D) lateral radiographs show a severely undermineralized skull vault. (E) Postmortem radiograph shows short fractured long bones and ribs.



**e-Figure 19.7. Microencephaly.** (A) Transverse fetal sonogram shows a small cerebellum *(calipers).* The head circumference and biparietal diameter also were small. (B) Sagittal fetal MRI shows a small, smooth brain and a backward sloping forehead. *(From Robinson AJ, Blaser S, Toi A, et al. The fetal cerebellar vermis: assessment for abnormal development by ultrasonography and magnetic resonance imaging.* Ultrasound Q*. 2007;23(3):211–223.)*



**e-Figure 19.8. Thanatophoric dysplasia.** (A) Axial fetal sonogram shows a strawberry skull caused by relative enlargement of the temporoparietal lobes compared with the frontal lobe. (B) Fetal sonogram shows the parasagittal oblique and thickened abnormal sulci in the temporal lobe *(arrow).* (C) Sagittal fetal MRI shows thickened abnormal temporal lobe sulci *(arrow).* (D) Postmortem T2-weighted MRI shows relative enlargement of the temporal lobes compared with the frontal lobes. (E) Postmortem radiograph shows typical skeletal features including severe micromelia, a curved femora, and platyspondyly. *(*A, B, *and* C, *From Fink AM, Hingston T, Sampson A, et al. Malformation of the fetal brain in thanatophoric dysplasia: US and MRI findings.* Pediatr Radiol*. 2010;40(suppl 1):S134–S137.* D, *From Miller E, Blaser S, Shannon P, et al. Brain and bone abnormalities of thanatophoric dwarfism.* AJR Am J Roentgenol*. 2009;192[1]:48–51.)*



**e-Figure 19.9. Lemon skull.** Axial fetal sonogram of the head shows bilateral indentation of the frontal bones *(arrows).*

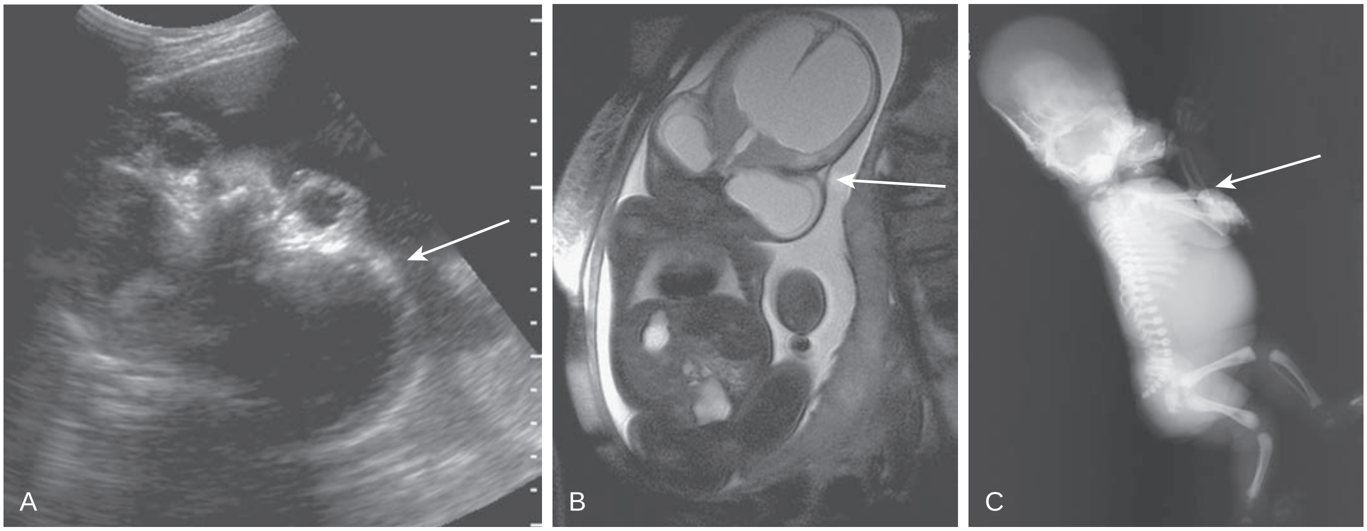


**Figure 19.10. Cloverleaf skull.** (A) Axial fetal sonogram shows bossing of the temporal bones *(arrow)* and bulging eyes in a case of acrocephalosyndactyly. (B) Coronal fetal MRI shows bossing of temporal bones *(arrow)* and frontal bones. Severe ventriculomegaly is noted. (C) Postmortem radiograph shows a severe cloverleaf skull with midface hypoplasia. Note elbow ankylosis typical of Pfeiffer syndrome. *(A, From Robinson AJ, Blaser S, Toi A, et al. Magnetic resonance imaging of the fetal eyes—morphologic and biometric assessment for abnormal development with ultrasonographic and clinicopathologic correlation.* Pediatr Radiol. *2008;38:971–981.)*

**Strawberry Skull.** A strawberry-shaped skull, characterized by flattening of the occiput and pointing of the frontal bones, is seen by ultrasound on the submentobregmatic section and is characteristic of fetuses with trisomy 18.[84] This appearance also has been described in fetal thanatophoric dwarfism.[85]

## KEY POINTS

- Prenatal MRI can be used to differentiate between simple ectodermal cysts and meningoceles or encephaloceles.
- Prenatal MRI can be used to differentiate between solid extracranial masses and encephaloceles or perforating intracranial tumors.
- Prenatal MRI can be used to differentiate (benign) skull foramina from more serious skull defects.
- Use of prenatal three-dimensional CT in the workup of skeletal dysplasias is growing.

# Craniosynostosis, Selected Craniofacial Syndromes, and Other Abnormalities of the Skull

Jason F. Tobler, Thomas L. Slovis, and Arlene A. Rozzelle

The clinical and radiologic features of craniosynostosis result from lack of sutural formation or premature fusion across membranous sutures. The premature sutural closure prevalence is displayed in e-Table 20.1.[1] Normal sutures permit skull growth perpendicular to their long axes. With early closure of one suture, there is compensation and excess growth in others resulting in a craniofacial deformity (e-Table 20.2; e-Fig. 20.1 and Figs. 20.2–20.4).

Calvarial deformities present before sutural changes. Only a portion of the bony suture needs to be closed to have craniosynostosis (e-Fig. 20.5). Abnormal head shape secondary to suture maldevelopment can present in utero at 13 weeks' gestational age.[2,3] Craniosynostosis is associated with genetic abnormalities (e-Box 20.1) and is a secondary finding in many systemic disorders (e-Box 20.2).[4]

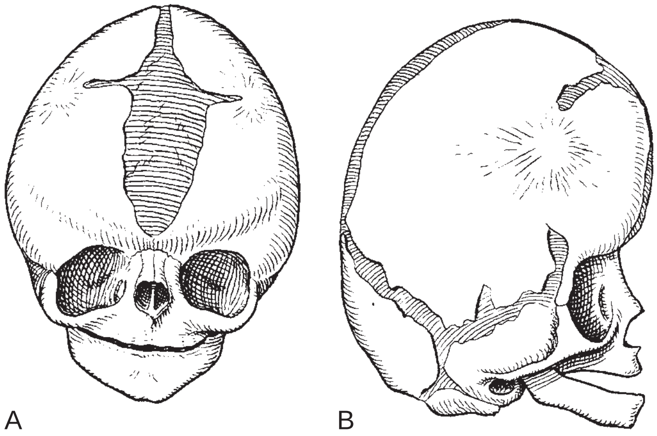

**Figure 20.2. Schematics of bilateral coronal suture synostosis in a child with Apert syndrome.** (A) Frontal, and (B) lateral schematics reveal coronal suture fusion except for short, open terminal segments and open segments near the sagittal suture and anterior fontanel. The metopic, sagittal, lambdoid, and temporoparietal sutures all are open. The calvarium shows anteroposterior shortening and craniocaudal elongation.

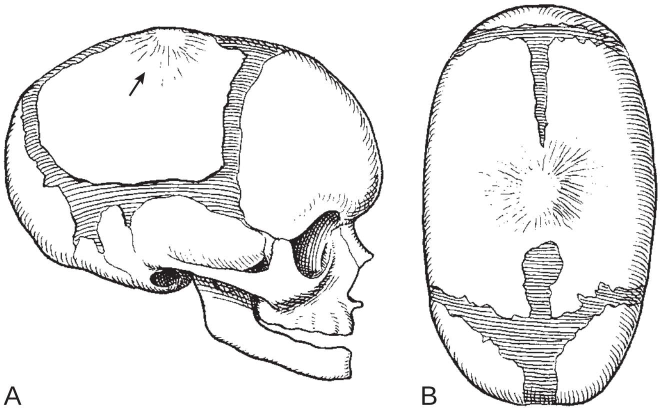

**Figure 20.3. Schematic drawings of premature sagittal suture synostosis.** (A) Lateral and (B) superior schematics are shown.

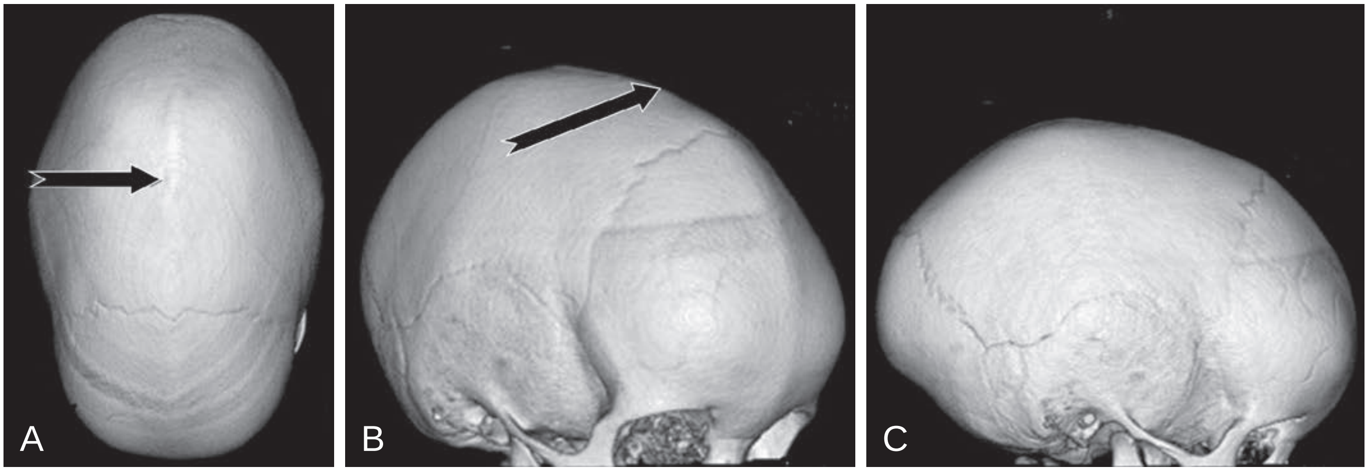

**Figure 20.4. Premature synostosis of the sagittal suture in a 3-year-old female.** (A) Vertex, (B) oblique, and (C) lateral reformatted 3D CT images show occipital-frontal elongation and decreased calvarial width. The sagittal suture *(arrows)* is fused and ridged.

## Abstract:

The subject of this chapter is craniosynostosis, craniofacial syndromes and other abnormalities of the skull that pertain to pediatric radiology. There is brief discussion of normal skull development. The different types of craniosynostosis are discussed with emphasis on the specific growth pattern abnormality and resultant radiology findings. Syndromes associated with craniosynostosis are highlighted. Radiologic hallmarks of major craniofacial syndromes are also discussed.

## Keywords:

Craniosynostosis
craniofacial syndromes

**e-Figure 20.5. Severe sagittal suture synostosis in a 2-week-old infant with scaphocephaly.** (A) Lateral radiograph reveals a deformity resulting from craniostenosis, but the sagittal suture is not seen *(superior black arrows).* Coronal *(black arrows)* and lambdoid sutures *(white arrow)* are widened. (B) Frontal radiograph demonstrates an open sagittal suture except for a short segment *(arrows)* only a few millimeters long.

Specific head shapes are associated with particular suture synostoses (e-Fig. 20.6). The normal head is oval, being widest in the parietal area with a rounded forehead (Fig. 20.7).[5]

*Sagittal synostosis* (scaphocephaly or dolichocephaly) is characterized by increased AP skull length, decreased width, bitemporal pinching, and a tendency for the vertex to be anterior rather than posterior (see Figs. 20.3 and 20.4). *Metopic synostosis* (trigonocephaly) results in a triangular, pointed forehead (Fig. 20.8A-C and e-Fig. 20.9, also see e-Fig. 20.6). The premature fusion of the metopic suture often results in what has been termed the "omega" sign as opposed to the normal "M" sign present in normal physiologic fusion of the metopic suture (Fig. 20.8D and E).

*Unilateral coronal synostosis* results in flattening of the ipsilateral forehead and occipital area, a "harlequin eye" (the sphenoid is drawn up toward the closed suture), contralateral forehead bossing, and deviation of the nose away from the synostosed side

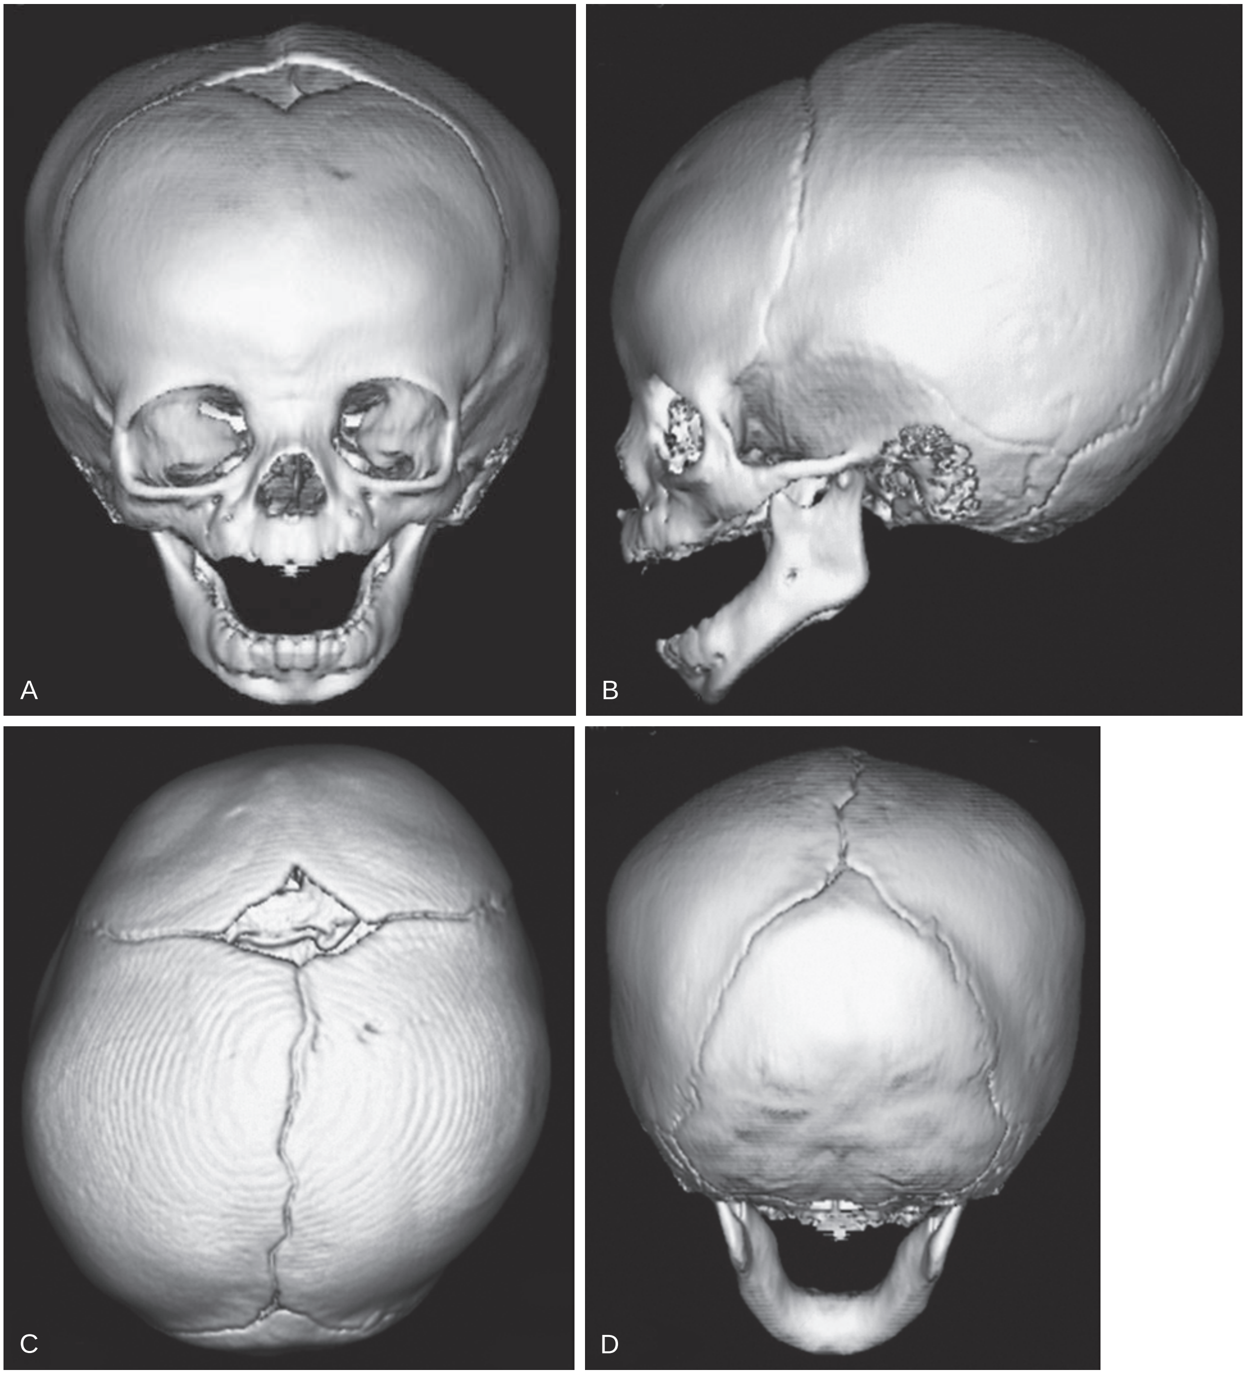

**Figure 20.7. Normal 3D CT of a 7-month-old infant.** (A) Frontal image shows the open anterior fontanel and coronal sutures. The metopic suture has closed. (B) Lateral view identifies the lambdoid, squamosal and coronal sutures. (C) Vertex image identifies the coronal, sagittal, and lambdoid sutures. (D) Posterior view shows the sagittal and lambdoid sutures. The normal head is egg (oval)-shaped, widest at the biparietal area.

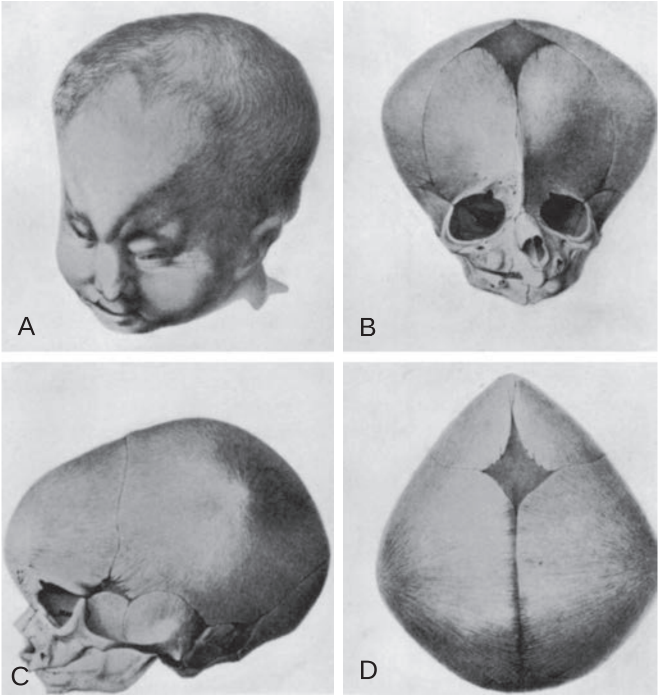
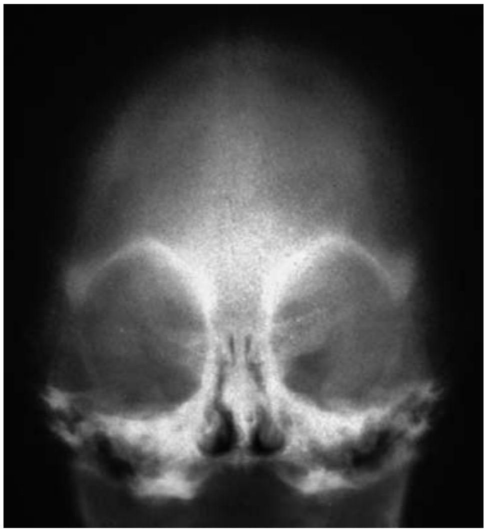


**e-Figure 20.6. Trigonocephaly in a newborn.** (A) Photograph of the calvarium, (B) frontal, (C) lateral and, (D) superior views of the skull. Note the ridge on the forehead, shaped like the keel of a boat. *(From Welcker H.* Untersuchungen über Wachstum und Bau des menschlichen Schädels, *Leipzig: W. Engelmann; 1862.)*



**e-Figure 20.9. Trigonocephaly.** Frontal radiograph shows the characteristic orbital hypotelorism and narrowing of the forehead. The metopic suture is invariably closed.

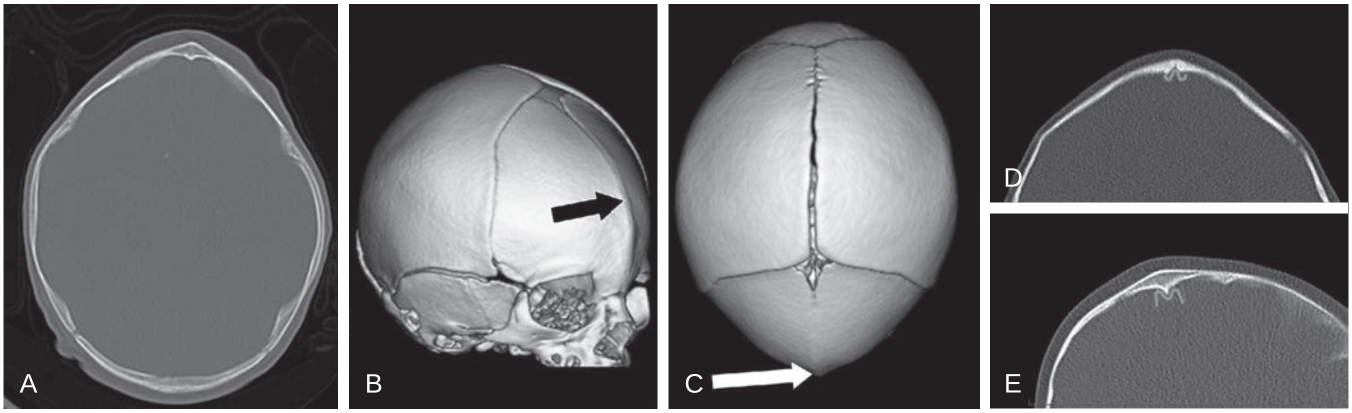


**Figure 20.8. Trigonocephaly in a 3-week-old male.** (A) Axial CT, (B) and (C) 3D CT images reveal metopic suture synostosis with sutural ridging *(black arrow)* and trigonocephaly *(white arrow).* Note that bicoronal and lambdoid sutures override without fusion. (D) and (E) Axial CT images demonstrated the "omega" sign of premature suture fusion, versus the "M" sign of normal physiologic fusion.

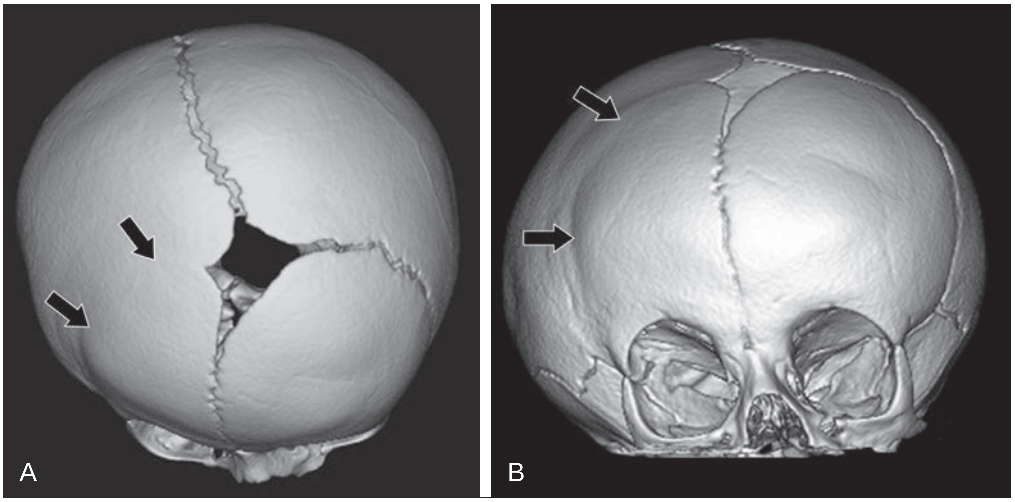

**Figure 20.10. Unilateral coronal suture synostosis in a 6-month-old infant.** (A and B) 3D CT images demonstrate complete fusion of the right coronal suture *(arrows).* The anterior fontanelle and left coronal suture remain patent. The cranial vault demonstrates pronounced right frontal flattening, mild right orbital roof elevation, contralateral frontal bossing and deviation of the nose away from the affected side.

(Fig. 20.10 and e-Fig. 20.11). Features distinguishing unicoronal synostosis from anterior deformational plagiocephaly are listed in e-Table 20.3.

*Bicoronal synostosis* causes brachycephaly (i.e., wide, short head). The supraorbital rims and forehead are recessed with bitemporal and forehead bulging (Fig. 20.12 and e-Fig. 20.13).

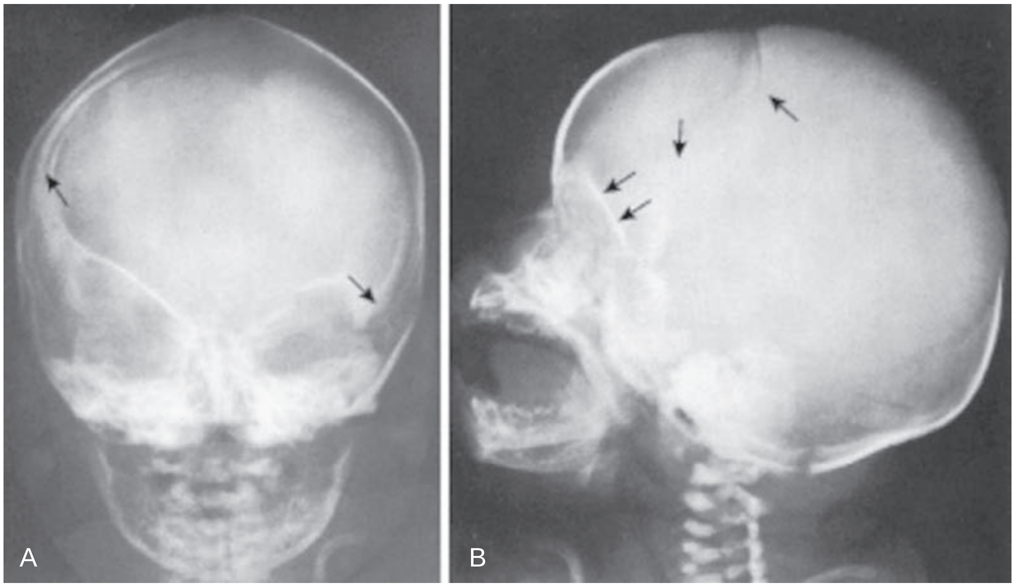
*Lambdoid synostosis* results in ipsilateral occipital flattening and elongation along the axis of the synostosed lambdoid with contralateral superior parietal bulge (Fig. 20.14 and e-Fig. 20.15). The features differentiating unilateral lambdoid synostosis from deformational plagiocephaly are listed in e-Table 20.4.

Multiple suture synostosis occurs in 14% of cases, and the head shape depends on which sutures are closed.[1] The *Kleeblattschädel*, or cloverleaf skull anomaly, occurs when all sutures except the squamosal are closed resulting in severe temporal and vertex bulging (Fig. 20.16 and e-Fig. 20.17). Isolated synostosis of the squamosal and skull base sutures can also occur particularly in syndromic cases.[6,7]

Microcrania, or a small cranium, may result when all sutures are closed. This usually occurs with failure of brain growth.[8] Rarely, it occurs without failure of brain growth, and increased intracranial pressure may develop (Fig. 20.18).

## DEFORMITIES MIMICKING CRANIOSYNOSTOSIS

Cranial deformities mimicking synostosis may result from static forces such as intrauterine crowding or prolonged recumbency. The term *plagiocephaly* refers to flattening of the calvarium without denoting an etiology and is preceded by terms that describe the location (e.g., right posterior plagiocephaly). Postnatal deformational plagiocephaly primarily affects the forehead or occipital area. Since the 1993 American Academy of Pediatrics recommendation to put infants to sleep on their backs, occipital deformational plagiocephaly cases have increased (Fig. 20.19). The ipsilateral occiput and contralateral forehead are flattened. Malposition of the ipsilateral pinna, protrusion of the ipsilateral cheek, and



**e-Figure 20.11. Premature synostosis of the caudal segment of the right limb of the coronal suture in a 3-week-old infant.** (A) On the frontal radiograph, *arrows* are directed at the caudal ends of the right and left limbs of the coronal suture. The roof of the right orbit is lifted into a more oblique position, as is the right wing of the sphenoid. (B) On the lateral projection, the right limb of the coronal suture stops abruptly a few centimeters below the anterior fontanel. The lifting of the right orbital roof also is well seen *(two lower arrows).*

**e-TABLE 20.3** Features That Differentiate Unilateral Coronal Synostosis From Anterior Deformational Plagiocephaly

| Features | Synostotic | Deformational |
|---|---|---|
| Ipsilateral superior orbital rim | Up | Down |
| Ipsilateral ear | Anterior, high | Posterior, low |
| Nasal root | Ipsilateral | Midline |
| Ipsilateral malar eminence | Forward | Backward |
| Chin deviation | Contralateral | Ipsilateral |
| Ipsilateral palpebral fissure | Wide, low | Narrow, high |
| Anterior fontanel deviation | Contralateral | None |

*Modified from Cohen Jr MM, MacLean RE. Anatomic, genetic, nasologic, diagnostic, and psychosocial considerations. In: Cohen Jr MM, MacLean RE, eds.* Craniosynostosis, *New York: Oxford University Press; 2000:126.*

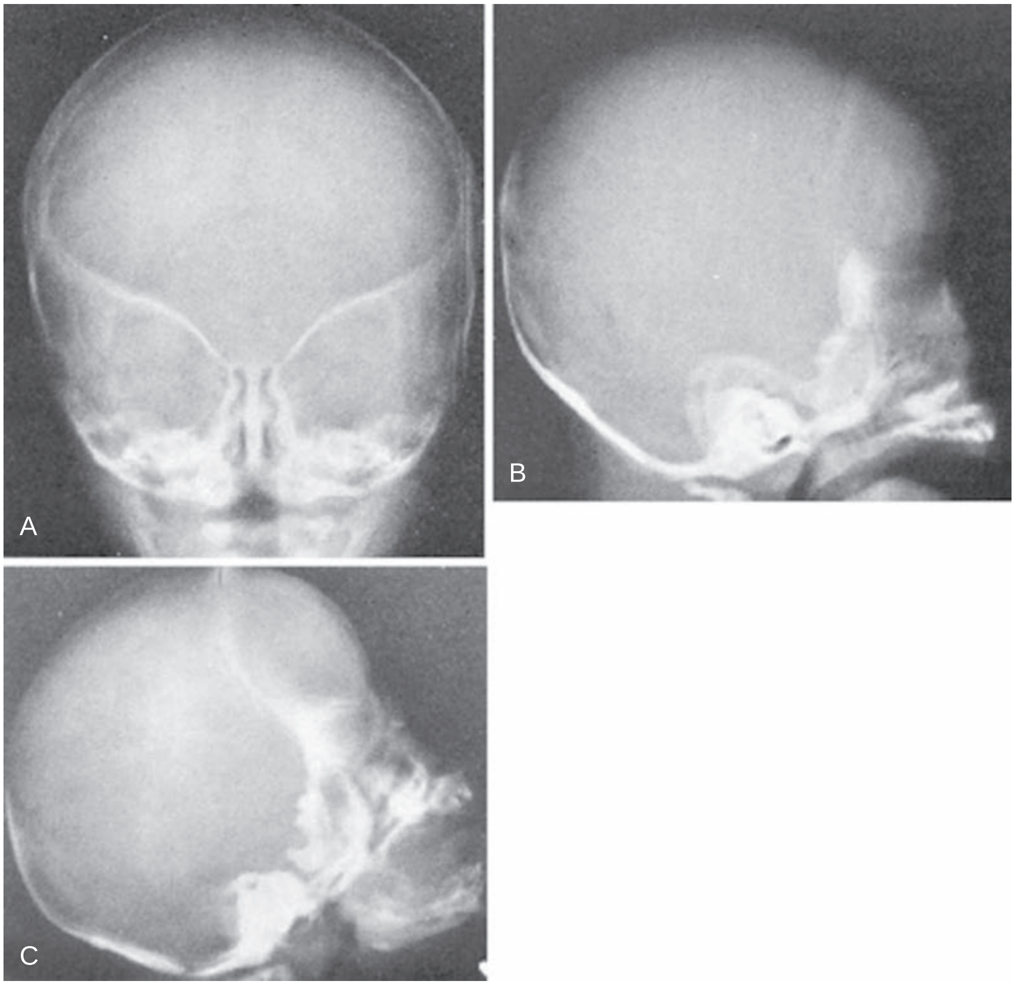
**e-TABLE 20.4** Features That Differentiate Unilateral Lambdoid Synostosis From Posterior Deformational Plagiocephaly

| Features | Synostotic | Deformational |
|---|---|---|
| Contralateral posterior bossing | Parieto-occipital | Occipital |
| Forehead | Contralateral frontal bossing | Ipsilateral frontal bossing |
| Ipsilateral occipitomastoid bossing | Present | Absent |
| Ipsilateral ear | Anterior, anteroinferior, posterior, or symmetric | Anterior |
| Skull base and face | Ipsilateral inferior tilt | Normal* |
| Head shape, vertex view | Trapezoid-shaped or parallelogram-shaped depending on severity | Parallelogram |
| Head shape, posterior view | Parallelogram | Normal |
| Lambdoid suture | Unilateral synostosis† | Patent suture |

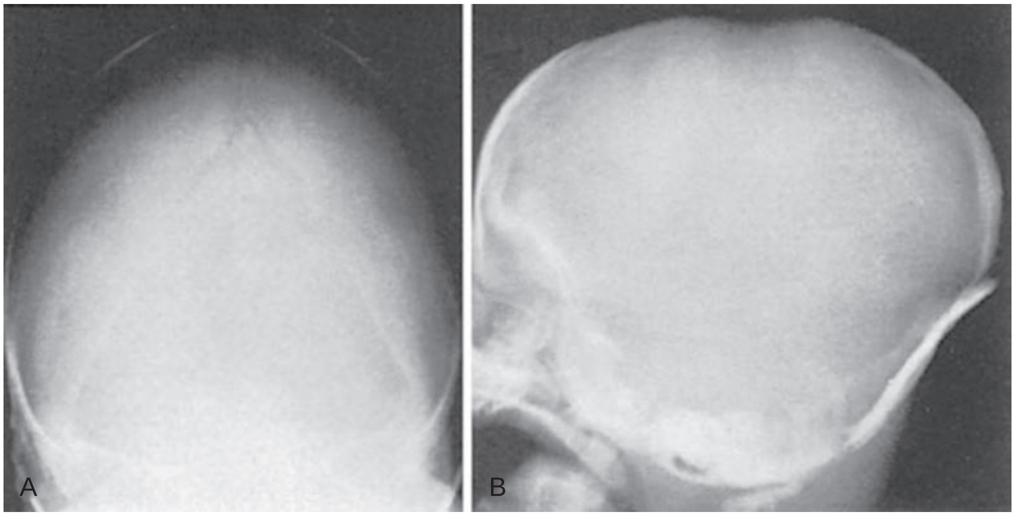
*Ipsilateral face prominent.

†Bulges at inferior and superior axes of location where suture should be.

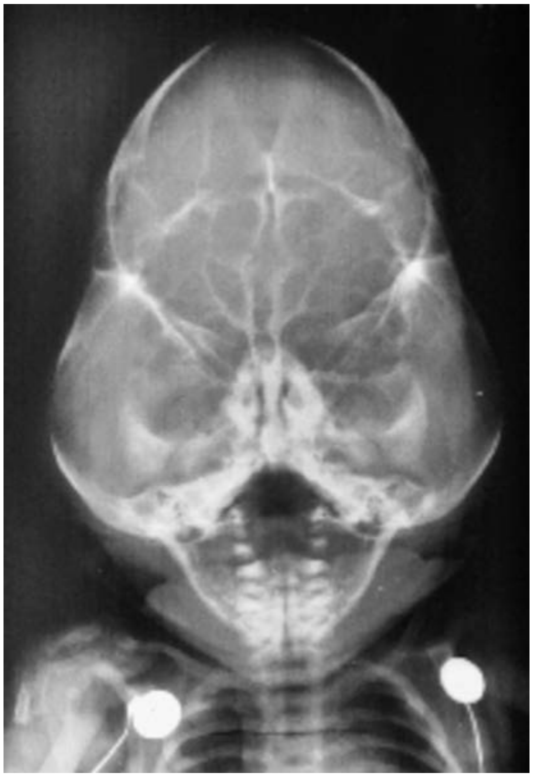
*Modified from Cohen Jr MM, MacLean RE. Anatomic, genetic, nasologic, diagnostic, and psychosocial considerations. In: Cohen Jr MM, MacLean RE, eds.* Craniosynostosis, *New York: Oxford University Press; 2000:127.*



**e-Figure 20.13. Bilateral coronal synostosis.** (A) Frontal radiograph shows the elevated orbital roofs. (B) On the lateral radiograph, the height of the skull is increased from caudad to cephalad and decreased in the anteroposterior dimension. The coronal suture is not seen. (C) Other lateral projection showing the absence of a complete coronal suture. The head is tall (towering) and short in the anteroposterior direction.



**e-Figure 20.15. Premature closure and ridging of the caudal two-thirds of both lambdoid sutures and flattening of the occipital squamosa in a 1-month-old infant.** The uppermost segment of the lambdoid suture is still open, and a small sutural bone is visible at the lambda itself. The sides of the occipital squamosa are straight, rather than convex, and the squamosa is narrower than is normal. (A) and (B) Anteroposterior (A) and left lateral (B) projections.



**e-Figure 20.17. Kleeblattschädel (cloverleaf skull) anomaly.** Multisuture closure has occurred, and a bizarre configuration of the face and head with bulging of the temporal region is seen on this frontal radiograph.

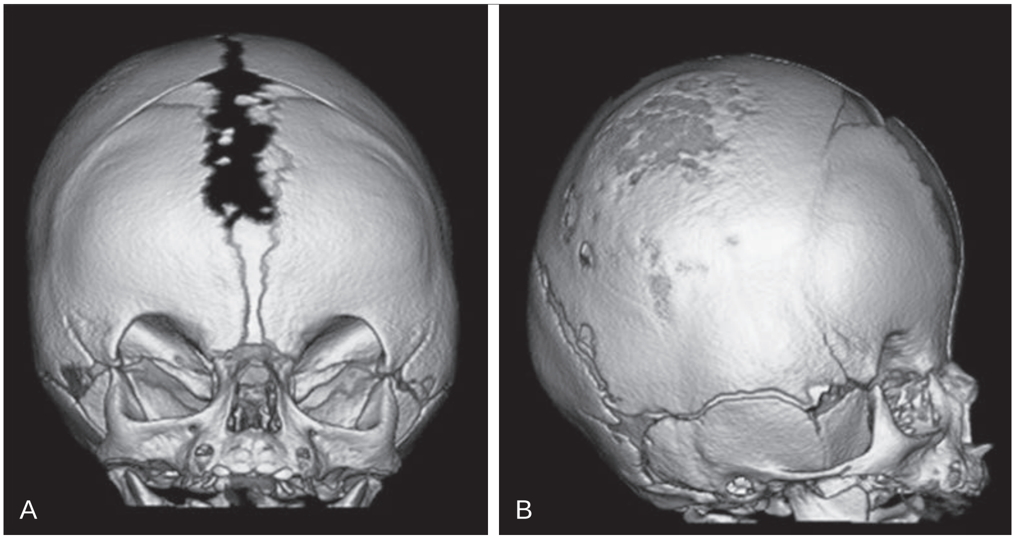


**Figure 20.12. Bilateral coronal synostosis in a 2-month-old male.** (A and B) 3D CT images demonstrate bilateral coronal suture fusion, elevated orbital roofs, a towering calvarium and anteroposterior shorting.

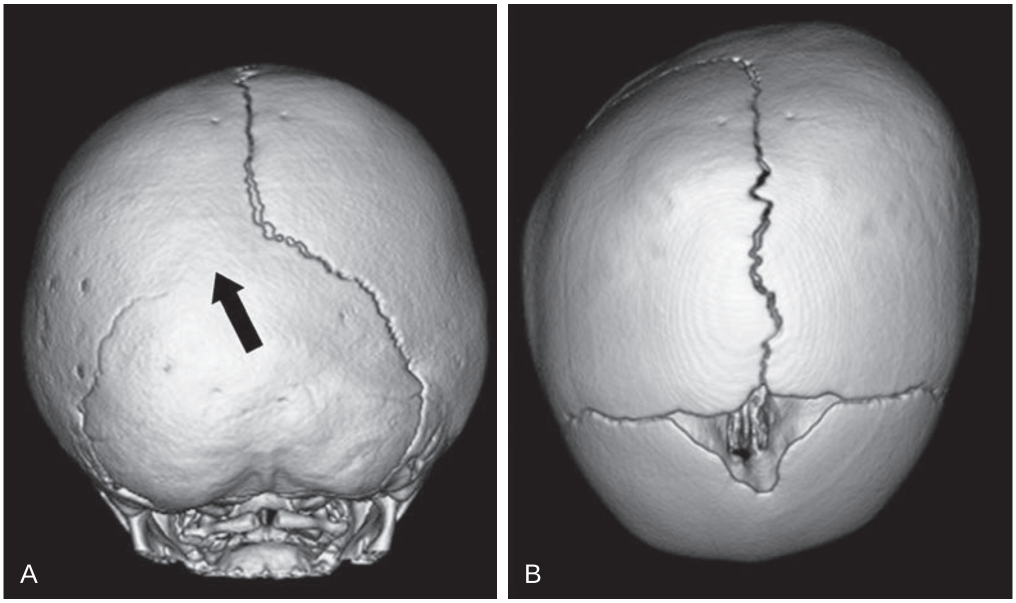

**Figure 20.14. Lambdoid synostosis in an 11-month-old male.** (A and B) 3D CT images show right occipital flattening and partial closure of the right lambdoid suture *(arrow).*

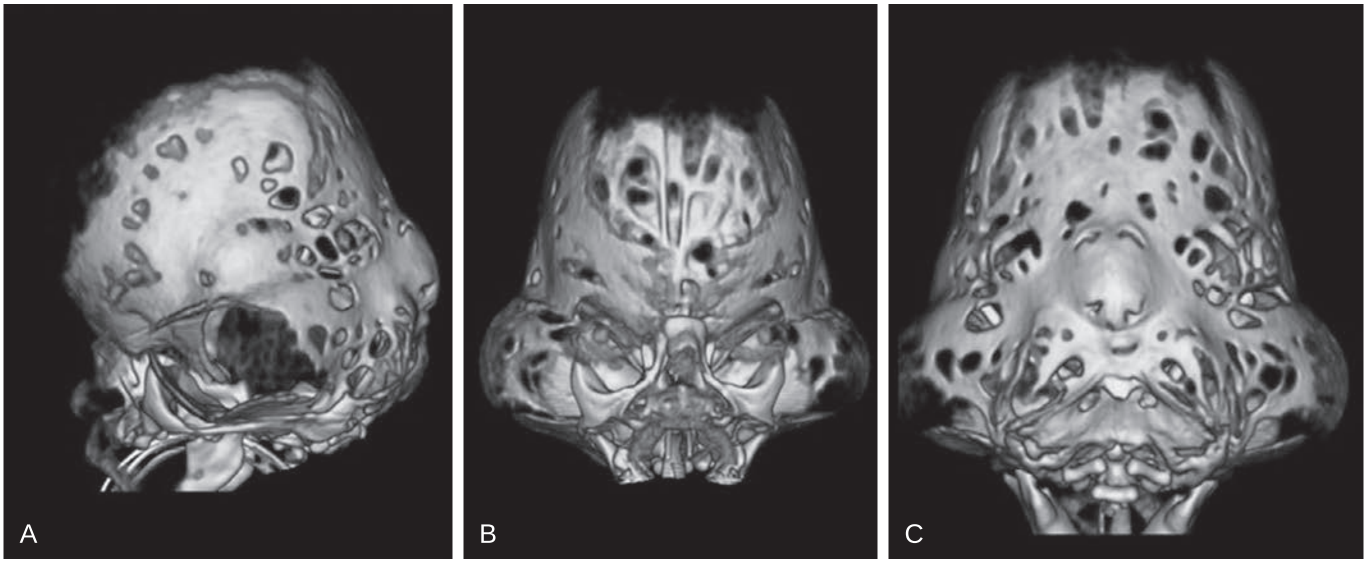

**Figure 20.16. Kleeblattschädel (cloverleaf skull) anomaly in a 1-day-old infant.** (A–C) 3D CT images reveal multiple closed sutures, a misshapen face, towering of the cranium, and temporal bulging.

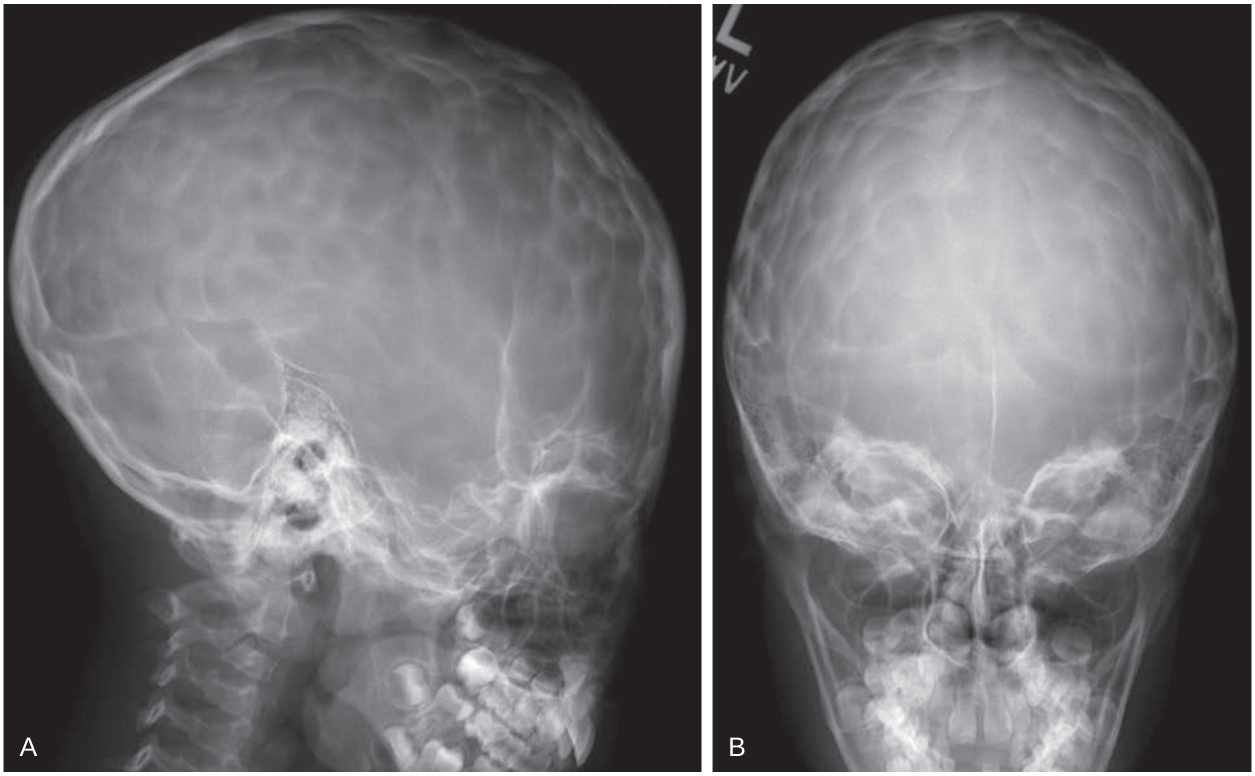

**Figure 20.18. Microcephalic type of craniostenosis in a 6-year-old child.** (A) Lateral and (B) frontal radiographs show obliteration of all sutures, and skull shortening. Long-standing increased intracranial pressure is indicated by heavy convolutional markings. Note poor visualization of the sella.

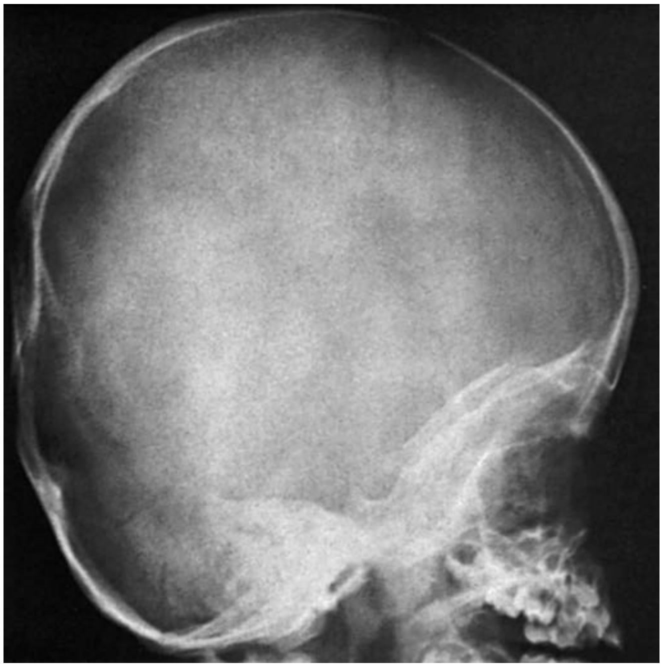

**Figure 20.19. Deformational (postural) plagiocephaly in a 22-month-old infant.** The occipital flattening shown on this lateral radiograph suggests coronal suture synostosis in general. However, the coronal sutures are open, the anterior fossa is deep, and the posterior fossa is shallow.

compensatory bulging of the ipsilateral forehead and contralateral occipital area are noted. Viewed from above, the head has a parallelogram shape (Fig. 20.20).

Perisutural lambdoid sclerosis may be seen on a plain radiograph; however, the suture is open. The concept of a "sticky lambdoid suture" is no longer considered valid.[9,10] Plagiocephaly also may occur with bony, muscular, or ocular torticollis.

In deformational plagiocephaly, the skull base (i.e., aligned from the crista galli through the foramen magnum) remains straight, with less than 7 degrees' angulation, whereas in unilateral coronal or lambdoid synostosis, the skull base curves (see Figs. 20.20 and 20.21). Pseudoscaphocephaly occurs when premature infants lie on the sides of their heads in the neonatal intensive care unit. Although the head is long and narrow, the sagittal suture is open.

## Radiographic Findings

Radiographic examination of the skull consists of anteroposterior or Caldwell, Towne, and both lateral views. The sagittal, coronal, and lambdoid sutures are all normally identified. The anterior fontanel is visible at least until 7 months of age. Although the metopic suture closes any time from before birth to after 3 months of age, as many as 10% remain open into adulthood.[11] The same head deformity results from partial and total suture synostosis (see e-Fig. 20.5). The key findings to diagnosis craniosynostosis are (1) abnormal head shape and (2) suture obliteration.

Cranial restructuring techniques have focused on (1) release of sutural synostosis, (2) cranial remodeling, (3) reduction of abnormal skull expansion, and (4) expansion of abnormally narrow areas.[12]

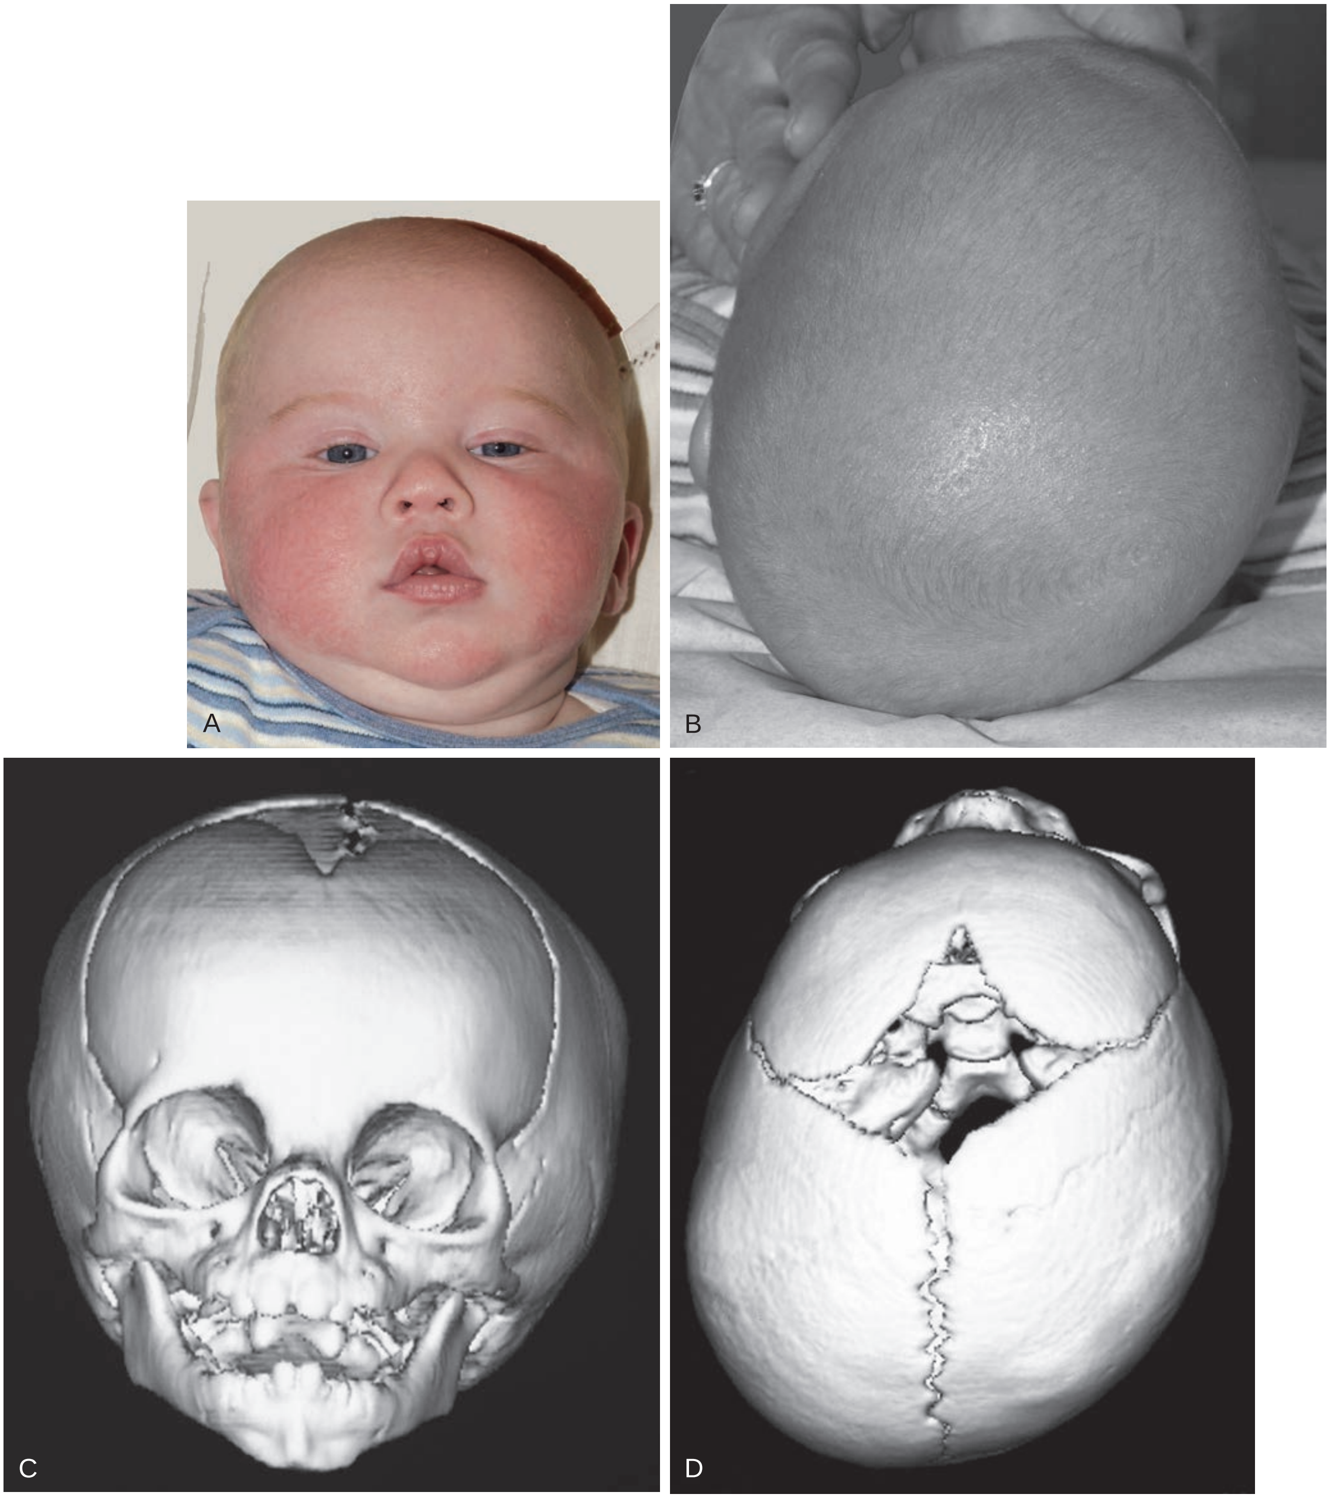

**Figure 20.20. Deformational plagiocephaly in an infant.** (A) Frontal and (B) bird's eye view photographs demonstrate a parallelogram skull shape. (C) Frontal and (D) vertex 3-D CT images confirm the clinical plagiocephaly with open sutures.

*Continued*

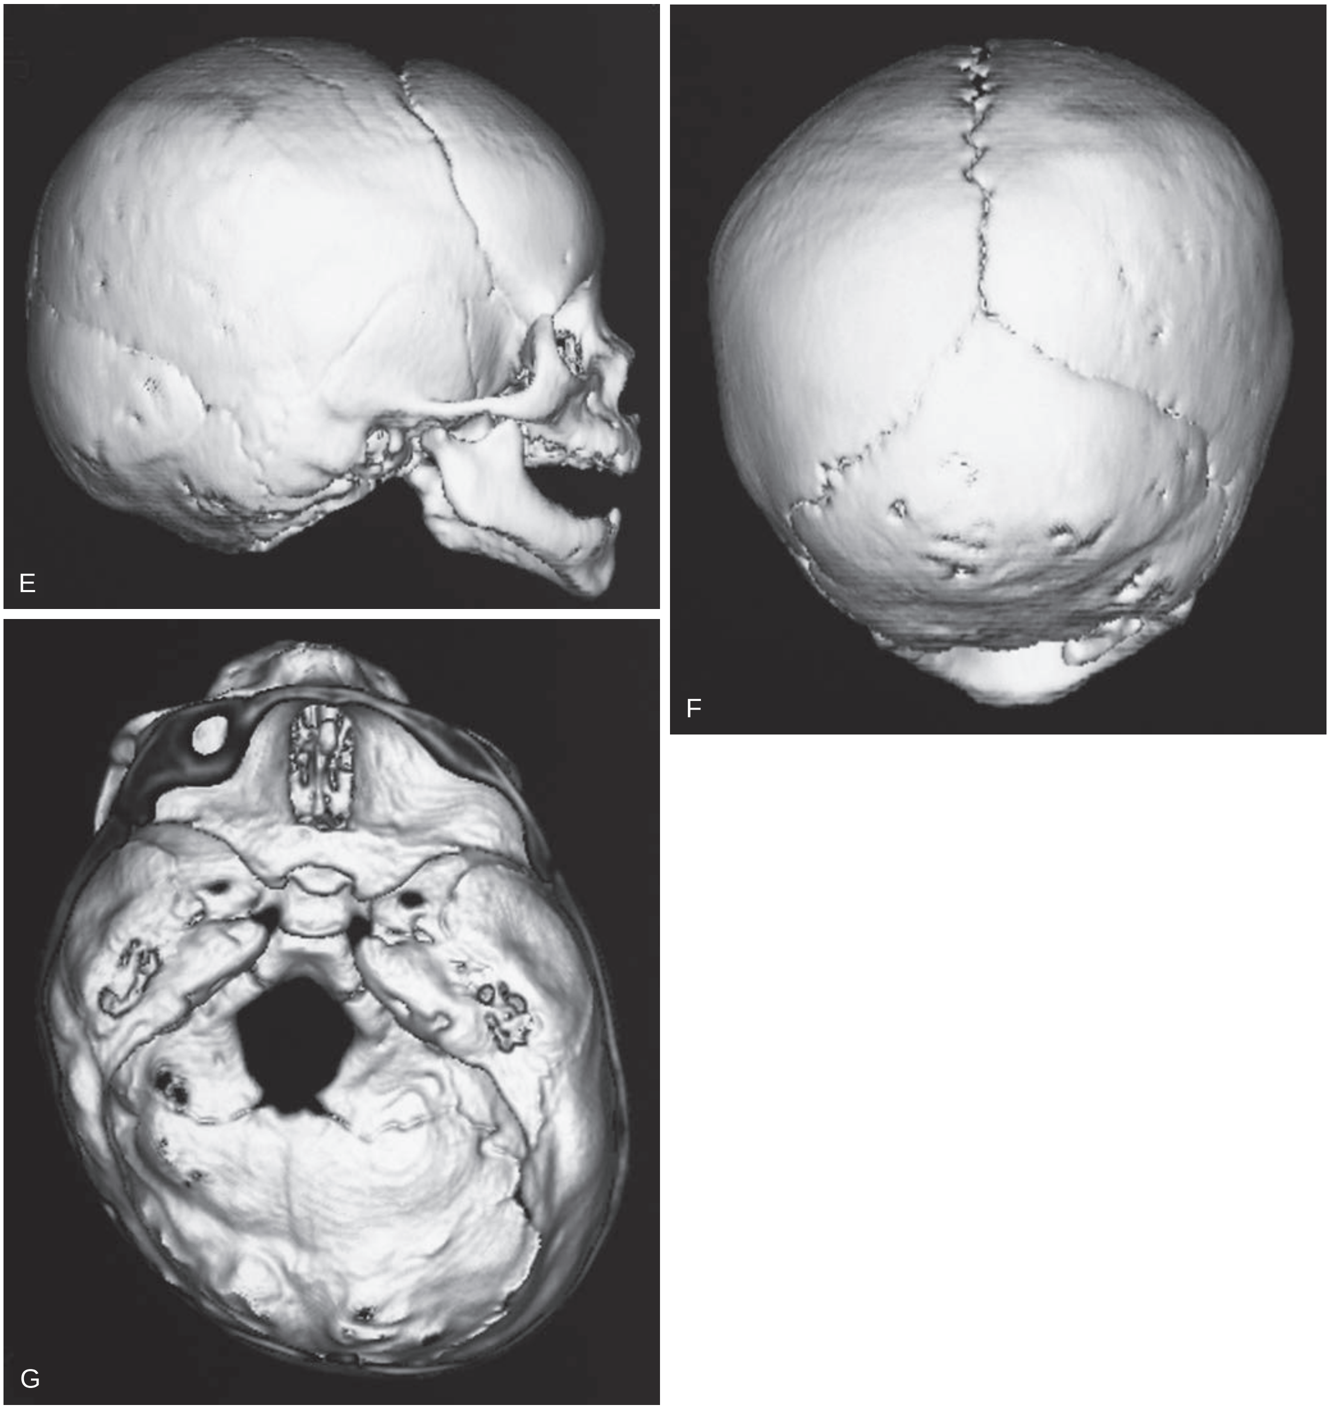

**Figure 20.20, cont'd.** (E) Lateral, (F) posterior, and (G) basilar CT images again confirm open sutures. Right occipital and left frontal flattening with compensatory right frontal and left occipital bulging are seen. No skull base angulation is present.

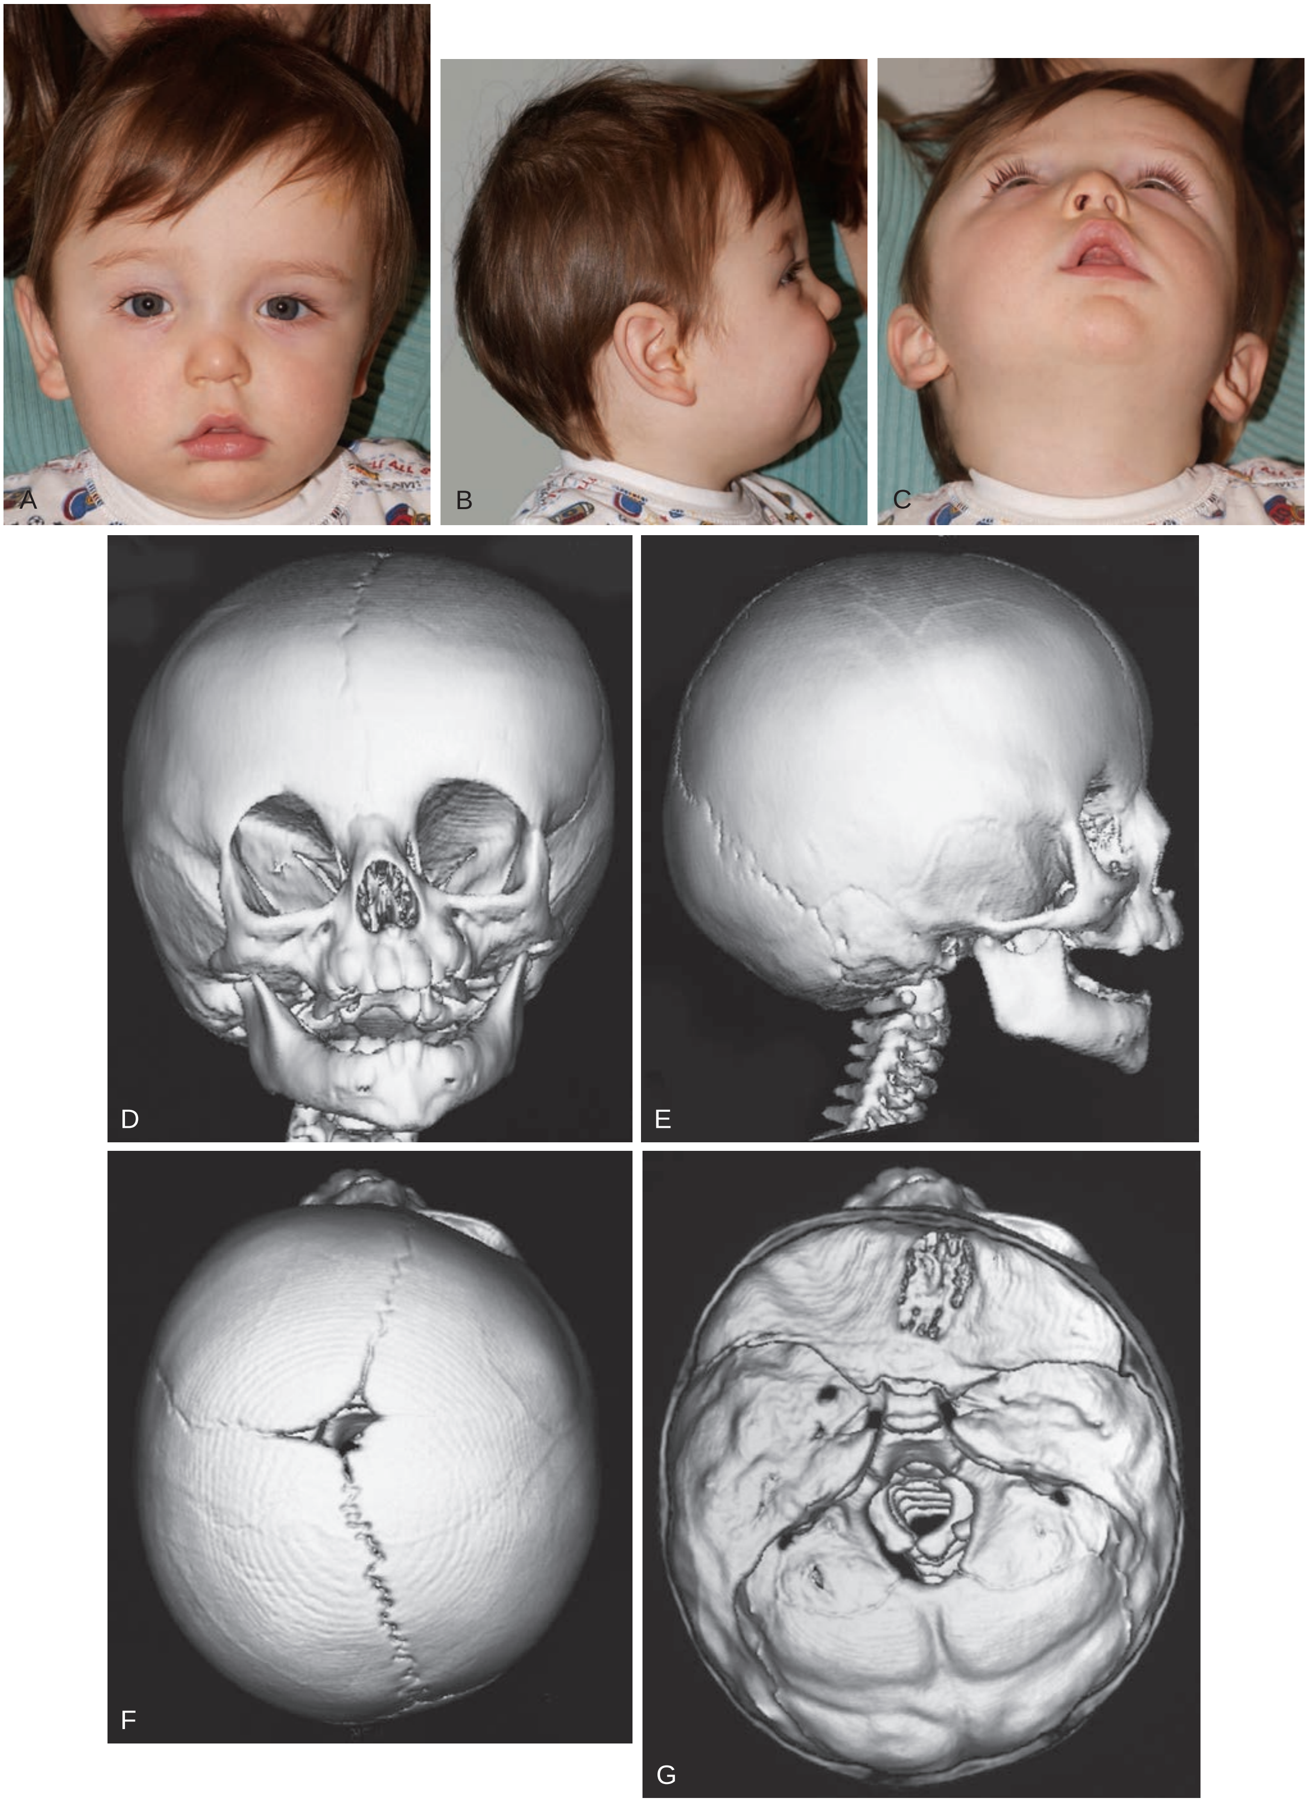

**Figure 20.21. Unilateral right coronal synostosis in an infant.** (A–C) Facial photographs show right frontal and occipital flattening with some right orbital recession. Note craniocaudal skull elongation (scaphocephaly) and anteroposterior shortening (D) Frontal, (E) lateral, (F) vertex, and (G) basilar 3D CT images confirm right coronal suture fusion, elevation of the sphenoid wing, right frontal and occipital flattening, compensatory ipsilateral and temporal contralateral frontal bulging. Also, note angulation of skull base toward side of coronal synostosis.

In most instances, three-dimensional (3D) computed tomography (CT) is required to plan for cranial restructuring. Radiation dose can be lowered to 65 mA and 80 kV at 0.5 second with a slice thickness of 1.25 mm and a CT dose index "dose" of approximately 2.37 mGy. Images are reconfigured to 0.625 mm for various reconstructions (Figs. 20.22–20.24 and e-Fig. 20.25).

Magnetic resonance imaging (MRI) is not well suited for identifying cranial sutures. However, a recently reported gradient echo sequence has been used to minimize soft tissue contrast allowing the cranial sutures to be hyperintense against the signal void of the cranial bones. In syndromic children, brain MRI is performed for developmental anomalies.

While there are reports of successfully using ultrasound for diagnosing synostosis, this has not gained widespread acceptance and, if positive, requires further imaging to be performed.

## Associated Abnormalities

Limb defects are the most common anomalies associated with craniosynostosis, occurring in up to 84%.[1] Syndactyly and polysyndactyly constitute 30% of the limb defects, and deficiencies account for 22%.

Several types of acrocephalosyndactyly and acrocephalopolysyndactyly have been described. Some are clearly defined; others are less clear and may undergo reclassification as further information becomes available.

The best-known acrocephalosyndactyly is *Apert syndrome* (acrocephalosyndactyly type I), in which bicoronal synostosis is associated with symmetric syndactyly of the second, third, and fourth digits, resulting in the "mitten or paddle hand" (e-Fig. 20.26). Developmental delay is variably present. Evaluation of

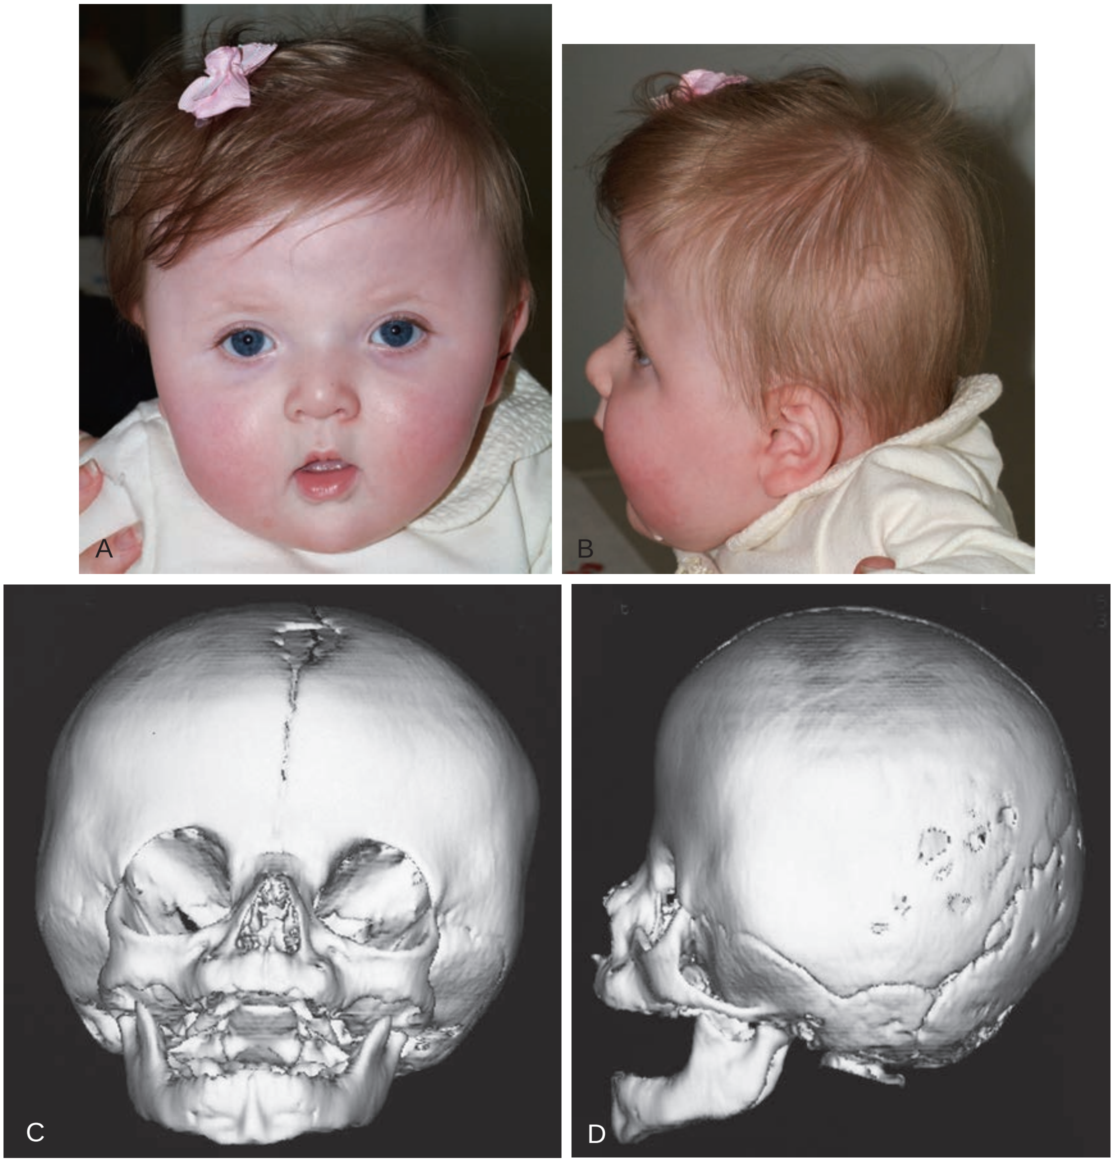

**Figure 20.22. Bilateral coronal synostosis in an infant with brachycephaly.** (A) Frontal and (B) lateral photographs show a towering calvarium with some temporal bulging and orbital recession. (C) Frontal, (D) lateral, and (E) vertex 3-D CT images, in addition to (F) sagittal and (G) axial CT reconstructions reveal coronal suture closure, a towering skull, decreased anteroposterior skull dimension, temporal bulging, and orbital recession.

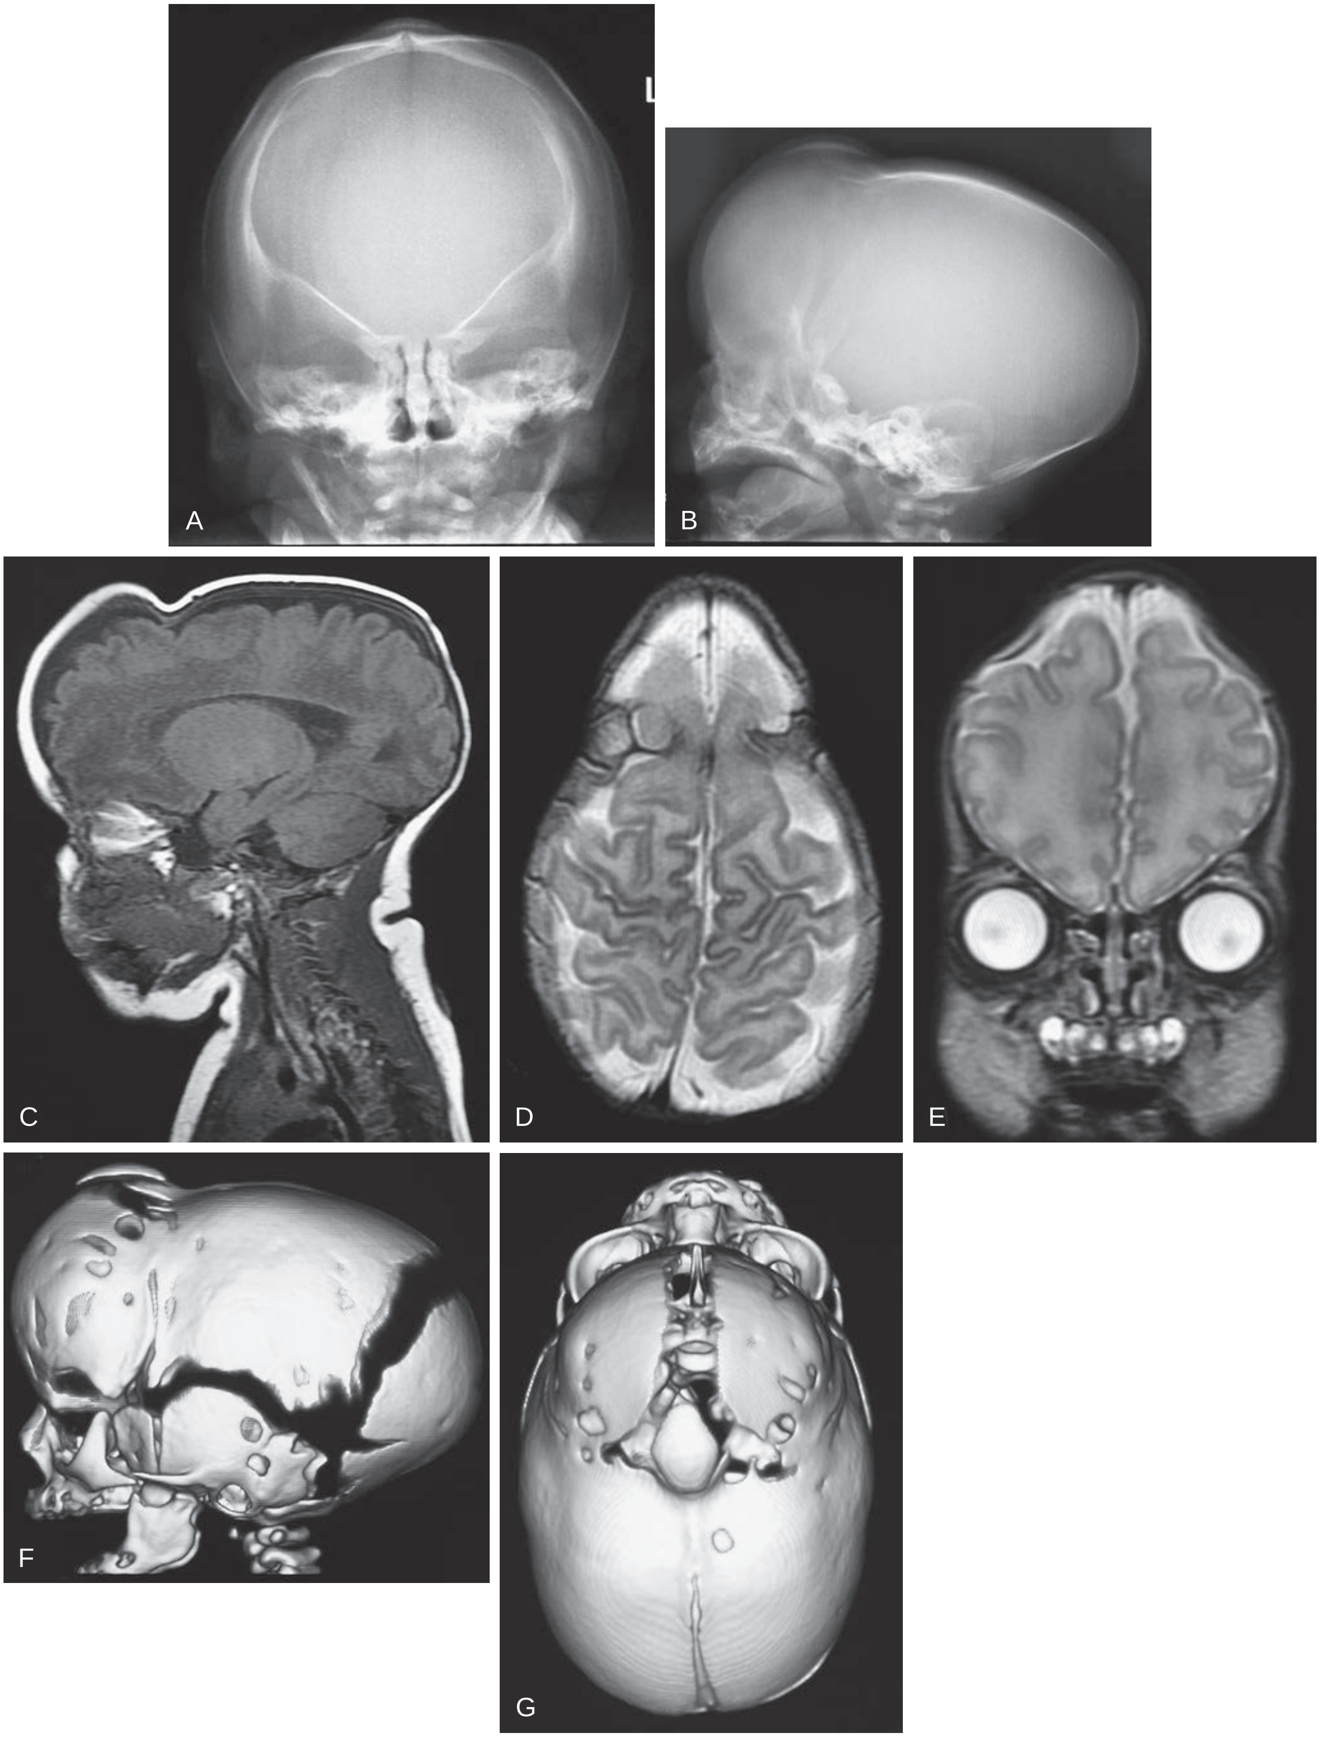
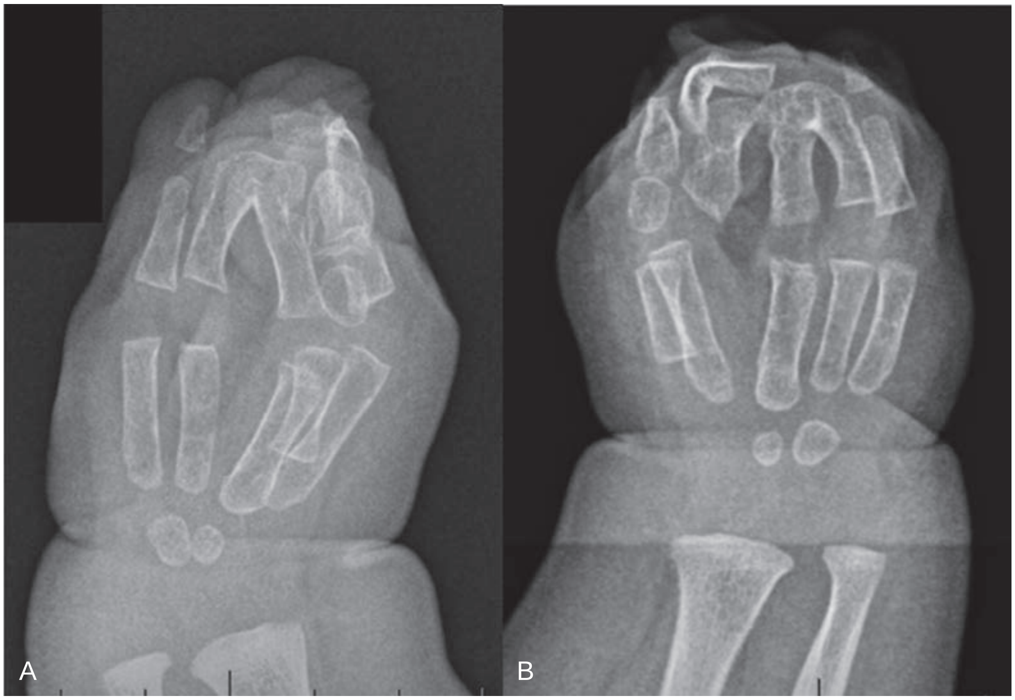


**e-Figure 20.25. Multiple suture closure.** (A) Frontal and (B) lateral radiographs show elevated orbital ridge, upper coronal suture closure, and ridging and closure of the sagittal suture. MRI sequences (C) sagittal T1-, (D) axial T2-, and (E) coronal T2-weighted images reveal normal brain, but severe deformity. (F) Lateral, and (G) vertex 3D CT images show coronal and sagittal suture closure.



**e-Figure 20.26. Bilateral acrocephalosyndactyly, type I (Apert syndrome).** (A and B) Osseous and soft tissue syndactyly of the phalanges are present. Typical of Apert syndrome, the findings are bilateral and symmetric.

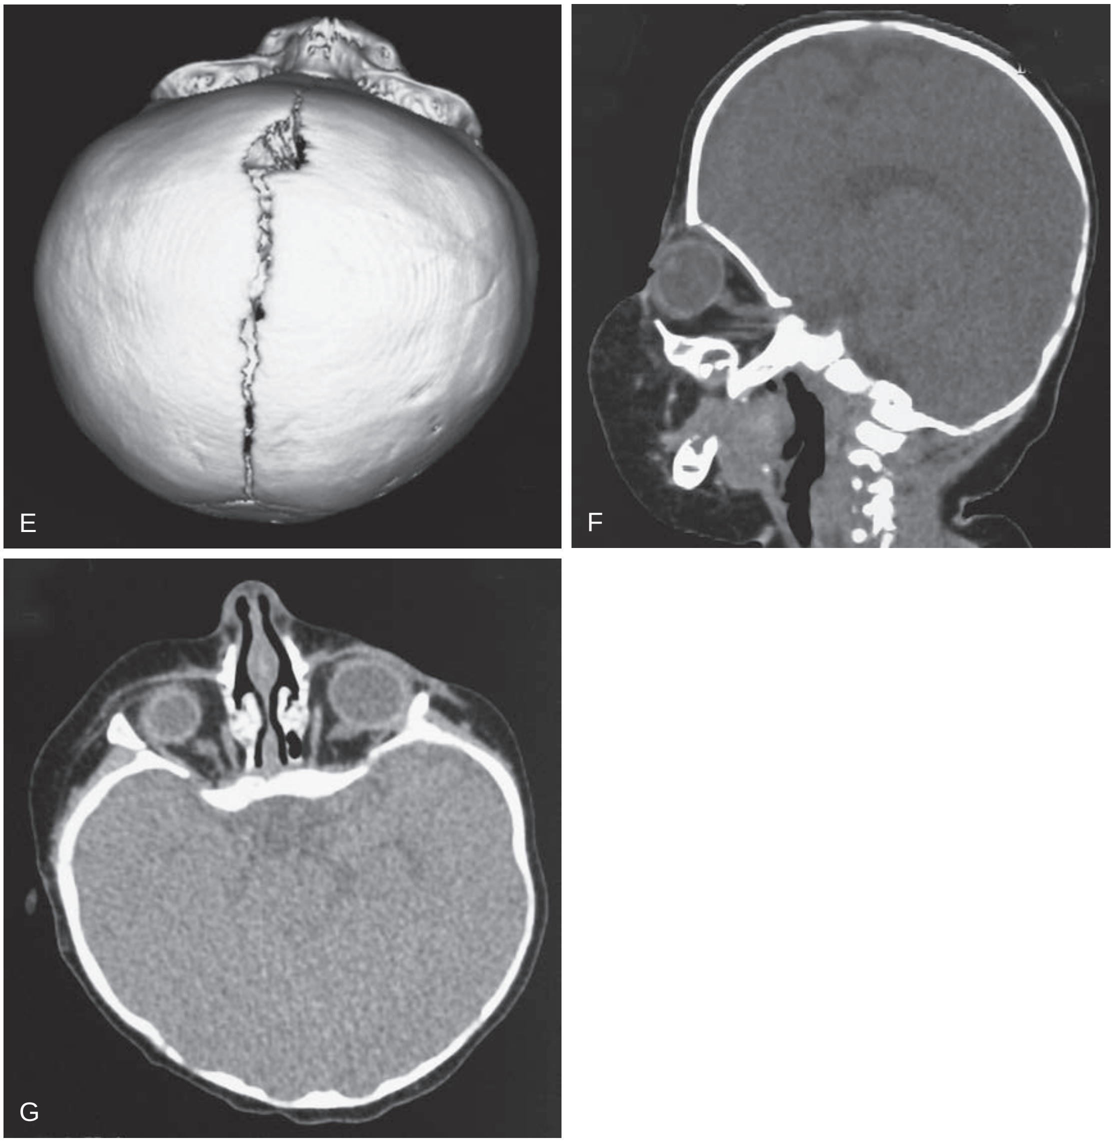


**Figure 20.22, cont'd.**

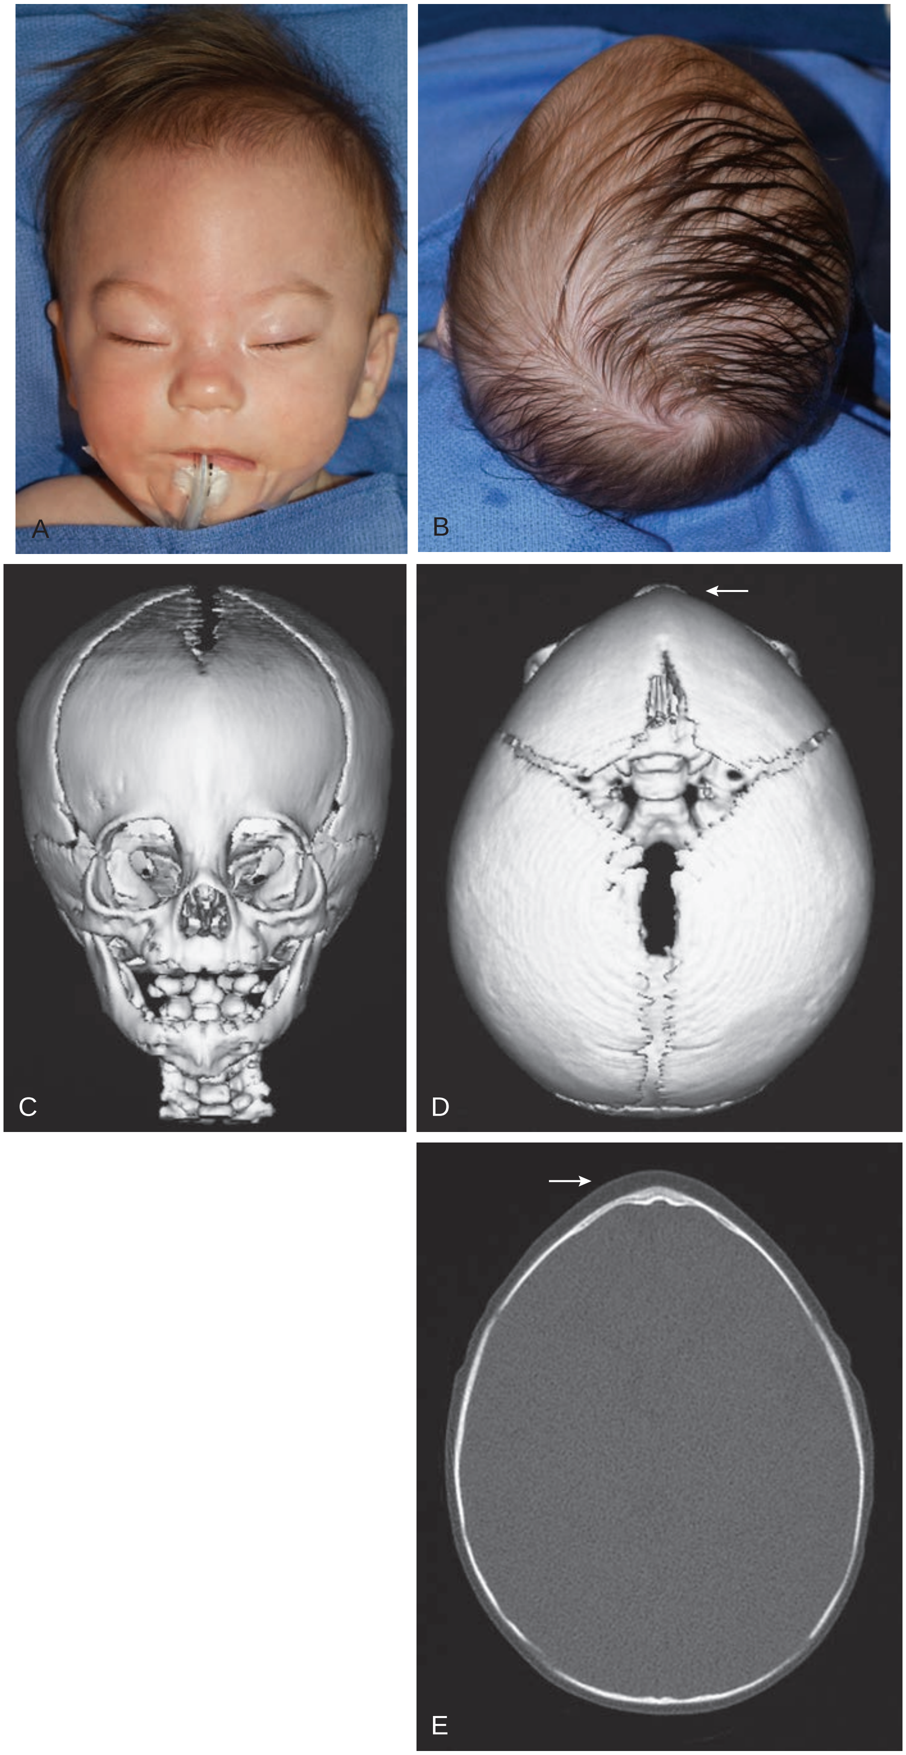

**Figure 20.23. Metopic synostosis in an infant with trigonencephaly and hypotelorism.** (A) Frontal and (B) vertex photographs show a keel-shaped, triangular forehead typical of trigonencephaly. (C) Frontal, (D) vertex, and (E) axial CT images reveal metopic suture fusion and confirm trigonencephaly *(arrow).*

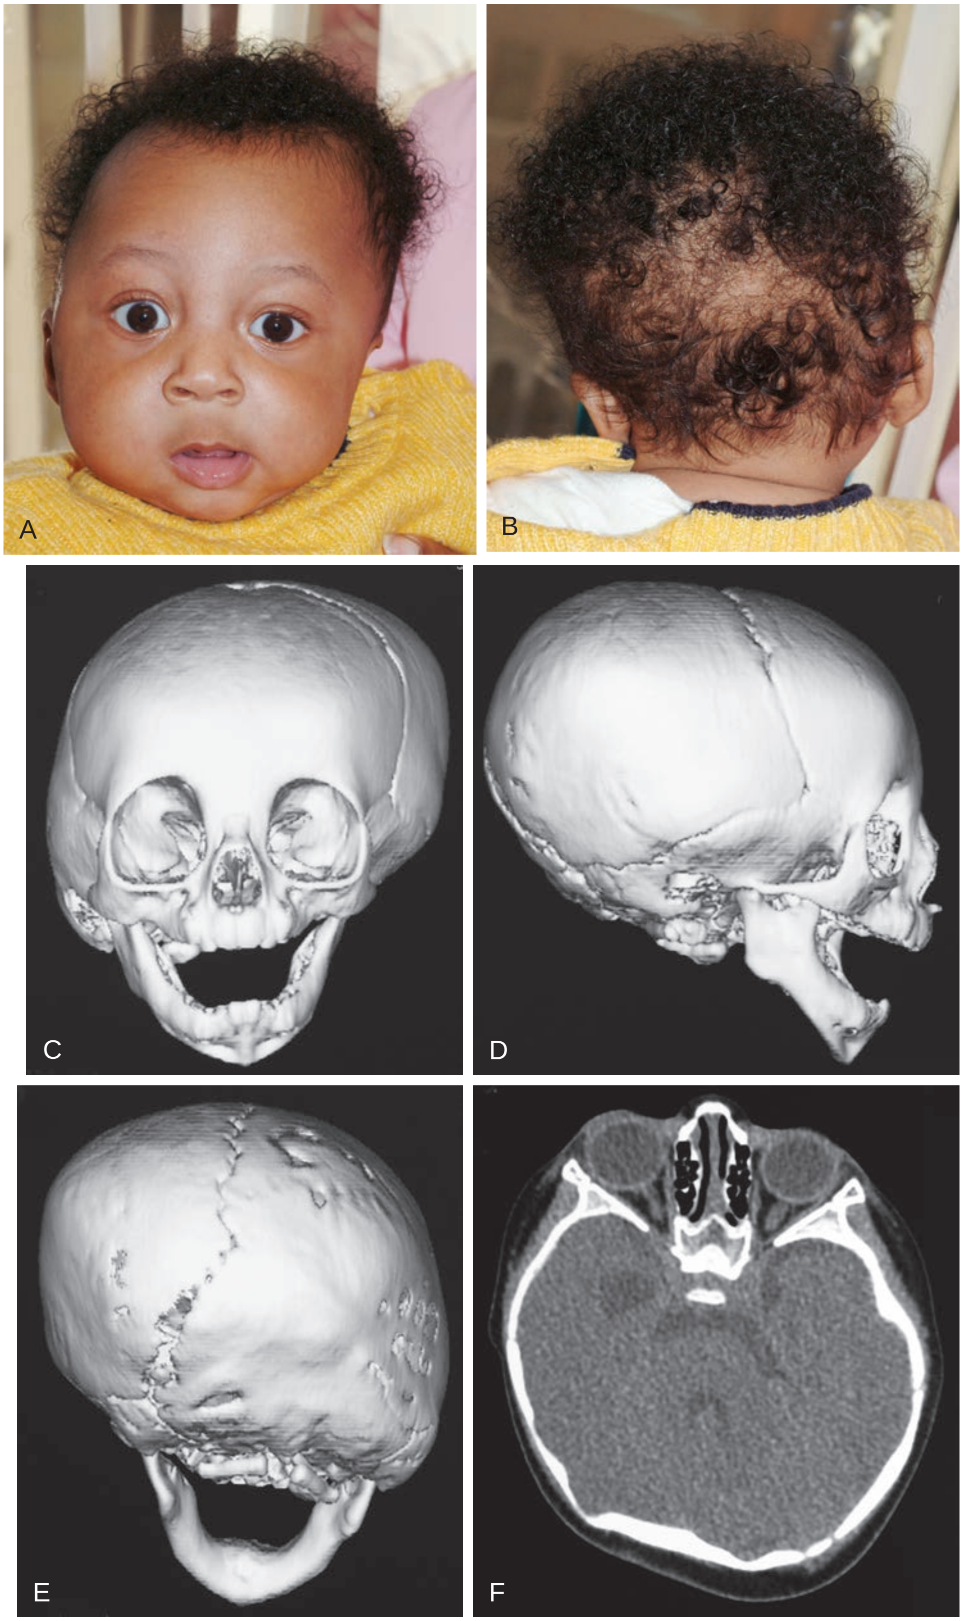

**Figure 20.24. Unilateral right lambdoid synostosis in an infant.** (A) Frontal and (B) posterior photographs show asymmetric bulging of the right inferior occipital region and compensatory left parietal bulging superiorly. (C) Frontal, (D) lateral, and (E) posterior 3D CT and (F) axial CT images demonstrate right lambdoid suture absence with compensatory bulging of the superior and inferior ends of the synostosal suture (i.e., left parietal and right occipital region). Skull-base angulation is evident.

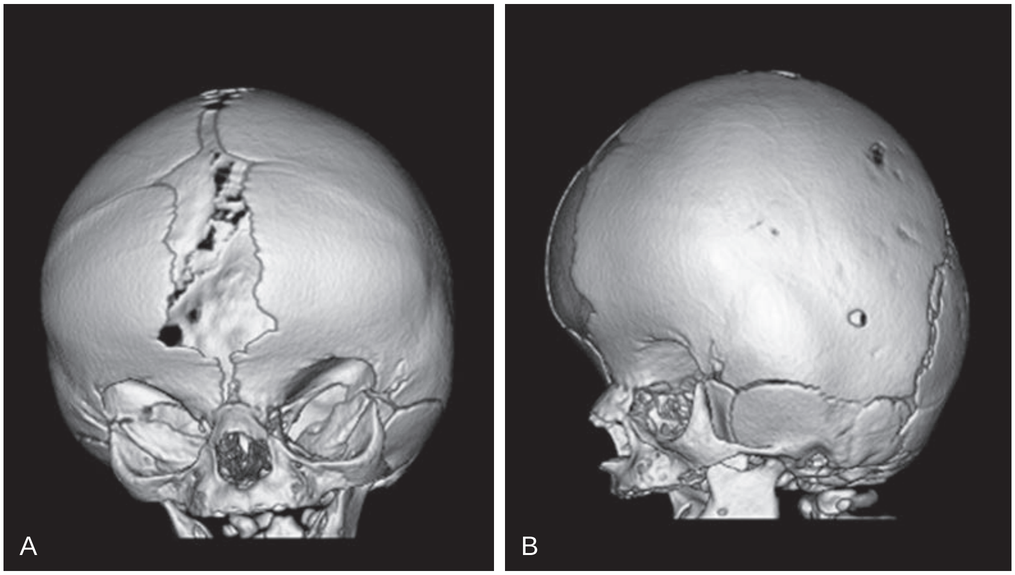

**Figure 20.28. Apert syndrome in an 8-day-old infant.** (A) Frontal and (B) lateral 3D CT images show classic bilateral coronal synostosis with brachycephaly and a towering skull with a gaping metopic suture. Also noted are exophthalmos, hypertelorism, and maxillary retrusion.

craniofacial deformities may be assisted by CT (e-Fig. 20.27, Fig. 20.28, and e-Fig. 20.29).

Acrocephalosyndactyly types II, III, and IV are known as *Apert-Crouzon disease*, *Saethre-Chotzen syndrome*, and *Waardenburg syndrome*, respectively; they involve varying degrees of facial abnormality and syndactylies in patterns particular for each type. Acrocephalosyndactyly type V, *Pfeiffer syndrome*, has only moderate soft tissue syndactyly, but the thumbs and great toes are deformed and broad (Fig. 20.30).

*Carpenter syndrome* (acrocephalopolysyndactyly type II) is characterized by developmental delay and preaxial polydactyly of the feet. Types I and III are known as *Noack syndrome* and *Sakati-Nyhan syndrome*.

In *Crouzon syndrome*, the cardinal elements originally included (1) brachycephaly, (2) facial dysostosis with a hooked parrot nose and small maxilla, (3) bilateral exophthalmos, and (4) genetic transmission and familial incidence (e-Fig. 20.31 and Fig. 20.32).

The complications of these syndromes include exophthalmos, loss of vision, increased intracranial pressure, and developmental delay. Maxillary hypoplasia may cause upper airway obstruction and sleep apnea. Surgical procedures are performed to improve the airway, dental occlusion, and deformities.

Kleeblattschädel (cloverleaf skull) results from closure of all sutures except the squamosal sutures, leading to severe temporal and vertex bulging with exophthalmos (see Fig. 20.16 and e-Fig. 20.17). Hydrocephalus develops in utero, deforming the skull into a superiorly elongated calvarium with dilated frontal and temporal regions. Most patients do not survive infancy (see Fig. 20.16). Kleeblattschädel may be found in thanatophoric dysplasia type II.

## CRANIOFACIAL SYNDROMES

A large number of conditions fall under the category of craniofacial syndromes; most are uncommon and beyond the scope of this book. Four of the relatively more common syndromes are discussed: Goldenhar, hemifacial microsomia, Treacher Collins, and Pierre Robin sequence (PRS).

### Goldenhar Syndrome and Hemifacial Microsomia

Goldenhar syndrome is part of the oculo-auricular-vertebral spectrum, which includes hemifacial macrosomia (HFM).[13,14] Most cases are sporadic, although there is an increased incidence of Goldenhar in infants of diabetic mothers. The phenotype has been associated with other conditions, including trisomy 18, maternal thalidomide, primidone, and retinoic acid use.

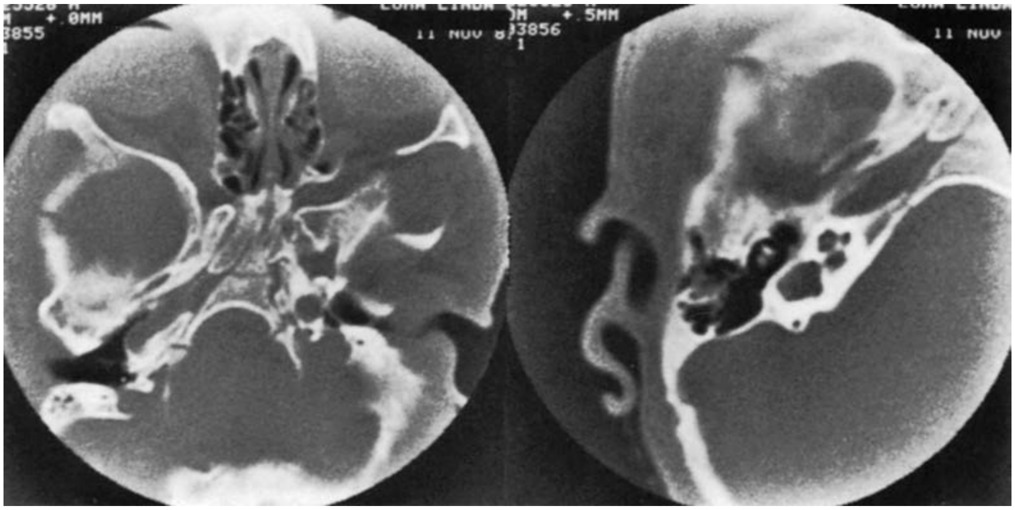
The hallmarks of Goldenhar syndrome are epibulbar dermoids, preauricular appendages, mandibular hypoplasia, microtia, and vertebral anomalies. Extreme variability of expression is characteristic of this anomaly. Most frequently, the orbital lesions, mandibular hypoplasia (Fig. 20.33), and microtia are ipsalateral.[15] Colobomas occur in 60% of patients, requiring urgent repair to prevent ulceration. Deafness is common because of associated anomalies of the middle and inner ear.[16] Vertebral anomalies, most often cervical, occur in 60% of patients including basilar invagination, occipitalization of the atlas, C1-2 instability, hemivertebra, butterfly vertebrae, scoliosis, kyphosis, and Sprengel deformities (e-Fig. 20.34).[17] Verterbral anomalies below the cervical spine are found in only 10% of patients but may be severe.

Hemifacial microsomia is a variable malformation of asymmetric facial hypoplasia, microsomia, unilateral microtia, and ipsilateral mandibular hypoplasia. HFM implies unilateral involvement, but the structures affected are bilateral and affected to different degrees. HFM may be caused by a hemorrhagic event involving the stapedial artery during early stages of craniofacial development.[18] Patients with HFM resemble those with Goldenhar syndrome, but the presence of epibulbar dermoids, lipodermoids, auricular appendices, pretragal blind-ending fissures, and vertebral anomalies favors a Goldenhar diagnosis.

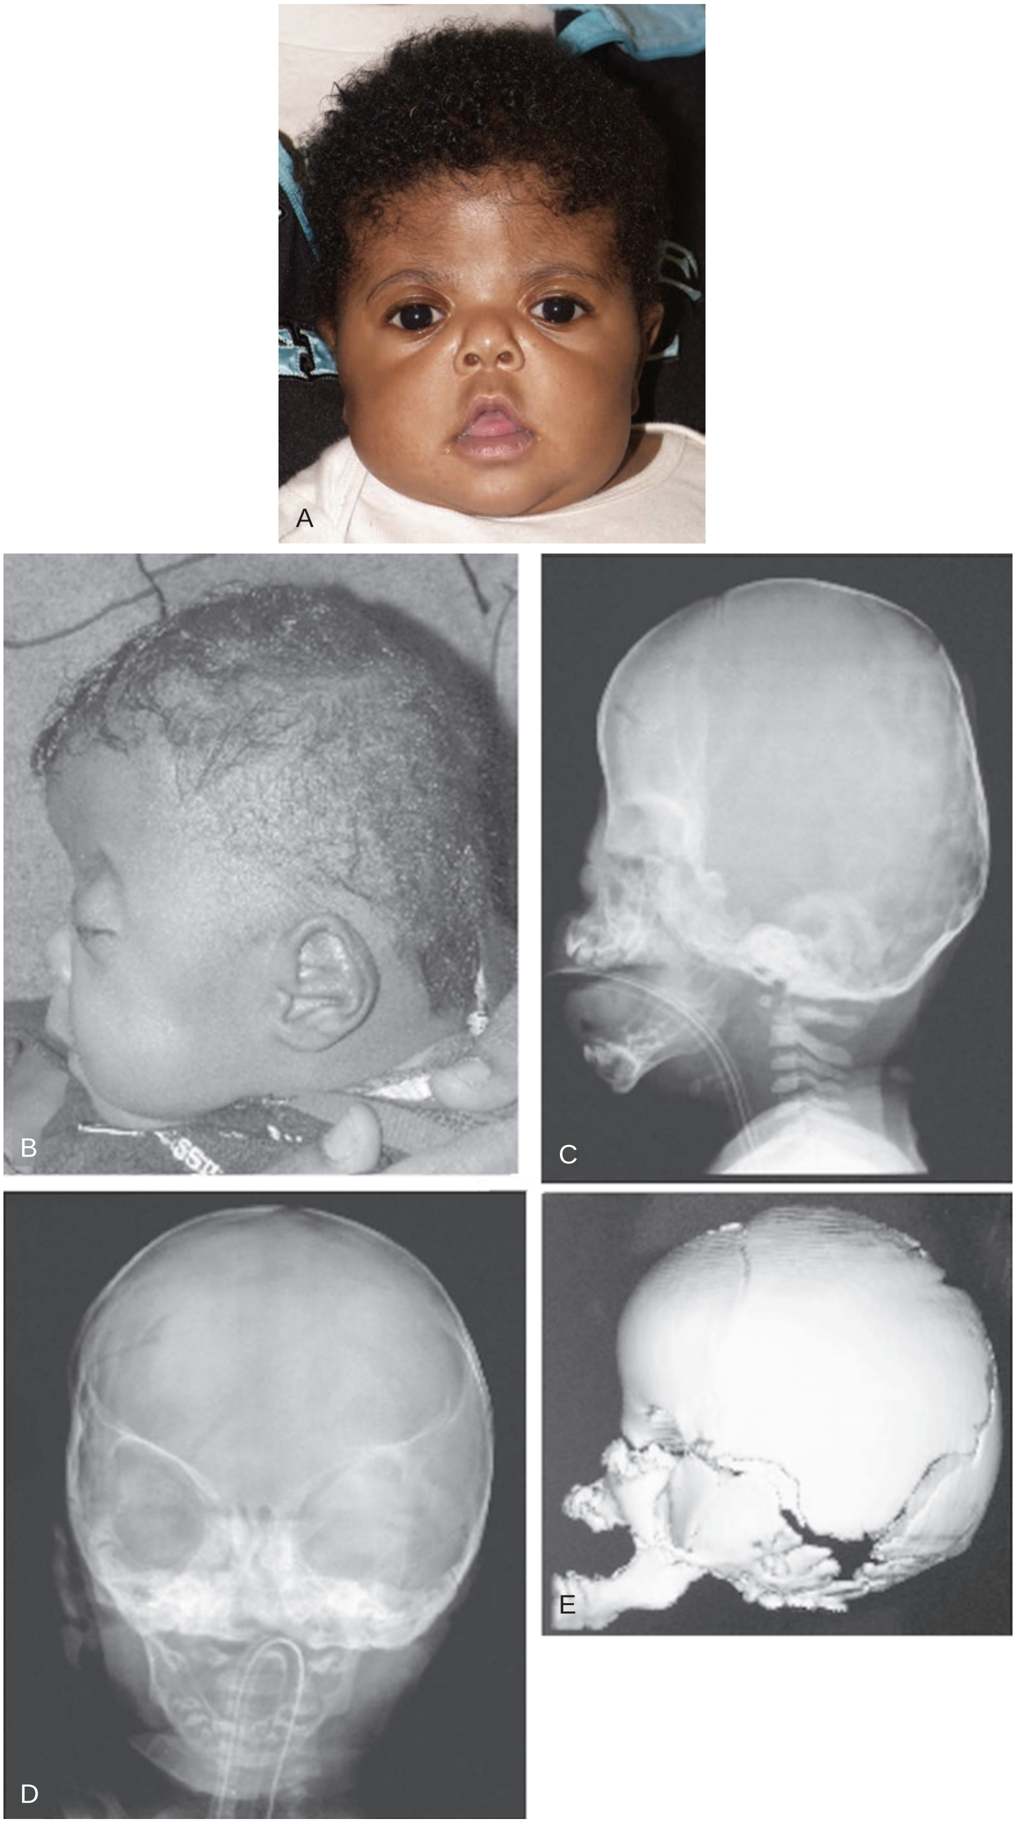
The mode of inheritance is autosomal or X-linked dominant in most cases.

### Treacher Collins Syndrome

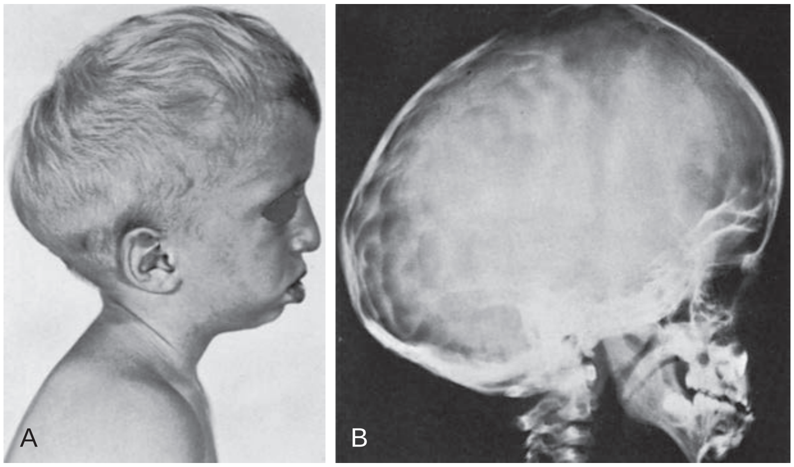
The condition has been diagnosed in utero by ultrasonography and is autosomal dominant with variable penetrance and expression.



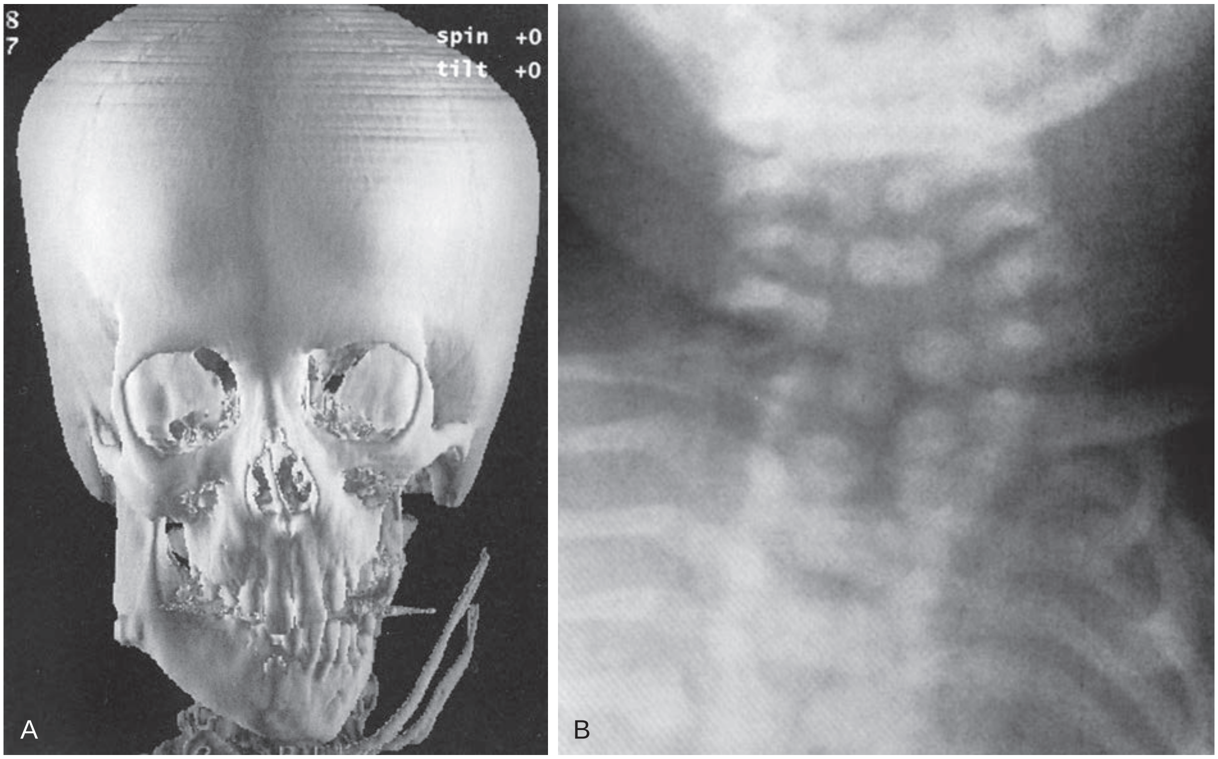
**e-Figure 20.27. Bizarre skull base deformity due to asymmetric craniosynostosis in a child with Apert syndrome.** *Left,* CT image demonstrates spheno-occipital synchondrosis. The basiocciput shows asymmetry and a partial cleft in the sphenoid body. *Right,* Magnified right inner ear view reveals a single cavity replacing the vestibule and semicircular canals. The ossicles are normal. *(Courtesy of Anton N. Hasso, MD.)*



**e-Figure 20.29. Apert syndrome.** (A) Frontal and (B) lateral photographs show brachycephaly and increased caudad-to-cephalad dimension suggesting bilateral coronal synostosis. (C) Frontal and (D) lateral radiographs of the same patient show the bilateral coronal synostosis and the expected contour of the calvarium. (E) 3D CT lateral view confirms closure of inferior coronal suture and maxillary retrusion.



**e-Figure 20.31. Crouzon disease (craniofacial dysostosis).** (A) Lateral photograph shows an enlarged, ventrodorsally elongated calvarium. Also noted are a small face, beaked nose, and marked bilateral exophthalmos. (B) Lateral radiograph reveals a large frontal squamosa, and externally bulging edges of the frontal and parietal bones at the anterior fontanel. Convolutional markings are heavy in the occipital squamosa. The facial segment is small, with a small maxilla and relatively larger mandible; the latter has an increased obtuse angle. The anterior cranial fossa is small and shallow compared with the middle and posterior fossae.



**e-Figure 20.34. Goldenhar syndrome (hemifacial microsomia).** (A) Marked left hemimandibular hypoplasia is present on 3D CT image. (B) Frontal cervical spine radiograph shows multiple segmentation anomalies.

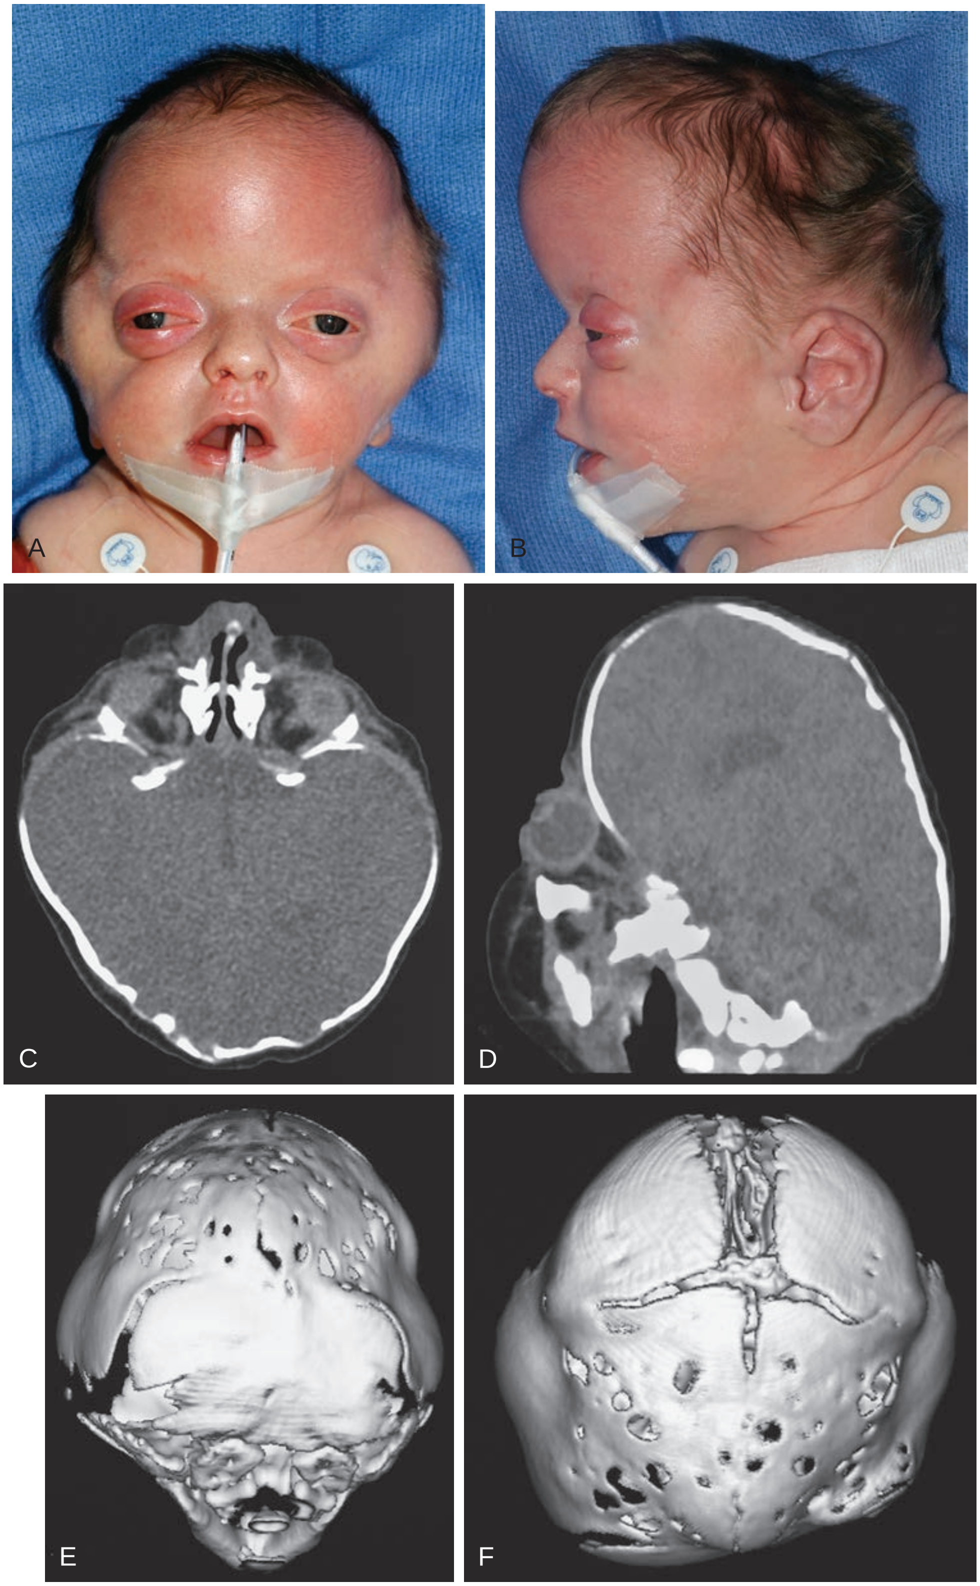


**Figure 20.30. Pfeiffer syndrome.** (A) Frontal and (B) lateral photographs show cloverleaf skull shape due to multisutural synostosis (bilateral coronal, bilateral lambdoid, and sagittal synostosis). (C) Axial and (D) reconstructed sagittal CT images show temporal bulging, bony fenestrations, maxillary retrusion, and exophthalmos. (E) Posterior and (F) vertex 3D CT images confirm coronal, bilateral lambdoid and sagittal suture closures.

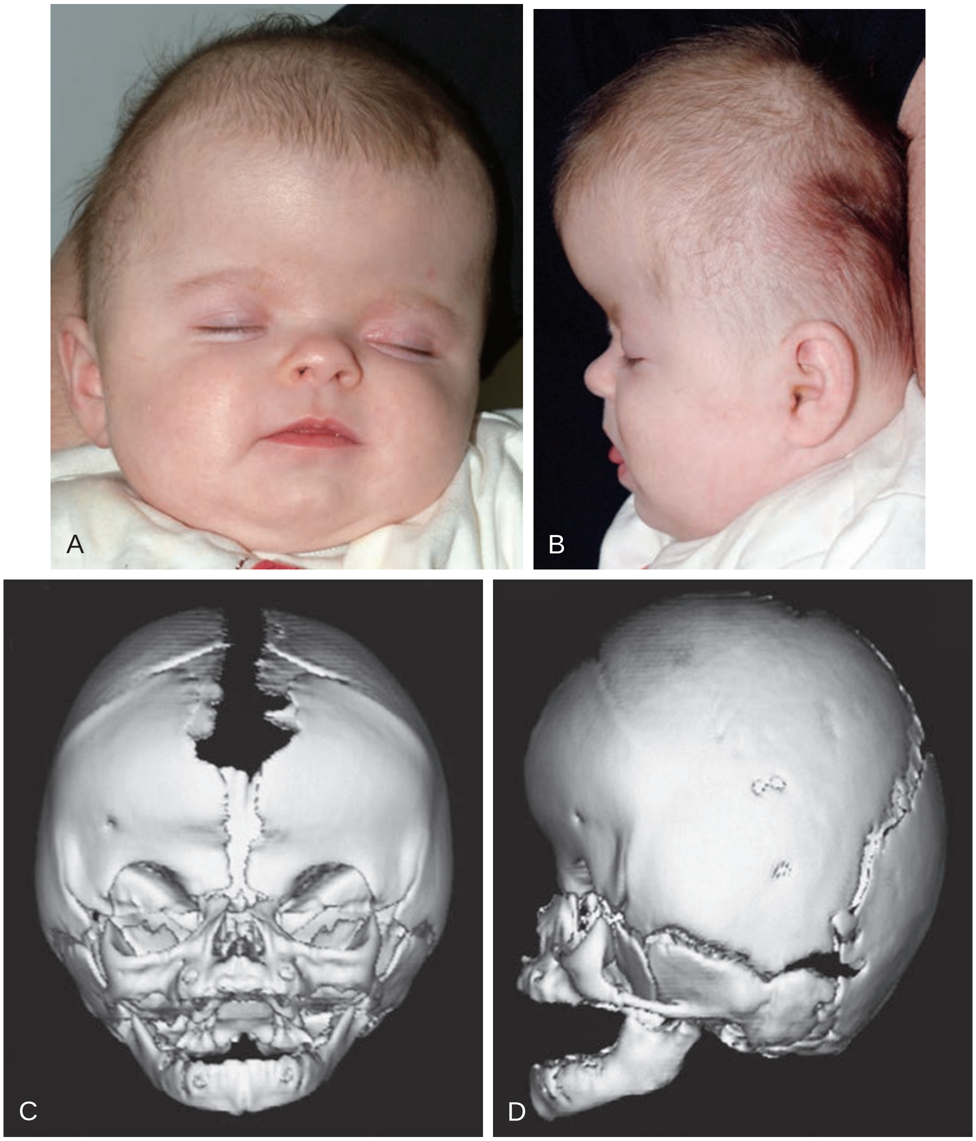

**Figure 20.32. Crouzon syndrome in an infant with brachycephaly.** (A) Frontal and (B) lateral photographs show increased craniocaudal and decreased anteroposterior dimensions. (C) Frontal and (D) lateral 3D CT images reveal brachycephaly due to bilateral coronal synostosis.

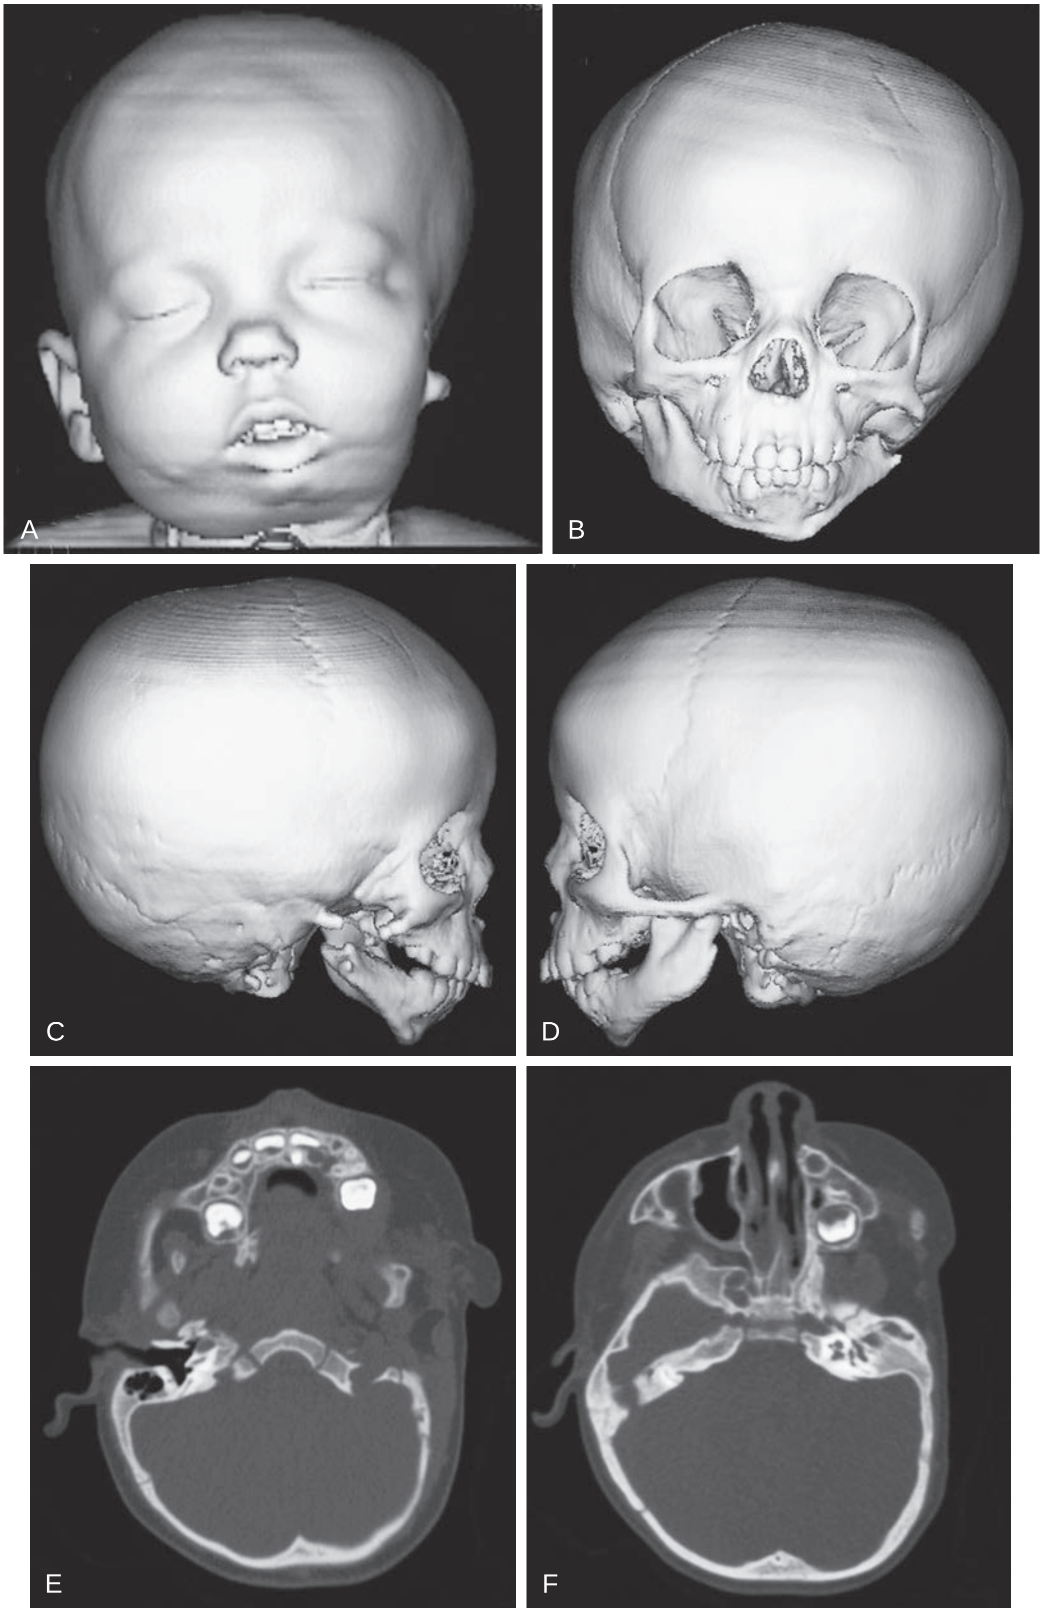

**Figure 20.33. Goldenhar syndrome in an infant with microtia.** (A) 3D CT surface rendering shows left hemifacial microsomia and left ear microtia. (B) Frontal 3D CT reveals a hypoplastic left mandible and zygomatic arch. (C and D) Lateral 3D CT images confirm asymmetry and left microsomia. (E and F) Axial CT images of the skull base reveal normal right external canal and temporal bone. The left face is hypoplastic and the external auditory canal is absent.

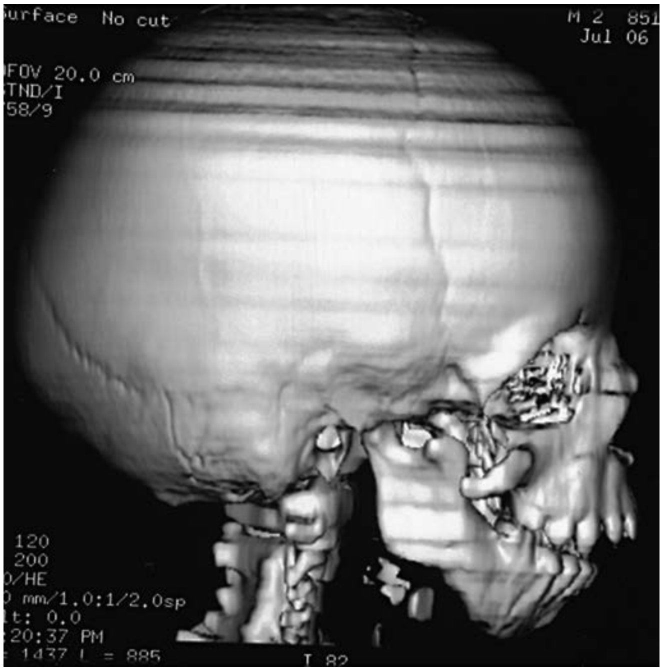

**Figure 20.35. Treacher Collins syndrome in a 3-month-old boy with micrognathia.** Lateral 3D CT image shows mandibular hypoplasia and absence of the zygomatic arch.

The facial features of Treacher Collins syndrome (TCS) are characteristic including bilateral, symmetric micrognathia, narrow face, depressed cheekbones, antimongoloid slant of eyes, malformed small ears, downturned mouth, high-arched or cleft palate, and conductive hearing loss.[19,20] The features are characterized by abnormalities derived from the first and second branchial arches.[20] Mutations in the *TCOF1* gene are associated with TCS.[21] The imaging features are primarily facial including mandibular, zygomatic, maxillary, and supraorbital hypoplasia. The orbits are described as egg-shaped. The mandible has a characteristic short body and ramus varying with patient age. The mandibular condyle and coronoid process may be severely hypoplastic, flat, or even absent (Fig. 20.35). Ear abnormalities include hypoplasia or absence of the middle ear. The ossicles and vestibular apparatus may be malformed. Zygomatic hypoplasia or aplasia is an important imaging finding for the diagnosis. Craniofacial 3D CT has become invaluable for surgical planning.[22]

### Pierre Robin Sequence

PRS, or Robin sequence, represents a nonrandom association of micrognathia, cleft palate, and glossoptosis.[23] PRS is causally heterogeneous, pathogenetically, and phenotypically variable.[24] Patients with PRS are classified as isolated (most common), syndromic, or with associated anomalies. Numerous syndromes, including Stickler and velocardiofacial syndromes, are associated with PRS.[25] Respiratory compromise from mechanical and central nervous system causes are common. The mandible may be small or normal-sized with retrognathia due to a large cranial base. Typically, a reduction in cranial base, maxillary and mandibular lengths are seen.[26]

Cardiovascular anomalies include septal defects and patent ductus arteriosus. Numerous skeletal anomalies of the ribs, sternum, spine, and limbs occur. Airway management is similar in both nonsyndromic and syndromic PRS. Infants may be managed with positioning, nasal pharyngeal airway, tongue-tie adhesions, or mandibular distraction.[27–30] Cine MRI or CT give dynamic and 3D information useful in airway evaluation of these patients.

## OTHER ABNORMALITIES OF THE SKULL

### Cranioschisis (Cranium Bifidum)

Cranioschisis usually occurs in the median sagittal plane, anteriorly or posteriorly (Fig. 20.36). It is characterized by bony defects and may accompany a meningocele or meningoencephalocele.[31] Meningoceles are characterized by a hernia sac, which is covered with skin and contains only meninges and cerebrospinal fluid (e-Fig. 20.37). Meningoencephaloceles also contain brain (e-Fig. 20.38). Rarely, cranioschisis may be heralded by a scalp nodule, with or without intracranial communication. Occasionally, small cranial defects (cranium bifidum occultum) through which no herniation occurs are encountered (e-Fig. 20.39). MRI is effective for evaluation.

Cranium bifidum with encephalocele often occurs in the sphenoid bone or the cribriform plate. In such cases, the protruding mass of brain and covering meninges may extend into the nasal cavity, nasopharynx, sphenoid sinus, posterior orbit, or pterygoid fossae. Important clinical signs include facial deformity hypertelorism and a broad nasal base.

### Lacunar Skull of the Newborn (Lückenschädel, Craniolacunia)

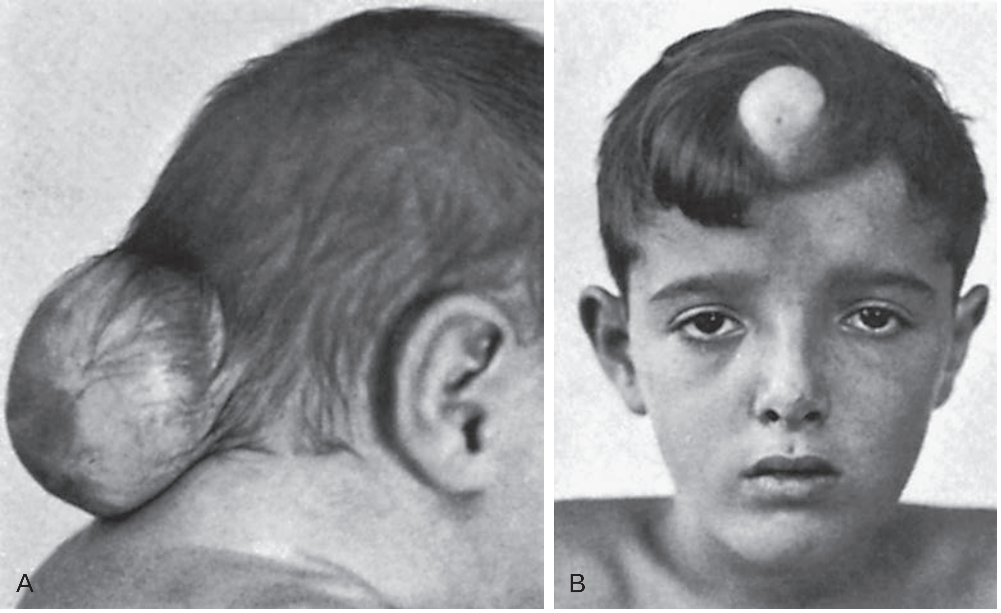
Lacunar skull develops during fetal life and is present at birth.[32] It is nearly always associated with meningomyelocele, myelocele, encephalocele or Chiari II malformation. The cause is unknown, but it is probably a dysplasia of the calvarium and the internal calvarial periosteum (i.e., the dura). It is not caused by increased intracranial pressure because it is found in infants whose skulls are normal or are small in size without hydrocephalus. The characteristic "soap bubble" rarefactions in the upper part of the calvarium are easily recognized (e-Fig. 20.40). These begin to fade after birth and usually disappear by 4 to 5 months of age. Normal convolutional rarefactions differ from lacunar rarefactions in that they are not obvious until the end of the first year and appear first in the posterolateral calvarium.

### *Sinus Pericranii*

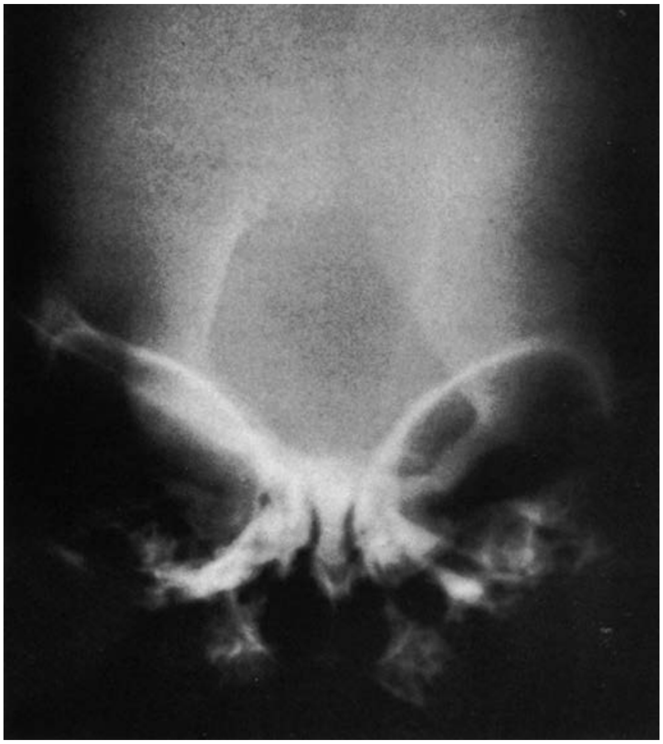
The term *sinus pericranii* is used for a soft, fluctuant, red-to-blue scalp mass over the sagittal or transverse sinuses. It changes size in response to maneuvers that increase intracranial pressure and may be associated with an underlying calvarial defect. It results from abnormal communication between the intracranial and extracranial venous systems, and its significance is cosmetic.[33–35] It must be differentiated from more serious lesions such as arteriovenous malformations, angiomas and hemangiomas, cephaloceles, and abscess. Ultrasound can suggest the diagnosis, but MRI is the best modality for demonstrating the abnormal vascular communication (Fig. 20.41).

KEY POINTS

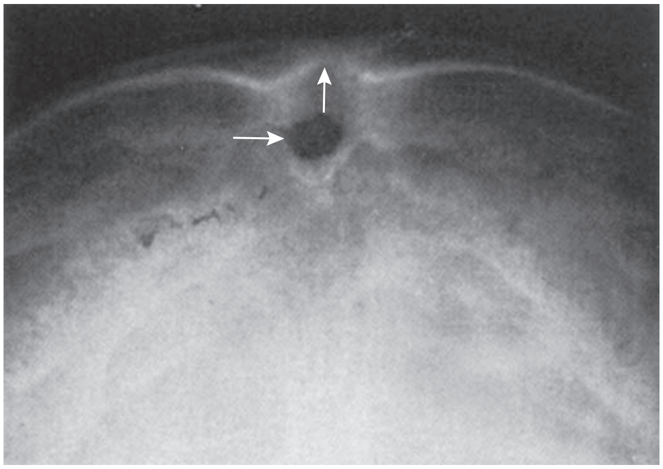
- Craniosynostosis deformities are complex, and secondary abnormalities at the base of the skull add to the structural changes.
- Plagiocephaly denotes abnormal skull shape (usually flattening) without defining a cause.
- Lacunar skull is not related to increased intracranial pressure.



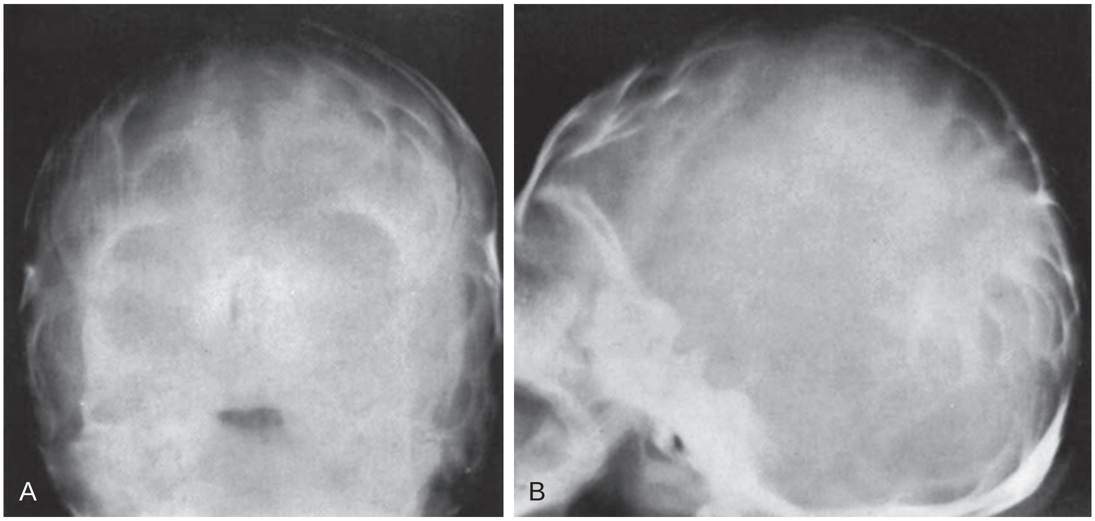
**e-Figure 20.37. Photographs of two children with skull defects and meningoceles.** (A) Lateral photograph of a 1-week-old neonate with an occipital meningocele. (B) Photograph of a 9-year-old male with a frontal meningocele.



**e-Figure 20.38. Cranium bifidum and occipital cephalocele in an infant with macrocrania.** Lucent osseous defect shown is in continuity with the foramen magnum. A Dandy-Walker cyst protruded through the bony defect *(not shown).*



**e-Figure 20.39. Cranium bifidum occultum in a 7-year-old infant.** Small round bony defect in the sagittal suture *(horizontal arrow)* without protrusion of a hernia sac. The groove for the sagittal sinus is shown *(vertical arrow).*



**e-Figure 20.40. Lacunar skull with occipital meningocele in a newborn.** (A) Frontal and (B) lateral radiographs demonstrate checkered skull rarefaction separated by bands of heavier density (lacunar pattern) resembling beaten copper or silver.

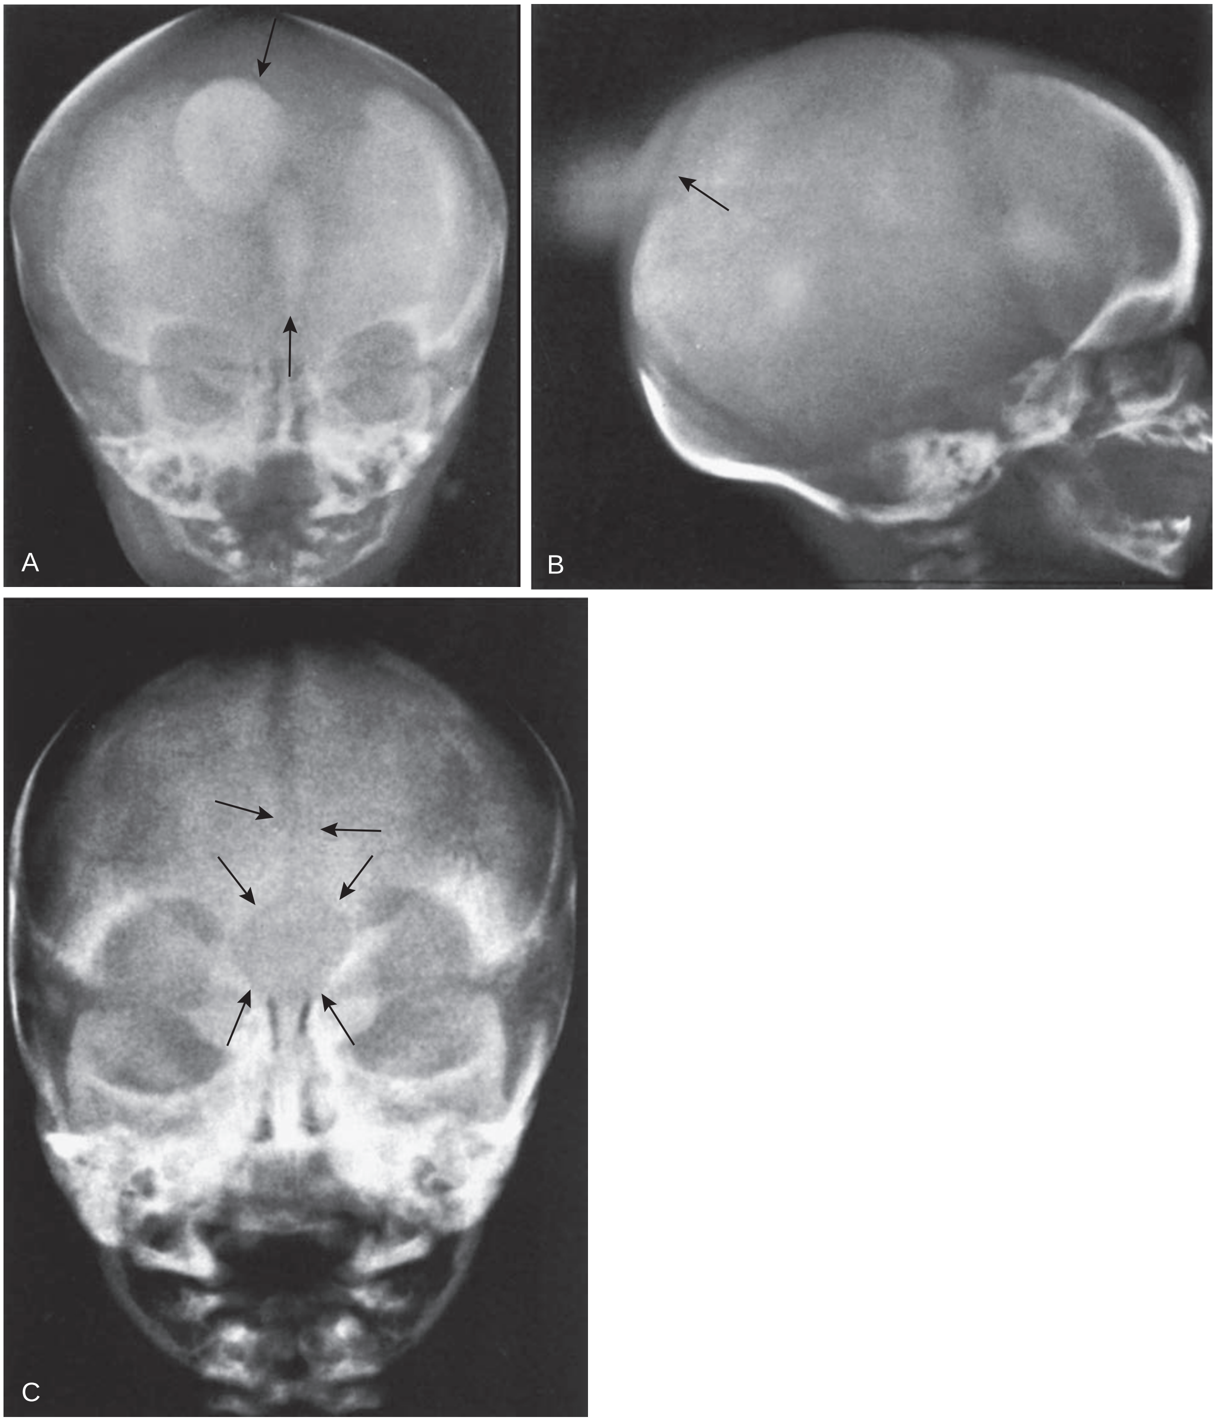


**Figure 20.36. Cranium bifidum and cephalocele in a 2-day-old girl.** (A) Frontal and (B) lateral radiographs show cranium bifidum in the metopic and sagittal suture, with protrusion of a meningoencephalocele at anterior and posterior sites. The metopic suture is open wide, and a smaller mass of soft tissue bulges externally between the frontal bones. In A, the larger superior patch of increased density *(upper arrow)* represents the interparietal protrusion, and the lower small patch *(lower arrow)* represents the smaller intrafrontal protrusion. (B) *(Arrow)* again denotes the protruding cephalocele. (C) Large circular glabellar osseous defect (cranium bifidum) in the metopic suture with an associated cephalocele *(arrows)* are shown.

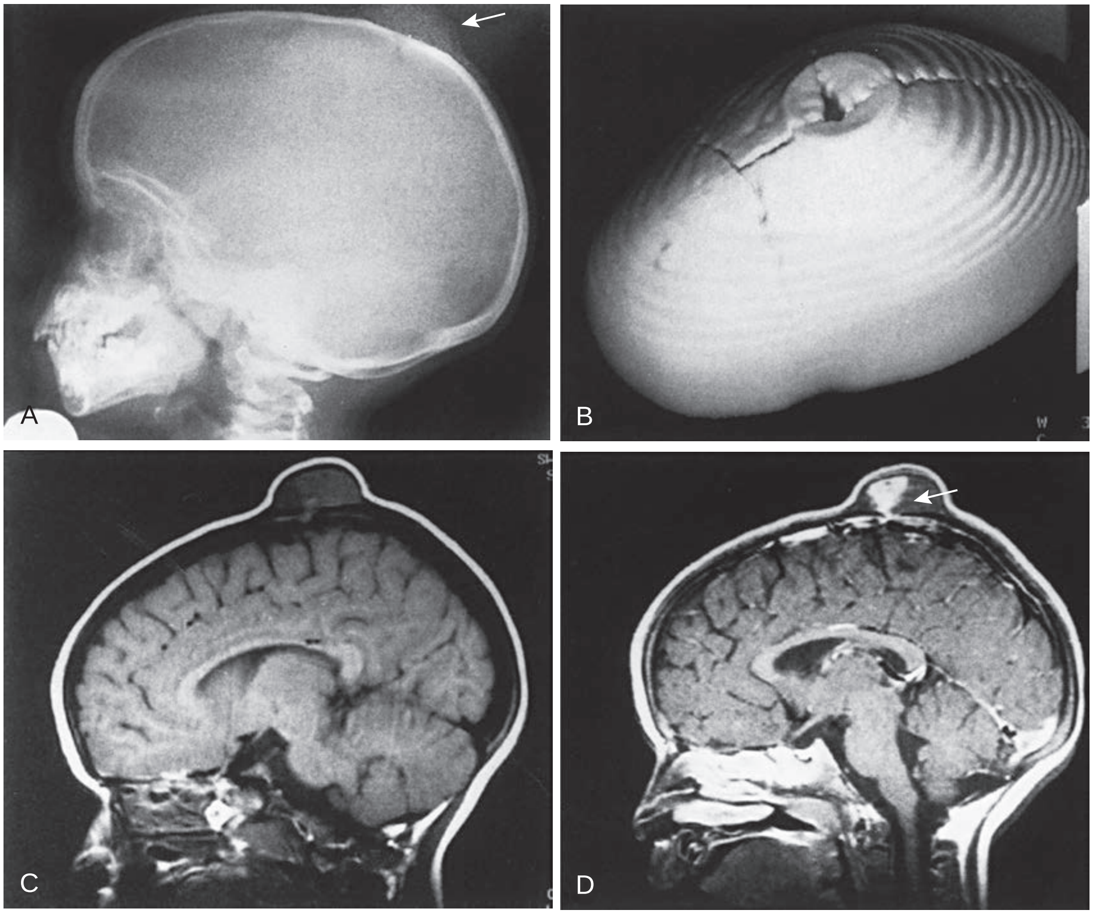

**Figure 20.41. Sinus pericranii.** (A) Lateral skull radiograph shows a soft tissue mass *(arrow)* and a well-defined defect in the midline of the parietal bones. (B) 3D CT image demonstrates erosion of both tables. (C) Precontrast T1-weighted magnetic resonance (MR) image confirms a midline interparietal mass with mixed signal intensity and areas of signal void indicating flowing blood. (D) Postcontrast T1-weighted MR image reveals heterogeneous enhancement and an emissary vein extending from the parietal bone to the superior sagittal sinus *(arrow). # 21

# Neoplasms, Neoplasm-like Lesions, and Infections of the Skull

*Travis H. Kauffman, David B. Nielsen, and Thomas L. Slovis*

## PRIMARY NEOPLASMS

Primary neoplasms of the skull are rare. The most common lesions in children with a solitary nontraumatic lump on the head are dermoid tumors (61%), cephalhematomas (9%), Langerhans cell histiocytosis (LCH) (7%), and occult meningoceles and encephaloceles (4%).[1,2]

Osteochondromas may arise from the cartilaginous bones of the skull base. Osteoblastomas have been reported in the calvaria of infants, and aneurysmal bone cysts have been noted in the skull base and the calvaria (Fig. 21.1). Osteomas are small and usually limited to the outer table, although osteoid osteomas may occur in the diploë. Osteoid osteomas may present as a button sequestrum. Malignant bone tumors are unusual, but osteogenic sarcoma and Ewing sarcoma have been reported (e-Fig. 21.2).[3-5]

Angiomas and neurofibromas of the scalp may affect the underlying skull and cause deformities, bony defects, and regional hyperostoses. Plain radiographs of neurofibromatosis (NF) most commonly show lytic defects in the lambdoid suture, but also include absence of the orbital roof and floor, partial absence of the greater sphenoid wing, anteroposterior enlargement of the middle cranial fossa with possible bony erosive changes, enlarged cranial nerve foramina, and J-shaped sella (Fig. 21.3).[6,7]

Venolymphatic malformations (formerly known as cavernous hemangiomas) of the skull are characterized by rounded areas of diminished density in which there may be a honeycomb or radial pattern of spiculation. These malformations (e-Fig. 21.4) thicken the outer table externally and are radially striated. They do not displace the inner table.

Epidermoids are ectodermal rests or inclusions that may be in the scalp, the diploic spaces, or between the internal surface of the inner table and the dura. Epidermoids are typically benign and grow slowly. When epidermoids involve bone, they produce lucent, sharply demarcated lesions with smooth, sometimes scalloped, margins (Fig. 21.5). These lesions are treated with surgical excision.[8,9]

Meningiomas are rare in children. Radiographic changes include reactive hyperostosis, an increase in the caliber and number of grooves for regional blood vessels, and calcifications in the meningioma itself. Occasionally, there are radiolucent patches due to overlying bone loss. Rarely, interosseous meningiomas occur (e-Fig. 21.6). Multiple meningiomas suggest NF. Calvarial lesions, like the lesions in NF, can occur in congenital fibromatosis.[10]

Chordomas are malignant neoplasms that are more aggressive in children than in adults.[11] Children and adolescents account for less than 5% of all chordomas, with the majority being in the clivus. They may present with headaches (due to increased intracranial pressure), cranial nerve palsies, and long tract signs. Children less than 5 years may present with torticollis. On magnetic resonance imaging (MRI) chordomas are lobulated masses with septations. They are predominantly T1 isointense/hypointense and T2 hyperintense with marked heterogeneous enhancement (Fig. 21.7).[12]

Melanotic neuroectodermal tumor of infancy (melanotic progonoma, retinal anlage) is rare. More than 90% of cases involve the head and neck; 70% in the maxilla, and about 11% in the calvarium, arising in the sutures with roughly half at the anterior fontanelle.[13] In the calvarium, the tumor most often presents during the first year of life as a movable scalp nodule that subsequently invades the bone, becomes fixed to it (often adhering to the dura), and grows very rapidly. Bone destruction creates a sunburst appearance tangential to the mass (e-Fig. 21.8). Occasionally, the mass presents as a soft tissue density. MRI signal is variable on T1- and T2-weighted images, but consistently shows marked enhancement. Malignancy has not been reported for tumors in the calvarium, whereas malignancy has been noted in extracalvarial tumors.[14-17]

## SECONDARY NEOPLASMS

Secondary tumors of the calvarium are more common than primary tumors and include leukemia, neuroblastoma, small round cell tumors, and LCH (Figs. 21.9 through 21.11 and e-Fig. 21.12).

## NEOPLASM-LIKE LESIONS

### Langerhans Cell Histiocytosis

LCH is addressed in more detail in Chapter 139; only the calvarial manifestations are presented here. Lesions in the skull are common, with an incidence of 28% to 54%.[18,19] The calvarium is affected more frequently than the skull base with the parietal bone being the most common. Multiple lesions are most frequently in children younger than 5 years. A solitary calvarial lesion in a child older than 5 years is likely to be LCH (Figs. 21.13 and 21.14). Sphenoid bone involvement may be associated with diabetes insipidus. Exophthalmos may occur when the bones of the orbit are involved.[20]

Mandibular LCH is more common than maxillary involvement and begins characteristically in the molar areas of the alveolar processes, where osseous destruction results in a characteristic finding of “floating teeth.” The teeth are frequently loose, and spontaneous shedding of teeth is common.

The radiographic hallmark of skull LCH is a “punched-out” radiolucent defect with little or no adjacent reaction. LCH lesions involve the full thickness of the calvarium and have a classic beveled edge. Lesions often have a soft tissue mass and may extend across sutures. LCH is the most common cause of a button sequestrum (which is also seen with infection). During healing, the margins of the lesions lose their sharpness, and the lesion gradually disappears.

### Fibrous Dysplasia

Fibrous dysplasia of the pediatric calvarium usually involves the frontal, sphenoid, and ethmoid bones (Fig. 21.15).[21] It most often presents with painless progressive scalp masses. Rarely, children may present with vision changes due to compression of the orbital apex or ischemia of the optic nerve.[22]

There are three CT patterns of fibrous dysplasia: ground-glass matrix (56%), homogeneously dense bone (23%), and cystic lucencies (21%).[23] On MRI, fibrous dysplasia shows well-defined geographic margins. It is T1 hypointense, and heterogeneous on T2-weighted images.[24,25] Fibrous tissue may markedly enhance, simulating a tumor.

## Abstract:

Primary neoplasms of the pediatric skull are rare but include a vast differential which can be focused by imaging features, anatomic location and patient age. Most primary skull neoplasms are benign. Secondary neoplasms of the skull are more common. Neoplasm-like lesions of the skull include Langerhans Cell Histiocytosis and fibrous dysplasia which are typically distinguished radiographically and can be symptomatic. Infections of the skull are due to direct extension or hematogenous spread. Specific infectious processes may have similar imaging appearances, but are usually distinguished by clinical history. Lesions involving the pediatric skull can be divided into primary neoplasms, secondary neoplasms, neoplasm-like lesions, and infections. Imaging features in conjunction with clinical history will help radiologists to narrow the sometimes broad differential and assist in arriving at a timely diagnosis to initiate appropriate treatment.

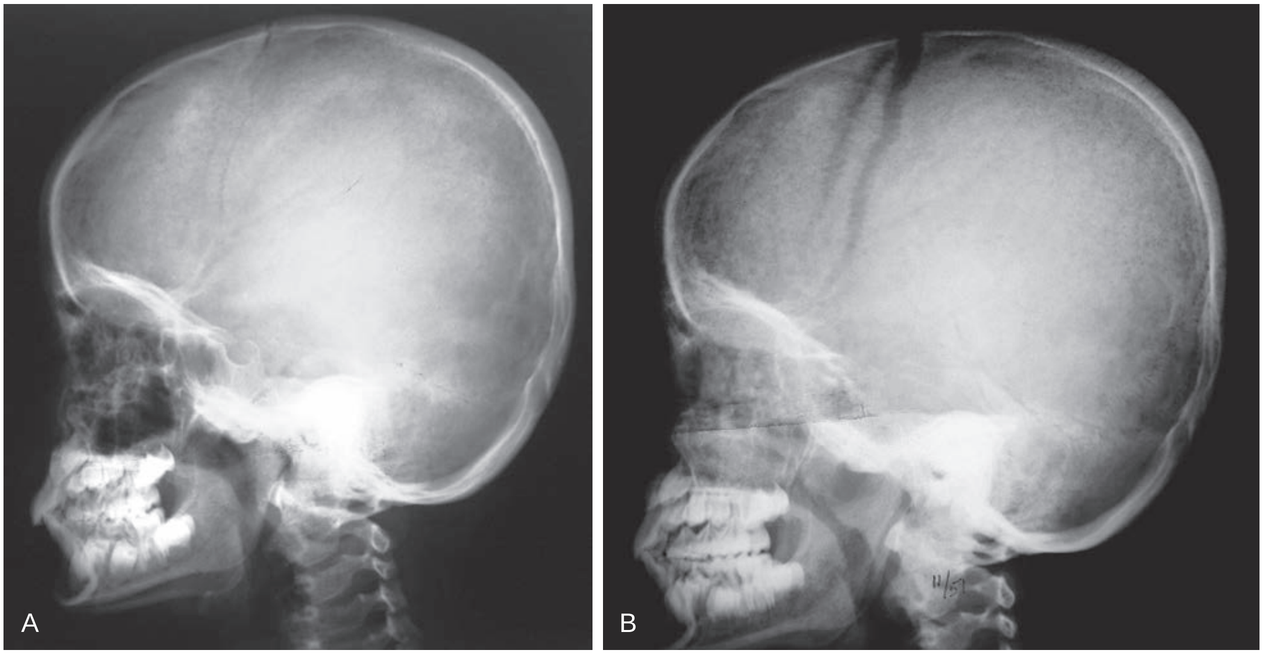

**Figure 21.9. Leukemia.** (A) Radiograph demonstrates a permeative area in the frontal calvarium with osseous spiculation in the parietal bone. (B) Radiograph in another child shows more pronounced osseous heterogeneity and widened coronal sutures indicating increased intracranial pressure.

## INFECTIONS OF THE CALVARIA

### Osteomyelitis

Osteomyelitis of the skull is rare in children and has many different etiologies.[26] Trauma is a common precursor.[27] Secondary infection after halo placement for traumatic injuries may occur. In such cases, halo pins may become loose.[28] Bones adjacent to the paranasal sinuses may become infected from direct extension of sinusitis. Clival osteomyelitis resulting from the spread of infection through the fossa navicularis magna has been reported after retropharyngeal abscess.[29] Systemic diseases can alter the body's defense and predispose to infections.

Hematogenous osteomyelitis may develop during bacteremia, by direct extension from scalp cellulitis or after fractures. Osteomyelitis can spread intracranially causing meningitis, or forming epidural or subdural abscesses. It may also cause extracranial subgaleal or subcutaneous abscesses. CT and MRI are useful to characterize infection extent.

Radiographic findings are normal during early osteomyelitis. However, when inflammatory lesions become visible, they involve the full thickness of the skull, including the diploic space, inner tables, and outer tables. Osteomyelitic lesions may be single or multiple, and are more common in the frontal and parietal bones. Lesions begin with fine lytic osseous foci that enlarge and coalesce, forming a permeative lesion. When chronic, osteomyelitis may

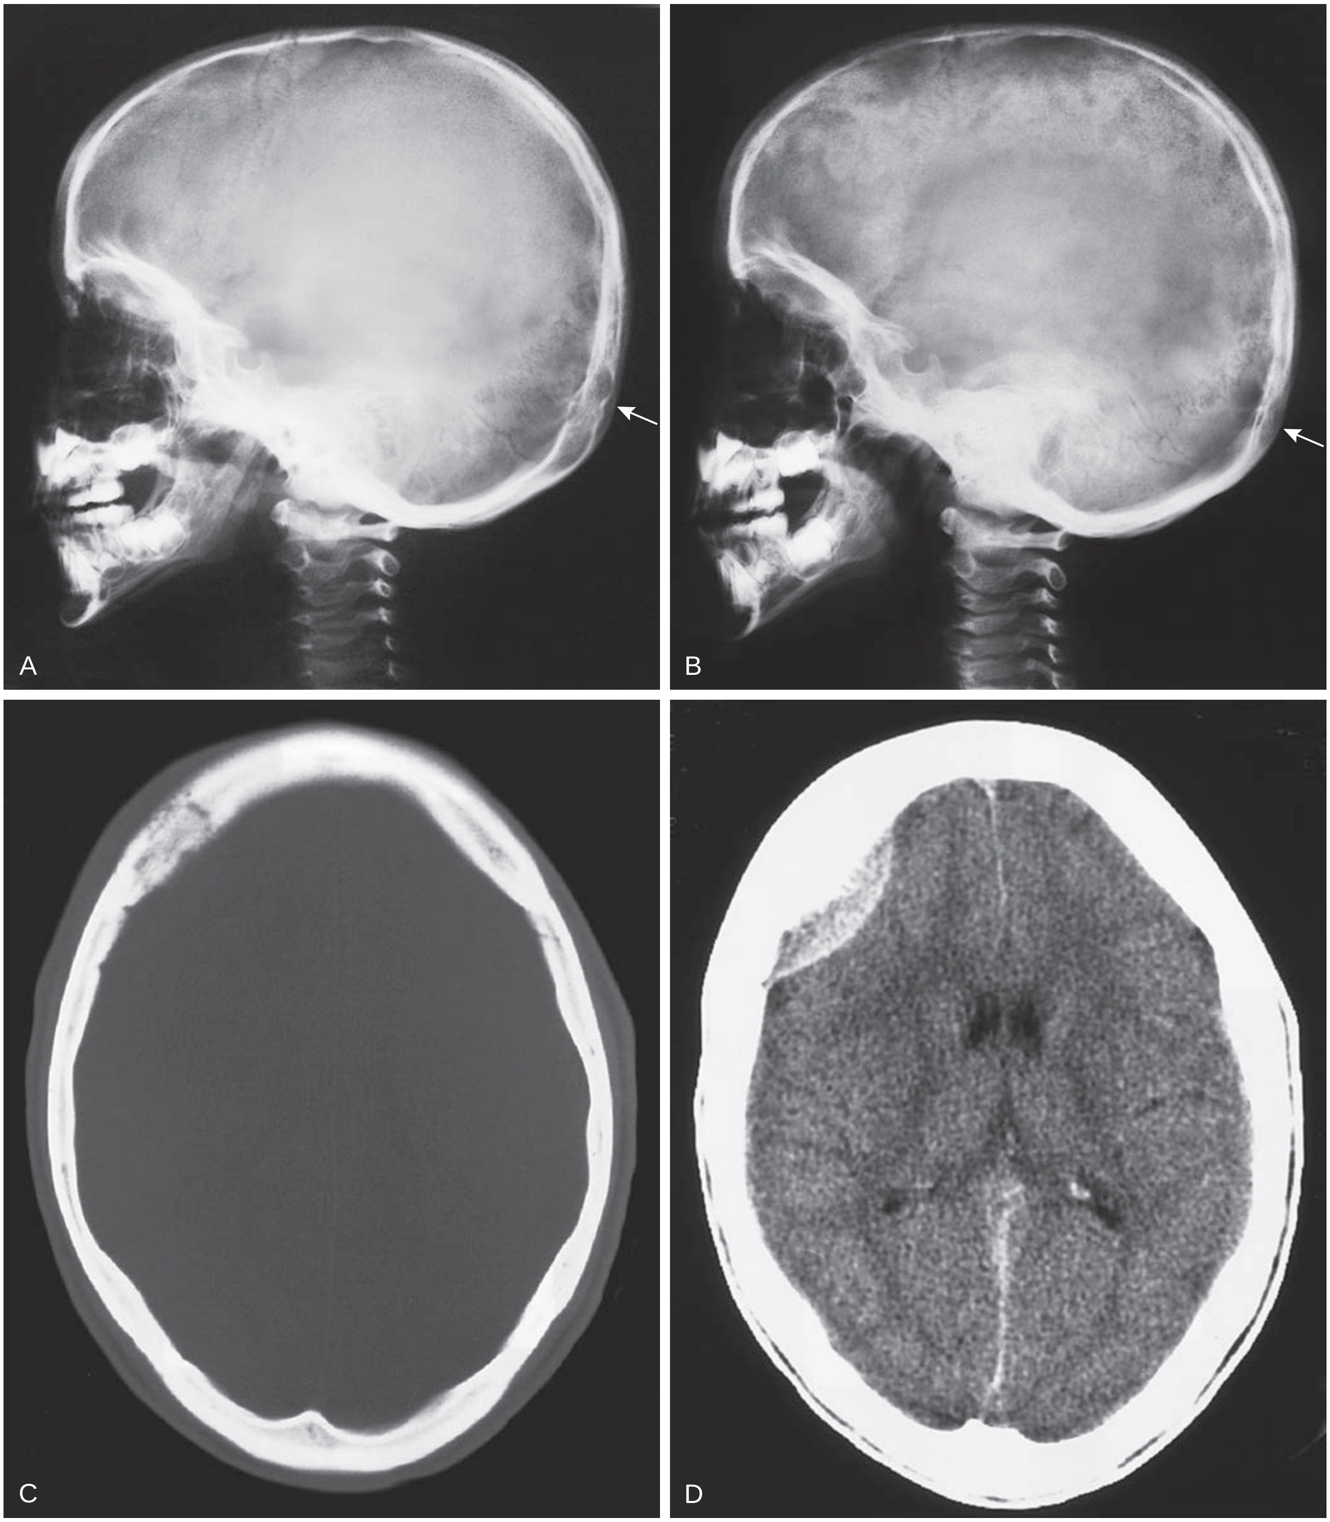

**Figure 21.10. Metastatic neuroblastoma in a child presenting with scalp pain.** (A and B) Plain radiographs demonstrate a destructive occipital lesion. Mild permeative changes are present in the frontal and occipital regions *(arrow).* Image (B) shows the finding to best advantage. (C) Bone and (D) soft tissue postcontrast CT images in another patient reveal a permeative right frontal lesion with an enhancing epidural mass.

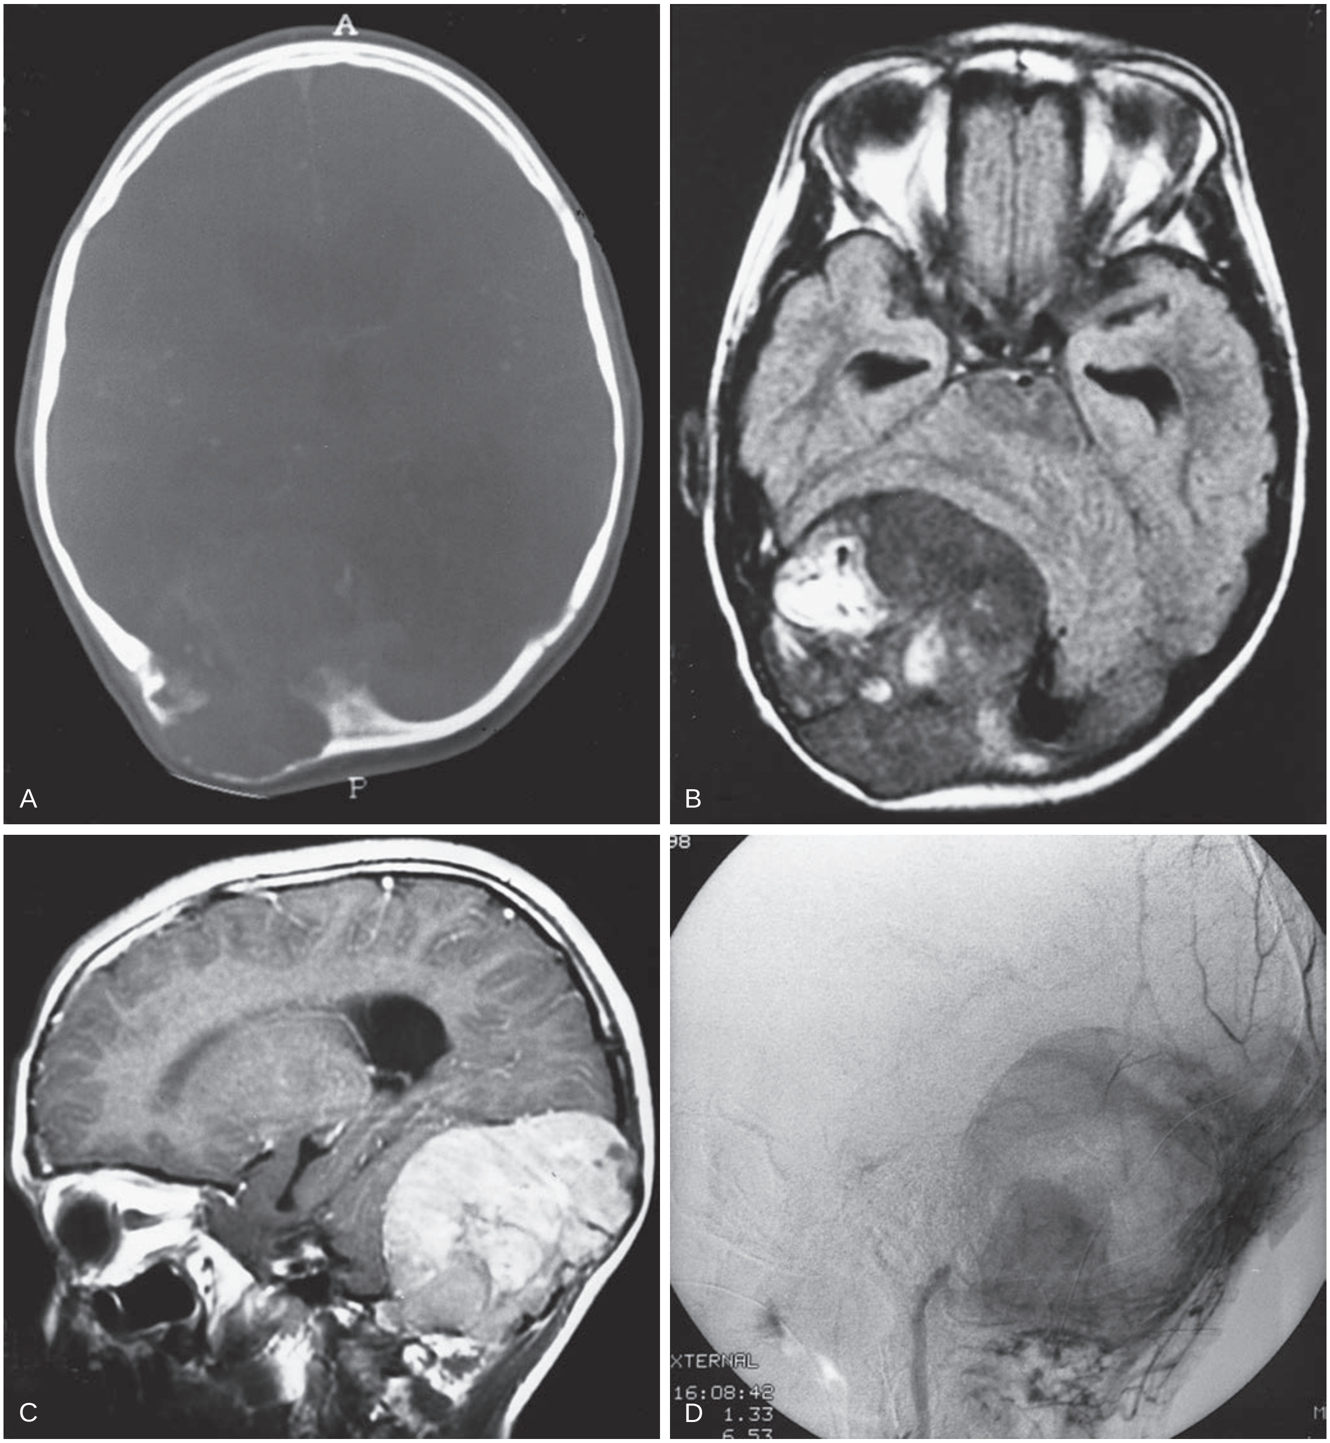

**Figure 21.11. Metastatic neuroblastoma.** (A) Axial CT shows an occipital mass with bone destruction. (B) Axial FLAIR and (C) sagittal T1-weighted enhanced MRI show the extradural mass. (D) Angiography shows a vascular mass.

develop peripheral sclerosis. In infants, the avascular sutures act as barriers to spread. The differential diagnosis of permeative skull lesions includes osteomyelitis, leukemia, metastatic neuroblastoma, and metastatic small round cell tumors (Ewing sarcoma, medulloblastoma, and retinoblastoma).[30]

Infection of a cephalhematoma, usually after bacteremia or attempted needle aspiration, may be complicated by osteomyelitis, septicemia, meningitis, or dural venous sinus thrombosis.

The accuracy of diagnosing an infected cephalhematoma is poor because infected and uninfected cephalhematomas both demonstrate radiolucencies. CT is the best modality to show bony changes, and MRI is superior for detecting intracranial complications such as venous sinus thrombosis and abscess.

Pott's puffy tumor, described in 1760 by Sir Percival Pott, consists of a subperiosteal abscess and osteomyelitis of the frontal bone.[31,32] It may result from acute frontal sinusitis or trauma

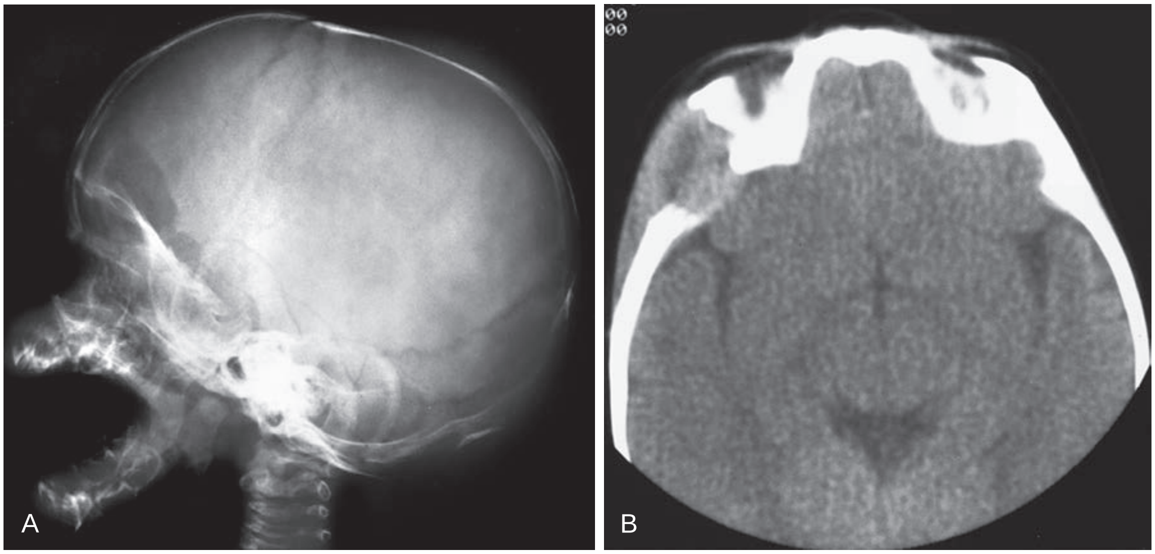

**Figure 21.13. Langerhans cell histiocytosis.** (A) Lateral skull radiograph shows a lytic, well-defined supraorbital, frontal lesion. (B) CT reveals bony destruction with a soft tissue mass. Note the beveled margins with greater outer than inner table destruction.

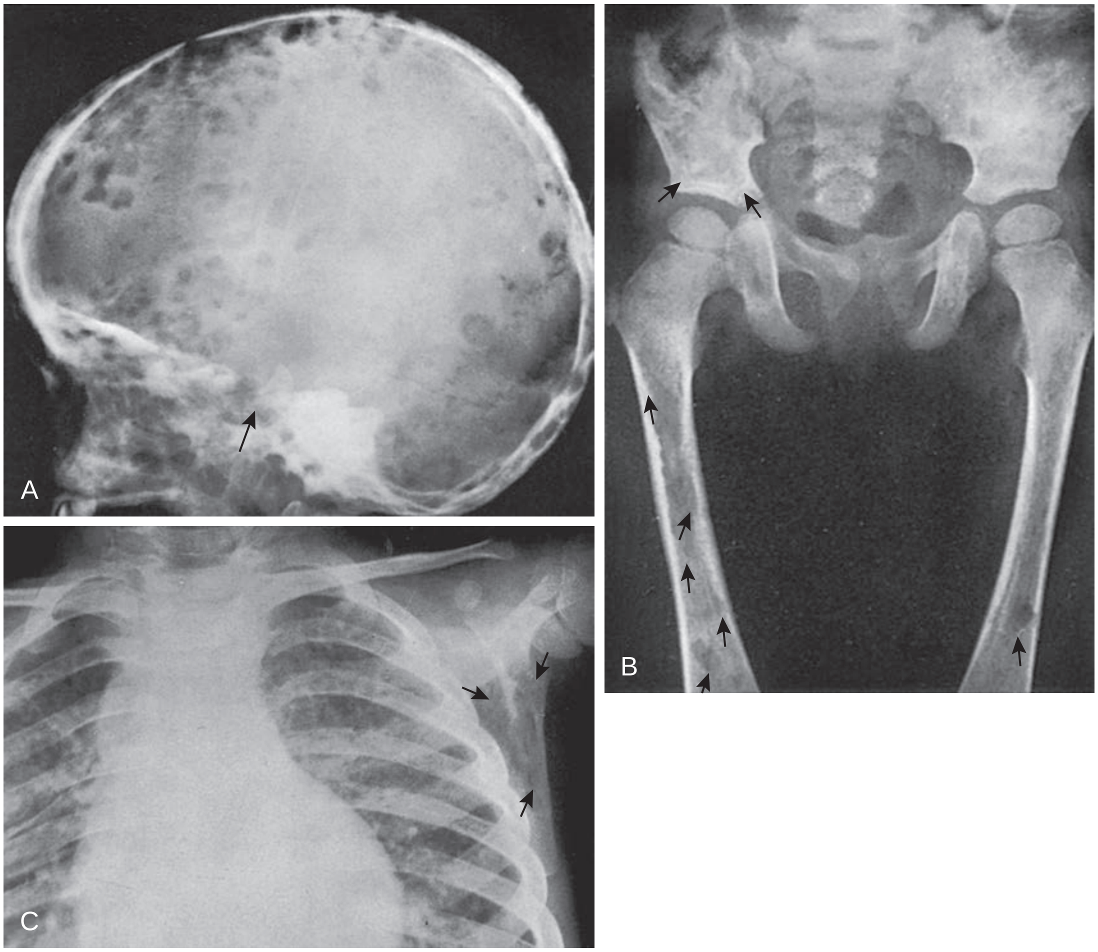

**Figure 21.14. Langerhans cell histiocytosis in a 3-year-old boy.** (A) Lateral skull radiograph shows numerous rounded defects in the calvaria and skull base *(arrow).* (B) Multiple defects *(arrows)* in the ilia and femora, the latter of which shows cortical erosion indicating a medullary cavity origin. (C) Scapular defects *(arrows)* and infiltration of the lungs and pleura.

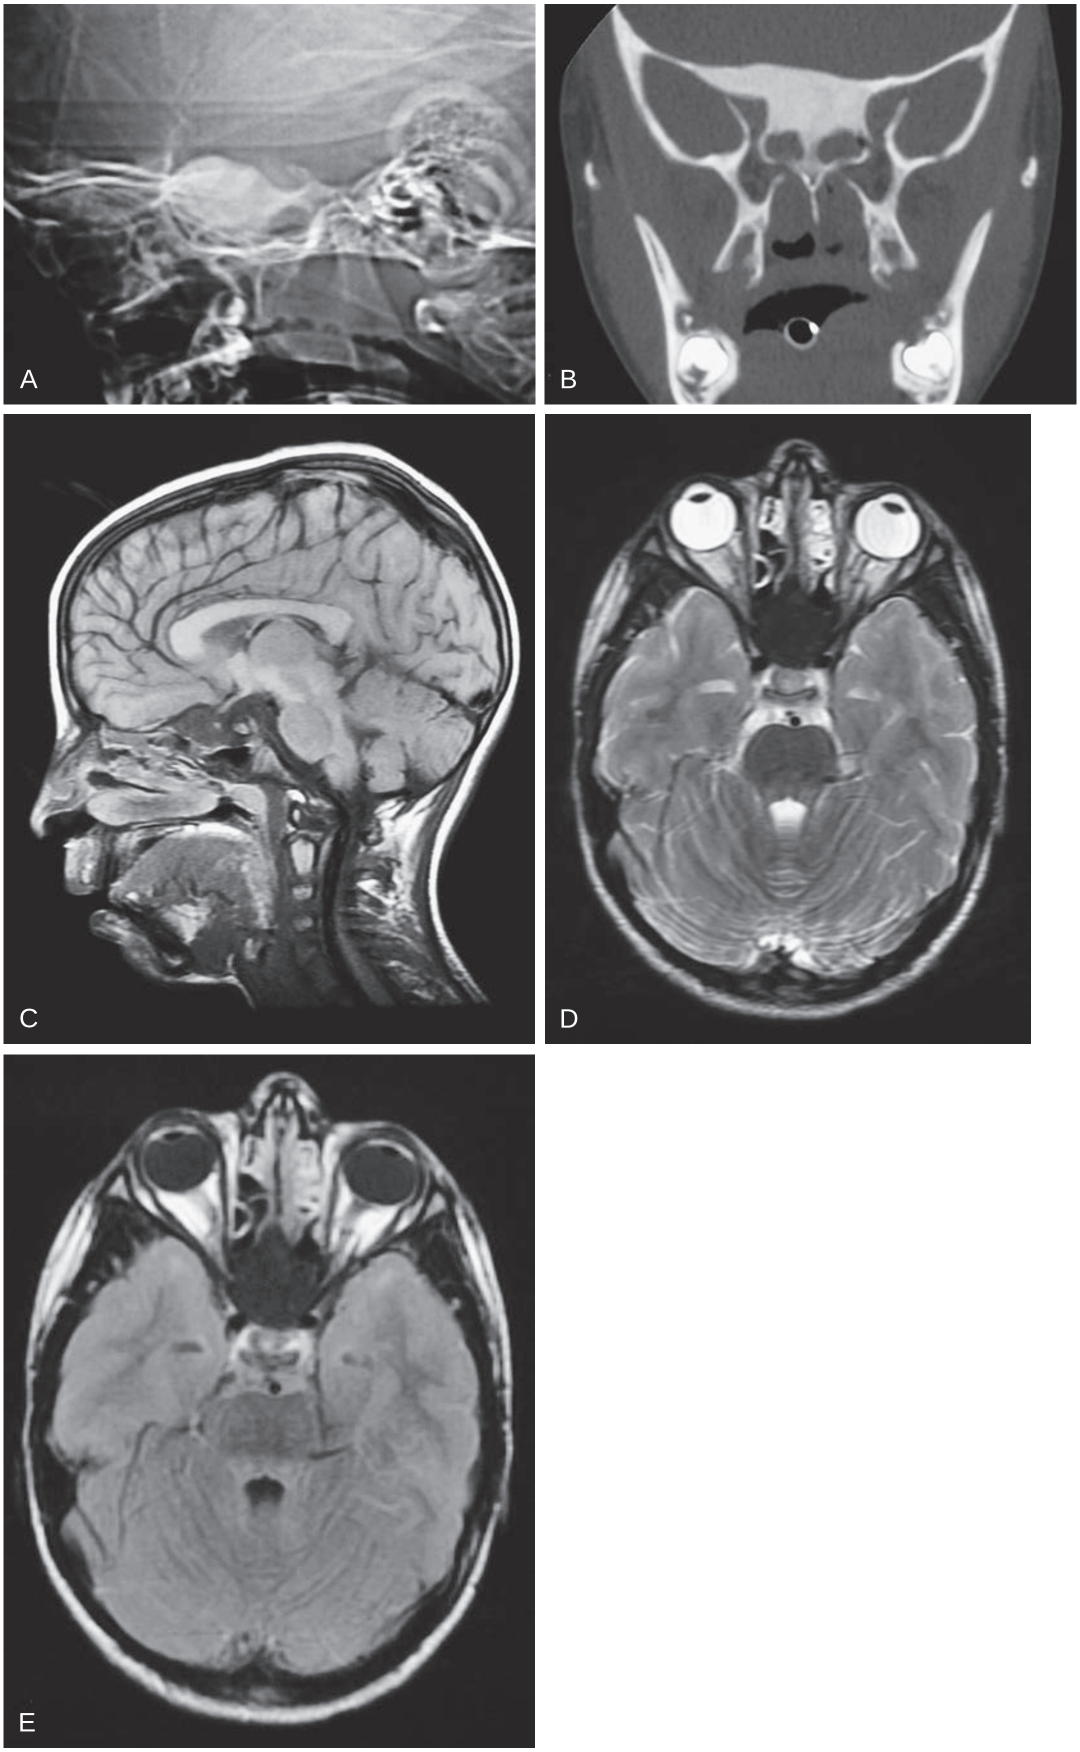

**Figure 21.15. Fibrous dysplasia of the skull.** (A) Scout CT image reveals a dense sphenoid bone. (B) Coronal CT image confirms the dense lesion with ground glass matrix. (C) Sagittal T1 image shows the lesion is hypointense. (D) On T2 and (E) FLAIR it is hyperintense.

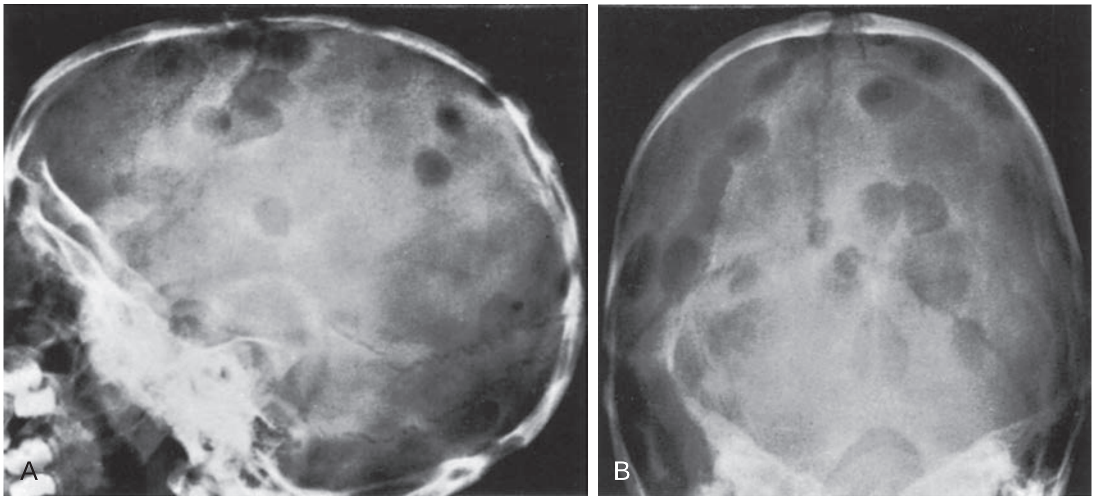

**Figure 21.17. Calvarial tuberculosis in a 3-year-old girl.** (A) Lateral and (B) frontal radiographs show multiple lytic foci.

(e-Fig. 21.16). The valveless diploic veins that drain the sinuses allow spread of septic emboli. Sonography can show subgaleal abscesses. However, CT and MRI are needed to demonstrate frontal sinusitis, osteomyelitis, and intracranial abscesses.

Petrous apicitis (Gradenigo syndrome) typically presents with middle ear disease, headache, cranial neuropathy, and elevated erythrocyte sedimentation rate. Characteristic CT and MRI findings include petrosal marrow T1 hypointensity, T2 hyperintensity, soft tissue inflammation, and bone destruction.

Unusual causes of calvarial osteomyelitis include cochlear implants and, rarely, cat scratch disease. The frontal and sphenoid bones have also been involved in chronic recurrent multifocal osteomyelitis.[33]

## Tuberculosis

Tuberculosis of the calvaria usually manifests as painless subgaleal scalp swelling with a discharging sinus. The lesions may be small, punched-out lytic areas (Fig. 21.17), spreading circumscribed sclerotic areas, or a combination.[34]

## Sarcoidosis

Sarcoidosis of the diploic space is associated with large radiolucent patches in the frontal, parietal, and occipital bones (e-Fig. 21.18).[35]

## Syphilis

The cranium can be involved in infantile syphilis in association with severe syphilitic osteitis of the long bones. Destructive and productive changes may be present, usually in the parietal and frontal bones.

## Mycotic Osteomyelitis

The cranium may be involved in chronic fungal infections, including actinomycosis, blastomycosis, coccidiomycosis, cryptococcosis, and candidiasis.[36] The radiographic features are similar to tuberculous, syphilis, and chronic osteomyelitis. The diagnosis requires identification of a responsible organism, and underlying immunodeficiency is frequent.[37]

### KEY POINTS

- Primary neoplasms are rare in children and most are benign.
- Secondary neoplasms are more common than primary neoplasms.
- LCH can have many appearances.
- Trauma and sinusitis are common precursors to osteomyelitis.
- Pott's puffy tumor includes osteomyelitis of the frontal bone and subperiosteal abscess.

# PART 2 Mandible

# 22 The Mandible

*Laura Dinneen and Thomas L. Slovis*

## ANATOMY

At birth, the mandible consists of two lateral halves united in the midline at the symphysis by a bar of cartilage (Fig. 22.1, e-Fig. 22.2, and Fig. 22.3). Bony fusion of the symphysis usually occurs before the second year, but segments of the fissures may persist beyond puberty. The body of the mandible is large at birth compared with the relatively short vertical rami with poorly differentiated coronoid and condylar processes. The rami form an angle of about 160 degrees with the body at birth.

The mandible is the only freely movable bone of the face; it articulates with the temporal bone in the temporomandibular fossa anterior to the external auditory canal (see Fig. 22.3). The range of motion is free in all directions, and the condyle moves downward and forward in the articular fossa upon opening of the jaw.

The temporomandibular joint (TMJ) (see Fig. 22.3) is a complex joint in which a biconcave fibrous disk divides the articular space into upper and lower compartments. Gliding movements occur in the upper compartment, whereas the lower compartment functions as a true hinge joint. The articulating bony surfaces are not covered by hyaline cartilage as in other synovial joints but by fibrocartilage separated from the underlying bone of the condyle by growth cartilage.

## DENTITION

By approximately the sixth week of embryologic development, the dental lamina develops along the length of the upper and lower jaws. It is the predecessor to dental bud formation and ultimately tooth development.

Teeth are situated in bony prominences along the mandible and maxilla known as *alveolar processes*. The alveolar processes and mandibular body atrophy when teeth are absent (e-Fig. 22.4). There are two sets of dentition, primary/deciduous teeth and permanent teeth. There are 20 total primary teeth and 32 total permanent teeth in the mouth in a normal situation (Fig. 22.5).[1] The developmental absence of some or all teeth, hypodontia and anodontia respectively, is demonstrated in a rare inherited disorder called *anhidrotic/hypohidrotic ectodermal dysplasia* (Fig. 22.6). Hyperdontia or supernumerary teeth may occur sporadically or in association with conditions such as Gardner syndrome and cleidocranial dysplasia. Other dental abnormalities in cleidocranial dysplasia include markedly delayed shedding of primary teeth and delayed or failed eruption of permanent teeth.[2]

Natal and neonatal teeth are uncommon but do occur in 1:2000–3000 live births. In the majority of cases, this is an isolated, nonsyndromic occurrence with early premature eruption of a normal primary tooth/teeth. Complications with suckling may occur for baby and mother.[3]

## EMBRYOLOGY

The branchial apparatus, also known as *pharyngeal apparatus*, comprises a series of paired embryologic structures—arches, pouches, clefts, and membranes—associated with the pharynx from which many adult craniofacial structures are derived. Branchial apparatus neural crest cells contribute to skeletal development in the face.

Between weeks 4 and 5 of development, the stomodeum (rudimentary mouth) forms in the center of the face surrounded by the first and second branchial pairs. The first branchial arch, the so-called mandibular arch, and its corresponding neural crest cells give rise to the mandible.[4]

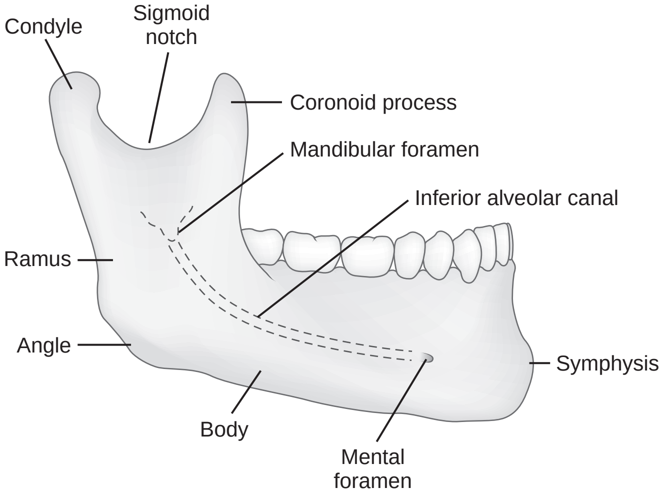

**Figure 22.1.** Important anatomic features of the normal mandible.

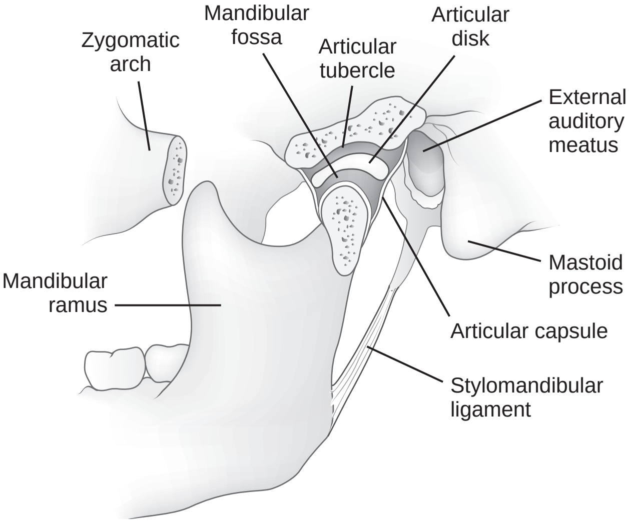

**Figure 22.3.** Anatomy of a normal temporomandibular joint. The zygomatic arch and a portion of the ramus of the mandible are cut away to expose the articular disk.

## Abstract:

Morphogenesis and anatomy of the mandible including teeth discussed. Craniofacial malformation as it pertains to mandible touched upon. Imaging pediatric mandibular pathology to include arthritic and nonarthritic TMJ disorders, mandibular fractures, osteomyelitis and CRMO, odontogenic and nonodontogenic mandibular cysts and masses, metastatic disease and other generalized skeletal diseases involving the mandible including fibrous dysplasia, infantile cortical hyperostosis and metabolic bone disorders like renal osteodystrophy highlited. CT, MRI and radiography including Panorex emphasized. Advances in fetal MRI included where applicable.

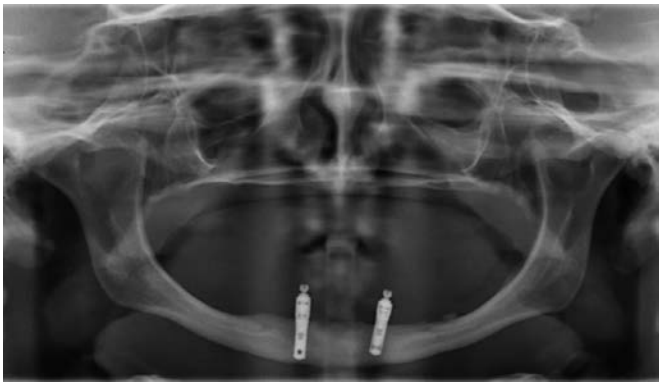
**e-Figure 22.2.** The relative size and shape of neonatal and adult mandibles. The rami form an angle with the body of 160 degrees at birth; this angle is reduced to 130 degrees at adolescence and 120 degrees in adulthood. *(Modified from Arey LB.* Developmental Anatomy. *Philadelphia: Saunders; 1942.)*



**e-Figure 22.4.** Edentulous mandibular hypoplasia. Panorex from a 10-year-old female with chronic neutropenia status after a full-mouth dental extraction for innumerable caries and peridontal pathology. Two mandibular post implants are in place for affixing dentures. The alveolar bone, which exists for the sake of the teeth, has resorbed postextraction.

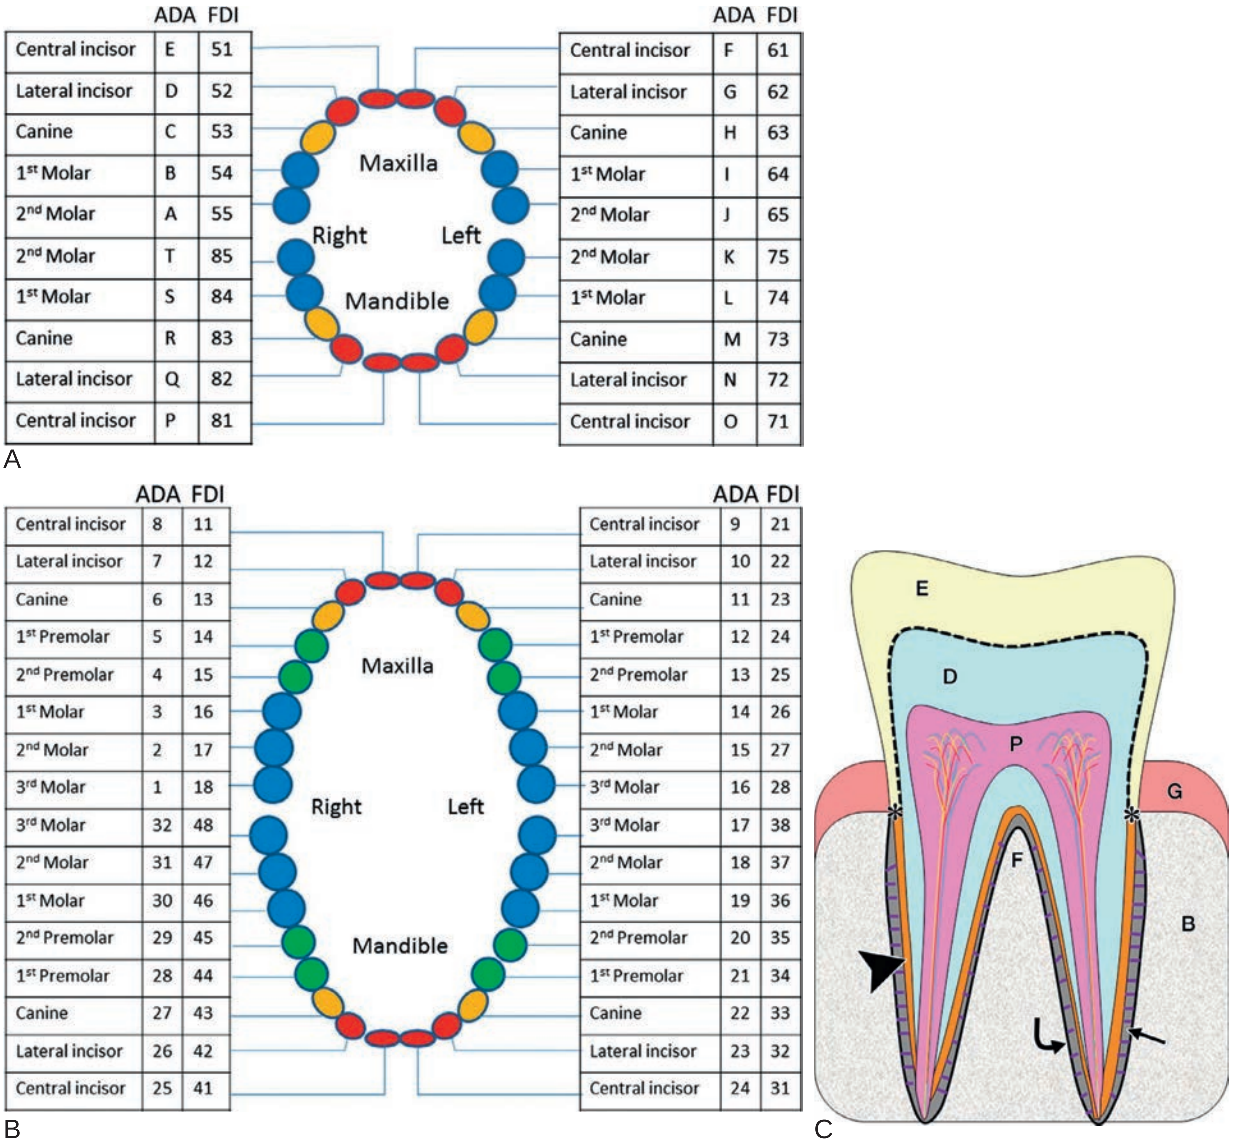


**Figure 22.5.** Tooth numbering nomenclature for (A) primary and (B) permanent teeth. *ADA,* American Dental Association; *FDI,* Feberation Dentaire Internationale. (C) Normal tooth anatomy. Enamel *(E)* covers the crown, and a thin layer of cementum *(arrowhead)* covers the roots. Dentin *(D)*, a calcified matrix, lies between the enamel or cementum and the pulp chamber *(P)* or root canal. Cementum and dentin cannot be distinguished at imaging because they have similar mineralization. The pulp chamber and root canal contain neurovascular elements. Gingiva *(G)* covers the maxillary and mandibular alveolar processes *(B)*. In teeth with multiple roots, the space between the roots is called the *furcation (F)*. Lamina dura *(curved arrow)*, a thin layer of dense bone, lines the socket. The periodontal ligament *(straight arrow)* lies between the lamina dura and cementum. * = cementoenamel junction, dashed line = dentinoenamel junction. *(C from Scheinfeld MH, Shifteh K, Avery LL, et al. Teeth: what radiologists should know.* RadioGraphics. *2012;32[7]:1927–1944. doi:10.1148/rg.327125717; A and B from Errata.* RadioGraphics. *2013;33[1]:312–312. doi:10.1148/rg.331125717.)*

First branchial arch neural crest cell insufficiency results in mandibular insufficiency (i.e., micrognathia). Micrognathia describes an undersized hypoplastic mandible (Fig. 22.7). Retrognathia describes a retropositioned mandible. Often micrognathia and retrognathia go hand-in-hand; a small jaw is also a retropositioned jaw. Prognathia describes an oversized mandible. Partial duplication of the mandible is very rare.

Transformation of the first branchial apparatus explains a developmental relationship between the jaw and the ear. The principal derivatives of the first arch include not only the bony mandible but also middle ear ossicles malleus and incus. The endodermal-lined first branchial pouch derivatives include the pharyngotympanic (Eustachian) tube and middle ear cavity. The ectodermal-lined first branchial cleft principal derivative is the external auditory canal. The intervening first branchial membrane develops into tympanic membrane.[5] Genetic conditions and environmental factors can adversely affect the complex transformation of the branchial apparatus. Gone awry, the interrelated transformations of the first and second branchial pairs can result in isolated mandibular anomalies (rare) to major syndromic categories of craniofacial malformation termed the *otomandibular dysplasias*, which include Goldenhar (hemifacial microsomia), Treacher Collins (mandibulofacial dysostosis), branchio-oto-renal syndrome, Nager preaxial/radial acrofacial dysostosis, and Pierre Robin sequence (PRS) (see also Chapter 20).[6]

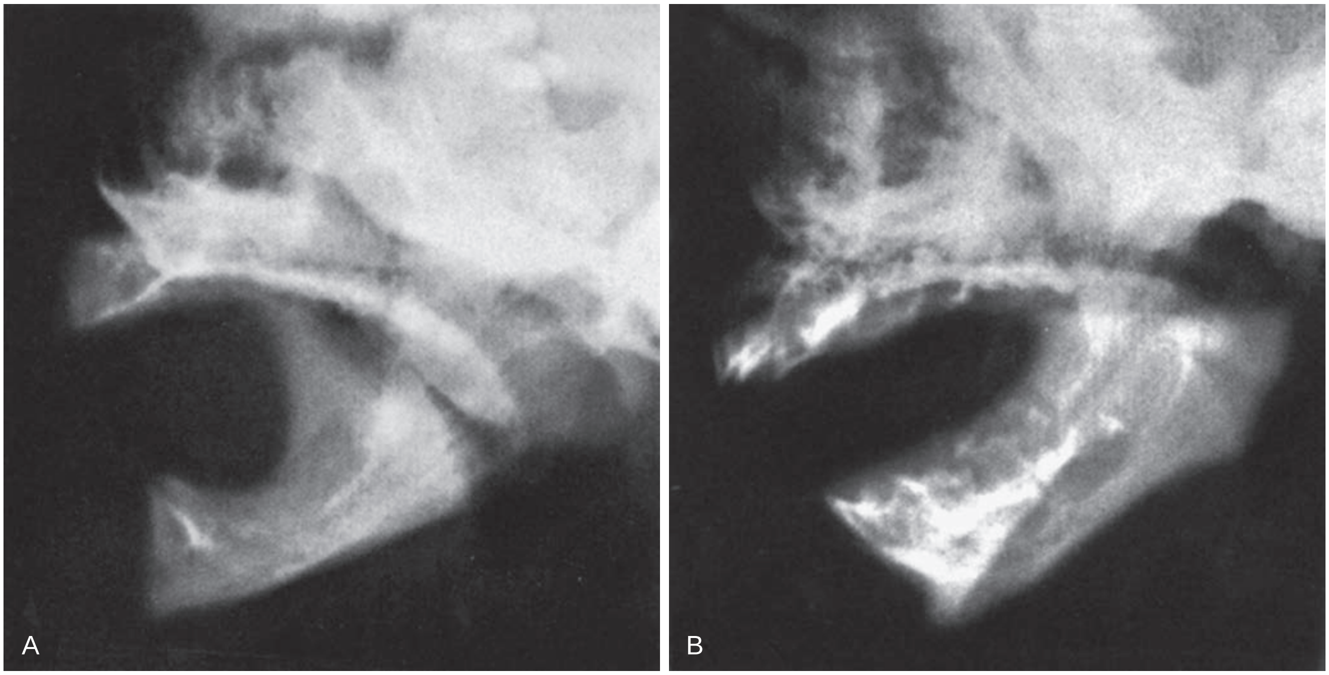

**Figure 22.6.** (A) A mandible in an 8-week-old infant with hereditary ectodermal dysplasia shows failure of calcification of dental crowns and defective dental sacs. (B) A radiograph of a normal 8-day-old newborn shows normal dental development in the neonatal period.

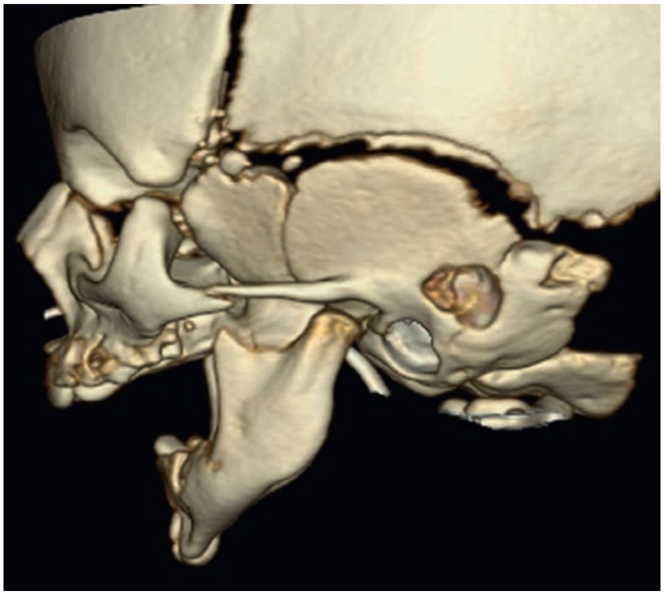

**Figure 22.7. Micrognathia in Pierre Robin sequence.** Newborn with a small retropositioned jaw, glossioptosis and cleft palate developed respiratory distress in the delivery room due to airway obstruction. Note short dorsoventral diameter of the micrognathic mandible on this sagittally oriented 3D craniofacial CT rendering.

Craniofacial and more specifically mandibular development is increasingly assessed in utero using prenatal magnetic resonance imaging (MRI) as an adjunct to screening ultrasound (US). MRI-based reference data for fetal mandibular growth with validated metrics to quantitatively evaluate fetal mandibular size and position (jaw index and inferior facial angle) have been derived improving the antenatal diagnosis of micrognathia and retrognathia.[7] Improved antenatal diagnosis of micrognathic conditions such as PRS, characterized by cleft palate, small jaw, and occlusive retropositioned tongue, could preclude perinatal airway emergencies and improve survival.[8]

## PATHOLOGY

### Temporomandibular Joint Disorders

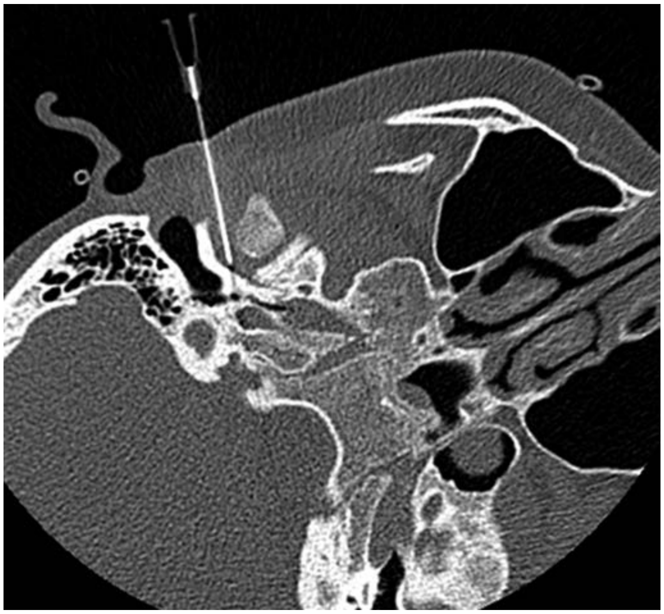
Juvenile idiopathic arthritis (JIA) is the most common rheumatic disease of childhood. It affects synovial joints. TMJ involvement in JIA is a well-recognized feature of the disease. TMJ involvement is often asymptomatic and clinically undetectable, so delayed diagnosis is not uncommon. The risk for growth disturbances in the TMJ is high and irreversible mandibular asymmetry, malocclusion, and dysfunction can occur. MRI is used for early diagnosis and to monitor for ongoing active inflammatory disease.[9] MRI signs of ongoing active inflammation can result in escalation of therapy or site-specific therapy such as intraarticular steroid injection (e-Fig. 22.8). Bone marrow edema, joint effusion, and synovial enhancement signal active disease (Fig. 22.9). Articular surface flattening, widening, and irregularity are signs of erosive remodeling (Fig. 22.10).[10]

Nonarthritic TMJ dysfunction can also occur and is best assessed with dynamic open- and closed-mouth MRI techniques to evaluate the integrity of the articular disk and the retrodiskal soft tissues vital to normal TMJ function (Fig. 22.11).[11]

Trauma and infection also affect the TMJ. Delayed or nontreatment could result in permanent joint damage and disability as in other joints.

### Mandibular Fractures

Direct trauma is the usual cause of fractures in the pediatric mandible. The incidence of traumatic mandibular fractures increases with age. Below age 5, fractures are rare. The incidence rises in school-age children and peaks during adolescence. In early life,



**e-Figure 22.8. CT-guided temporomandibular joint (TMJ) injection.** Site-specific therapeutic steroid injection for ongoing active unilateral TMJ inflammatory arthritis. Injections of the TMJ are frequently imaging guided as up to 20% of injections given using landmarks alone are extraarticular.

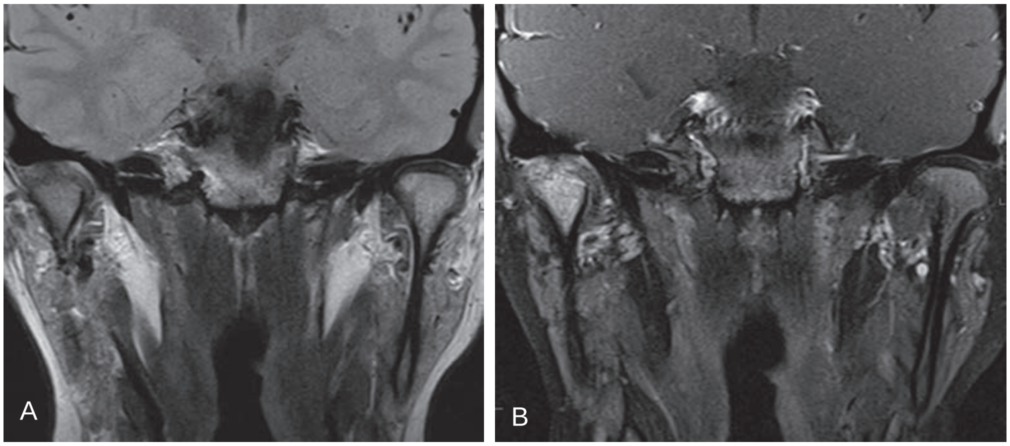


**Figure 22.9. Mild ongoing right temporomandibular joint (TMJ) arthritis on therapy.** An 11-year-old female with polyarticular juvenile idiopathic arthritis (JIA) on etanercept. (A) Coronal PD MR image shows a dysmorphic right mandibular condyle with an irregular eroded articular surface. (B) T1W FS +C image demonstrates unilateral right TMJ synovial enhancement and condylar bone marrow enhancement.

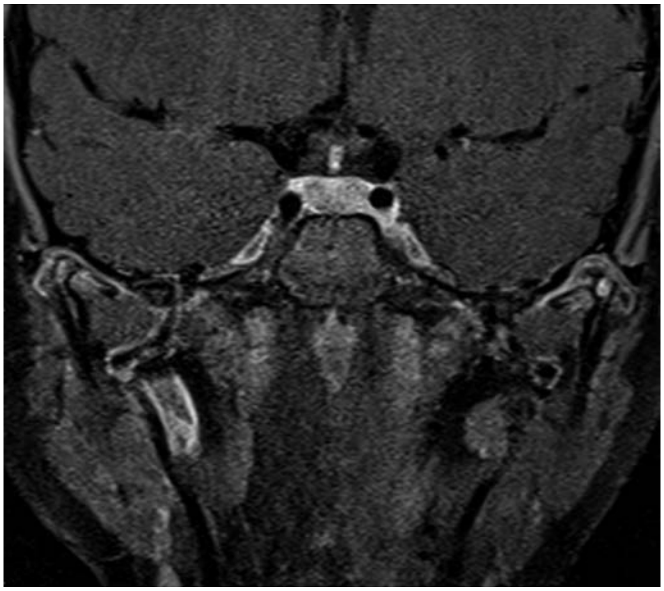

**Figure 22.10. Ongoing deforming bilateral temporomandibular joint arthritis.** A 13-year-old female with juvenile idiopathic arthritis. Coronal contrast-enhanced fat-saturated T1-weighted MR image shows severely whittled down dysplastic bilateral mandibular condyles with continued enhancement in the condylar marrow and joint soft tissues bilaterally.

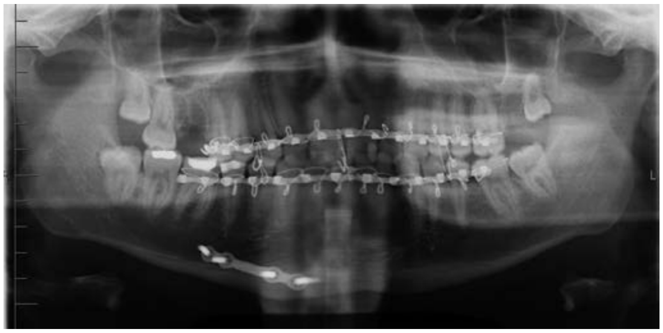
the midface and mandible are retruded relative to the cranial vault, and the incidence of fracture is low. With increasing age and skeletal maturity, the midface and mandible become more protrusive relative to the neurocranium, and the incidence of fracture increases. This changing craniofacial ratio along with decreasing mandibular plasticity and more independent and unsupervised activity as a child grows coincide with the increased incidence of mandibular fracture. The most common causes of mandibular fracture in childhood are vehicular trauma and falls. The most common site of pediatric mandible fracture is the condyle. The alveolar bone of the mandible, containing teeth in different stages of eruption, is also subject to fracture along the lines of developing dental crypts. When one mandibular fracture is seen, another should be sought. Many double mandibular fractures are of the coup-contracoup variety with ipsalateral condyle and contralateral body being a common combination (Fig. 22.12).

Though treatment goals for fracture are similar in children and adults—restoration of the preinjury skeletal and dentoalveolar anatomy and function—management is different. In children, rapid union of mandibular fractures occurs, so fractures must be detected and reduced without delay. Immobilization periods are shorter in children. Closed reduction methods are preferred. With open reduction and internal fixation (ORIF) techniques, miniplate(s) and screws can be used at the inferior non–tooth-bearing border of the mandible. Applied screws are directed away from the developing dental buds (e-Fig. 22.13). Mandibular fractures without displacement or malocclusion are observed with clinical management of diet and analgesia. Ankylosis of the TMJ is a complication of a high/intracapsular condylar fracture and may be avoided by a shorter immobilization period and early physical therapy.[12] In patients with facial trauma, multidetector CT with reformations is important for not only accurate diagnosis but also multidisciplinary treatment planning. Treatment progress can be monitored using plain film techniques such as the panoramic radiograph.[13]

## Mandibular Osteomyelitis

Osteomyelitis due to infection in the mandible is rare but can occur as a result of dental infection or trauma. Hematogenous spread of infection to the mandible is rare. Risk factors for bacterial osteomyelitis include impaired immunity and conditions that affect blood supply such as sickle cell anemia, collagen vascular disease, and metabolic bone disorders such as osteopetrosis. Bone necrosis, sequestrum formation, sinus tract formation through the buccal and lingual cortices, and cloaking periosteal new bone formation are all features.[14]

Chronic recurrent multifocal osteomyelitis (CRMO) is non-bacterial osteomyelitis of children and young adults that causes multifocal bone pain, tenderness, and swelling secondary to sterile osseous inflammation. The disease is defined by a protracted course, involvement of more than one bone, and relapses at old and new sites. Mandibular CRMO, also known as *diffuse sclerosing osteomyelitis of the mandible*, can be isolated or multifocal. In its initial phases, it is actually more lytic with associated soft tissue inflammation but no abscess. In time, it becomes more sclerosing causing mandibular hyperostosis and bone enlargement. When mandibular disease is present, other craniofacial sites may be present. Biopsy



**e-Figure 22.13. Mandible fractures, postreduction.** An 18-year-old male was assaulted. Panorex status post maxillomandibular closed reduction of a left subcondylar fracture and open reduction internal fixation (ORIF) of a right parasymphyseal fracture with plate and screws applied well below the dentition along the inferior border of the mandible.

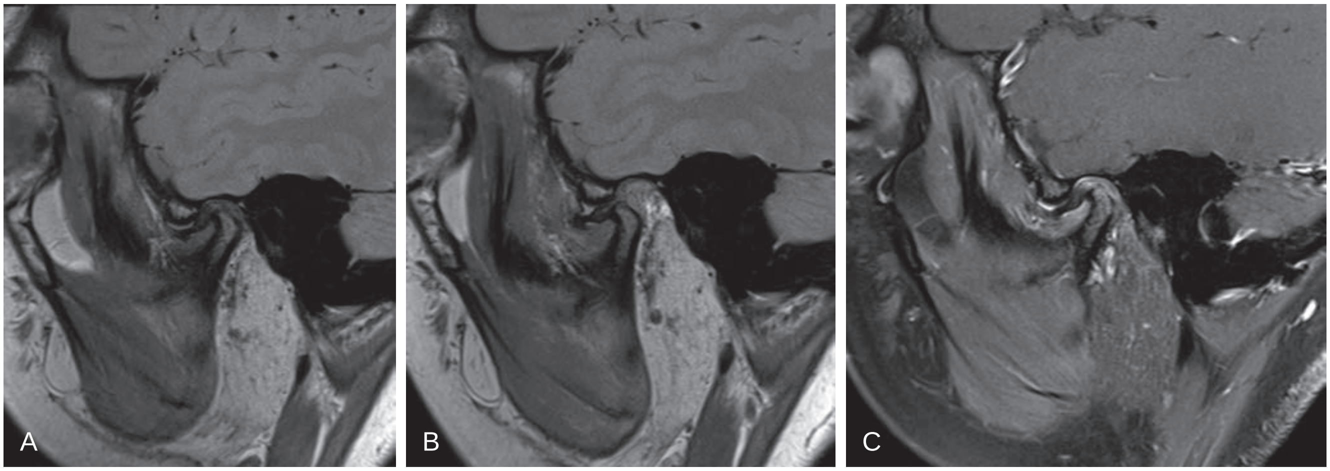


**Figure 22.11. Right temporomandibular dysfunction (TMJ) dysfunction due to an irreducible articular disk.** Proton-density MRI sagittal (A) closed- and (B) open-mouth views right TMJ demonstrate an irreducible anteriorly displaced articular disk with crumpling of the posterior band when the jaw is open. (C) T1-weighed fat-saturated contrast-enhanced MRI demonstrates abnormal enhancement in the retrodiskal soft tissues and condylar marrow.

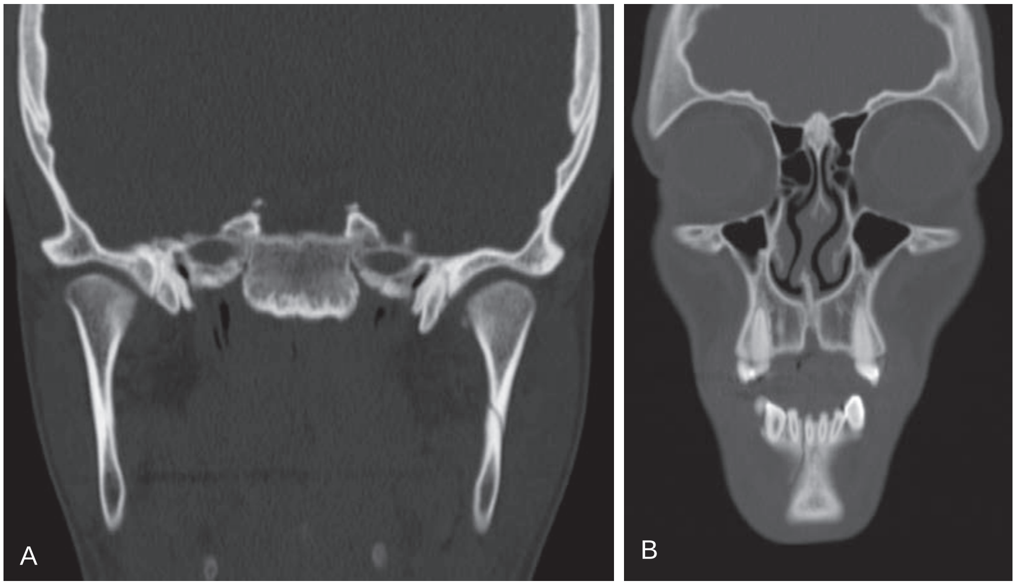

**Figure 22.12. Traumatic mandible fractures.** An 18-year-old male was assaulted. Coronal CT images of the mandible. Nondisplaced mandibular fractures (A) left subcondylar and (B) right parasymphyseal.

results yield a culture-negative chronic osteomyelitis. Recognizing CRMO as a distinct entity will help to avoid unnecessary invasive procedures and antibiotic therapy.[15]

## Mandibular Cysts and Masses

Primary mandibular lesions can develop from odontogenic and nonodontogenic tissues. Lesions originating superior to the inferior alveolar canal are odontogenic and inferior to the canal are nonodontogenic. Most primary mandibular lesions are odontogenic with cysts seen 2.25 times more frequently than tumors. CT and MRI can help to differentiate cysts from tumors and very precisely localize lesions for treatment planning.

Benign odontogenic cysts of the mandible classified mainly by location include periapical (also known as *radicular cyst*), pericoronal (also known as *dentigerous* or *follicular cyst*), or lateral periodontal cysts. Periapical cysts are often small, less than 1 cm, and always acquired resulting from inflammation at the apices or roots of a tooth due to caries or trauma (Fig. 22.14). In contradistinction pericoronal cysts may become very large and are developmental in origin forming around the crown of an unerupted tooth typically the mandibular third molar (Fig. 22.15). Another benign odontogenic cystic lesion despite its aggressive behavior and growth pattern is the odontogenic keratocyst (OKC). Though reclassified by the World Health Organization in 2005 as keratocystic odontogenic tumor (KOT), use of the outdated nomenclature OKC is widespread. OKCs contain keratinaceous “cheesy” debris and have aggressive behavior and high postresection recurrence rates. Most arise in the posterior mandible. OKCs are unilocular or multilocular, have scalloped margins, and grow along the long axis of the mandible resorbing dental roots and displacing or extruding teeth. Multiple OKCs in a young patient raise the possibility of nevoid

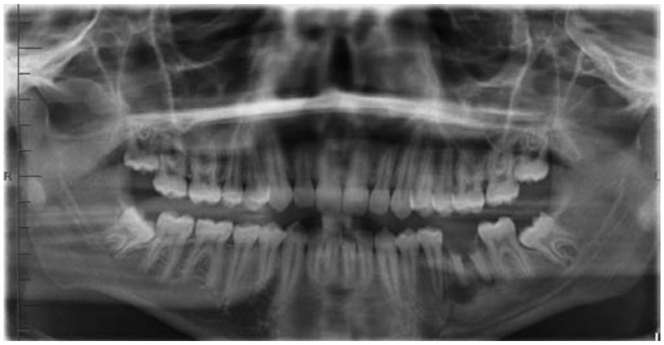

**Figure 22.14. Periapical abscess.** A 15-year-old male with 2 days of left facial pain, swelling, and fever. Panorex image shows a carious crown left first mandibular molar and rounded radiolucencies at the root apices along with root resorption. Periapical dental abscess diagnosed, incised, and drained.

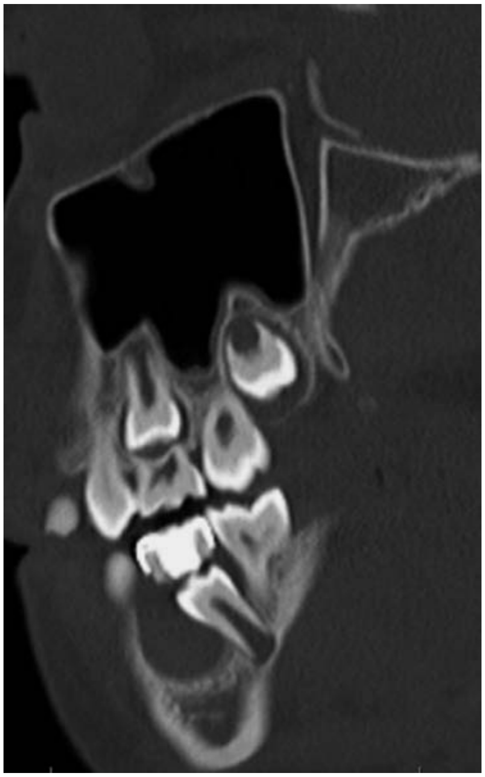

**Figure 22.15. Pericoronal or dentigerous cyst.** A 10-year-old male with a painless left mandibular cyst discovered incidentally on a dental x-ray. Sagittal CT image shows a well-circumscribed lucency enclosing the crown of the unerupted left second premolar tooth. No significant adjacent tooth displacement nor root resorption. Patient underwent cyst enucleation and extractions of the left second premolar (unerupted, permanent) and left second molar (erupted, deciduous) teeth.

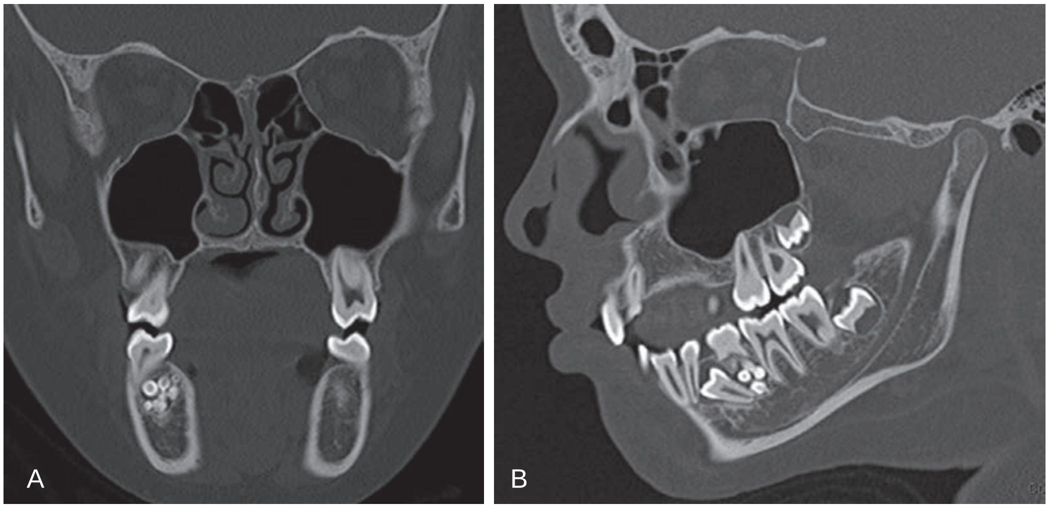
basal cell carcinoma syndrome (NBCCS, also known as *basal cell nevus syndrome*, also known as *Gorlin-Goltz syndrome*) (Fig. 22.16). Incidence of OKCs in the maxilla and mandible of children with NBCCS is reported between 66% and 92%. Besides multiple OKCs, NBCCS patients have many basal cell epitheliomas and carcinomas of the skin and can develop posterior fossa medulloblastoma. As NBCCS children are more susceptible to developing secondary cancers with ultraviolet and ionizing radiation exposure, early diagnosis of NBCCS is absolutely key to avoiding unnecessary medical radiation (e.g., CT imaging of multiple OKCs, radiotherapy for posterior fossa medulloblastoma). A vigilant radiologist who can link multiple OKCs to the diagnosis of NBCCS will dramatically affect a patient's long-term outcome.[16]

Benign nonodontogenic cysts, simple and aneurysmal, can also occur in the mandible, mainly posterior.

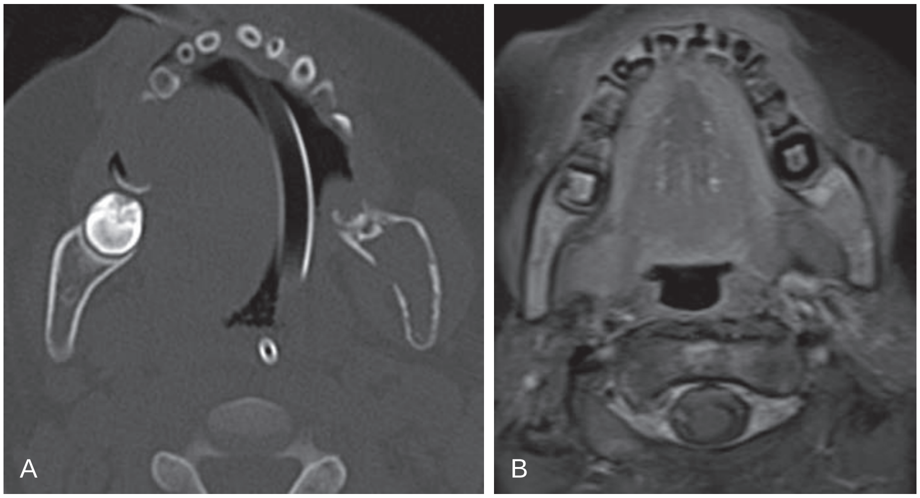
Benign solid mandibular tumors of dental origin include odontoma, ameloblastoma, and cementoblastoma. Odontoma is the most common odontogenic "tumor" of the mandible typically diagnosed in the first two decades of life and subdivided into two types: compound (e-Fig. 22.17) and complex (Fig. 22.18). Odontomas are hamartomatous lesions consisting of various tooth components; a compound odontoma is better differentiated than a complex odontoma. Ameloblastomas arise from enamel-forming cells and can occur in the pediatric age group. Ameloblastomas are slow-growing, expansile, admixed solid and cystic masses most commonly found in the posterior mandible third molar region classically described as "soap-bubbly" in appearance. Despite their typically benign pathology (ameloblastoma can only be distinguished from ameloblastic carcinoma histopathologically), it can erode cortex, resorb dental roots, and expand into the oral and perioral soft tissues (Fig. 22.19).[17] Cementoblastoma is a rare jaw tumor occurring primarily in children and young adults, 50% in the first two decades of life, 75% in the first three decades of life. It is sharply marginated and sclerotic (cementum-laden) with a low-attenuation halo. Located periapically, it fuses to the root(s) of the involved premolar or molar tooth (usually first molars).

Benign mandibular tumors not of dental origin include two fibro-osseous lesions with ground-glass attenuation, ossifying fibroma and fibrous dysplasia, and one giant cell lesion called *central giant cell granuloma (CGCG)*. Ossifying fibromas (also known as cemento-ossifying or cementifying fibroma) occur over a wide age range but can be seen in pediatrics. Classically ossifying fibroma is described as solitary, sharply marginated, focally expansile ground-glass lesion in the posterior mandible without a lucent halo that becomes more radioopaque over time as the osteoid component of its matrix mineralizes. It has a centrifugal growth pattern perpendicular to the long axis of the bone. Tooth displacement is common. Juvenile ossifying fibroma is a notable destructive variant of ossifying fibroma seen in boys under 15 years of age with highly aggressive growth. Fibrous dysplasia, another ground-glass attenuation lesion, can be distinguished from ossifying fibroma because it causes less of a focal alteration in the shape of the bone expanding along, rather than perpendicular to, the mandible's long axis. Unlike ossifying fibroma's narrow zone of transition, fibrous dysplasia has a wide zone of transition but does not displace teeth. Histopathologically, osteoblastic rimming is seen with ossifying fibroma but not fibrous dysplasia.[14] CGCGs are thought to result due to altered vascular and reactive responses within bone and are also referred to as *giant cell reparative cysts*. Seen most frequently in adolescent and young adult females, CGCGs are classically radiolucent, located in the anterior mandible, and have a multilocular honeycomb appearance due to "wispy" internal bony septae, which orient perpendicular to the edge of the lesion. These slow-growing lesions may expand, erode, and remodel cortex and resorb dental roots.[18] Multiple giant cell lesions of the mandible and maxilla are described in a molecular variant of Noonan syndrome.[19] Other benign nonodontogenic tumors that are defined by their relationship to the inferior alveolar canal include neural and vascular lesions such as neurofibroma and schwannoma, central hemangioma, and arteriovenous malformation. Finally, exophytic and nonexophytic osteomas can occur in the mandible.

Malignant tumors of the mandible are usually not primary. Neuroblastoma is the most common metastatic disease to the mandible (e-Fig. 22.20). Other malignancies seen in the pediatric mandible include leukemia, lymphoma (including Burkitt), and sarcomas (including Ewing, osteosarcoma, rhabdomyosarcoma, and chondrosarcoma) (Fig. 22.21). Originally described and thought pathognomonic for



**e-Figure 22.17. Compound odontoma.** A 12-year-old asymptomatic female. Unenhanced (A) coronal and (B) sagittal oblique reformat CT images show a hamartomatous mass of well-differentiated tooth structure that comprises multiple miniteeth (denticles) surrounded by a radiolucent rim resembling, in this case, a tiny bag of teeth. It is developing above the inferior alveolar nerve canal (where a tooth would normally develop). Note the conspicuity of the inferior alveolar nerve canal on the sagittal oblique reformat image.



**e-Figure 22.20. Metastatic neuroblastoma.** A 4-year-old female with right suprarenal neuroblastoma and metastatic disease to the mandible at initial presentation. (A) Unenhanced axial CT image through the mandible with an endotracheal tube in place demonstrates a permeated “disappearing” cortex at the expanded angle of the left mandible. (B) T1-weighted contrast-enhanced fat-saturated axial MR image demonstrates a corresponding hypoenhancing but aggressive mass, a path-proven neuroblastoma metastasis.

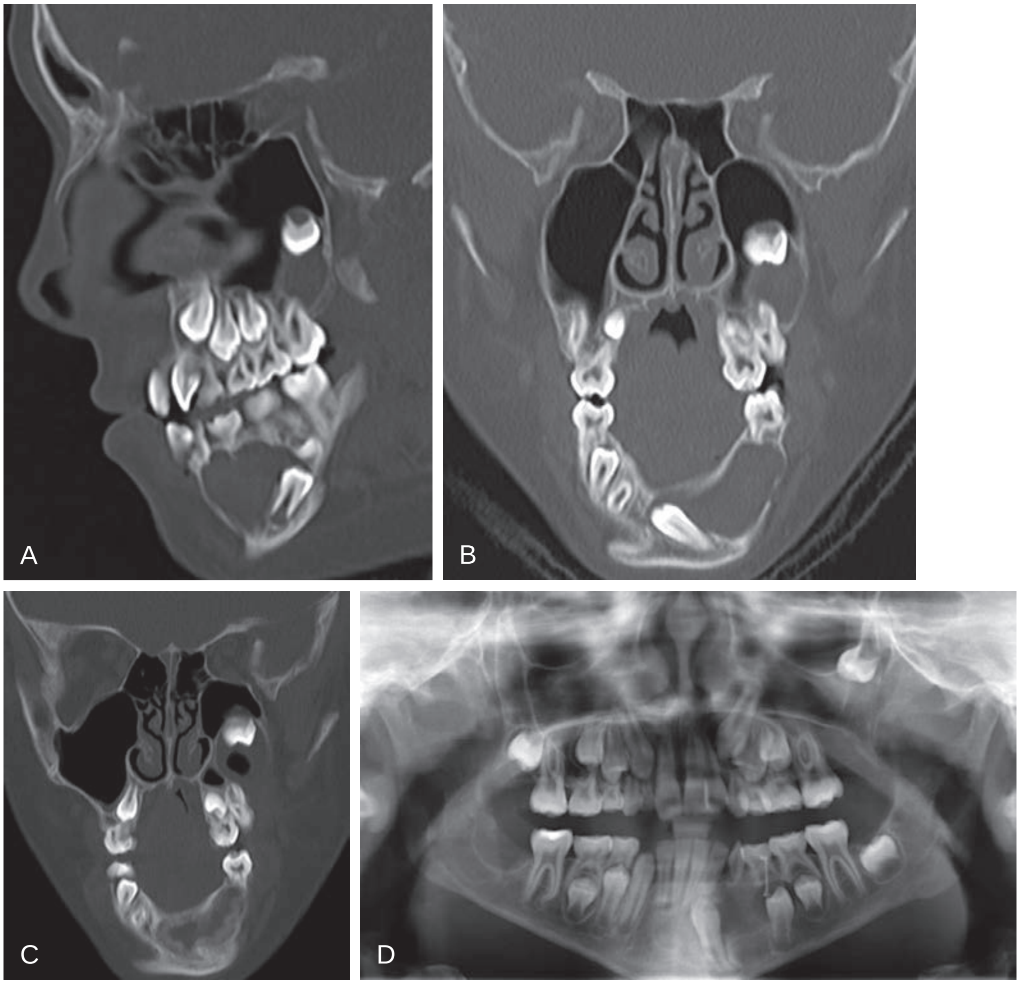


**Figure 22.16. Multiple odontogenic keratocysts (OKCs) in nevoid basal cell carcinoma syndrome (NBCCS).** A 9-year-old female with NBCCS. Initial (A) sagittal and (B) coronal CT images show multiple OKCs, left parasymphyseal mandibular, and left maxillary. (C) Coronal CT image 3–4 months postmarsupialization shows a shrinking, sclerosing left parasymphyseal OKC. Left maxillary OKC is enlarging after drainage tube fell out prematurely. (Both lesions were subsequently enucleated.) (D) Note how difficult it is to identify the large left maxillary OKC on this panorex, even with unnaturally high left maxillary molar tooth displacement. Also take note of progressive shrinkage left parasymphyseal OKC and a new right posterior mandibular OKC.

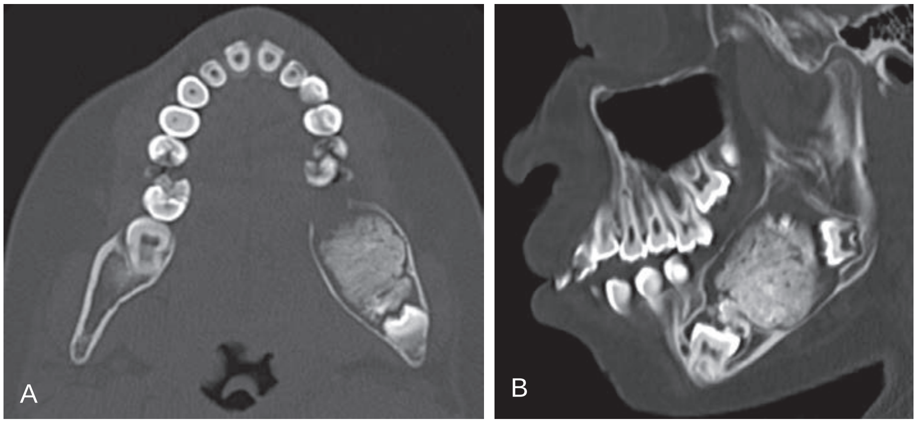

**Figure 22.18. Complex odontoma.** A 9-year-old female with left facial swelling and a palpable mandibular abnormality. Unenhanced (A) axial and (B) sagittal oblique MPR CT images show an amorphous mineralized mass of enamel and dentin resembling a clump of cotton in the molar region of the mandible associated with the crown of an impacted molar tooth. Note the characteristic perilesional lucent halo.

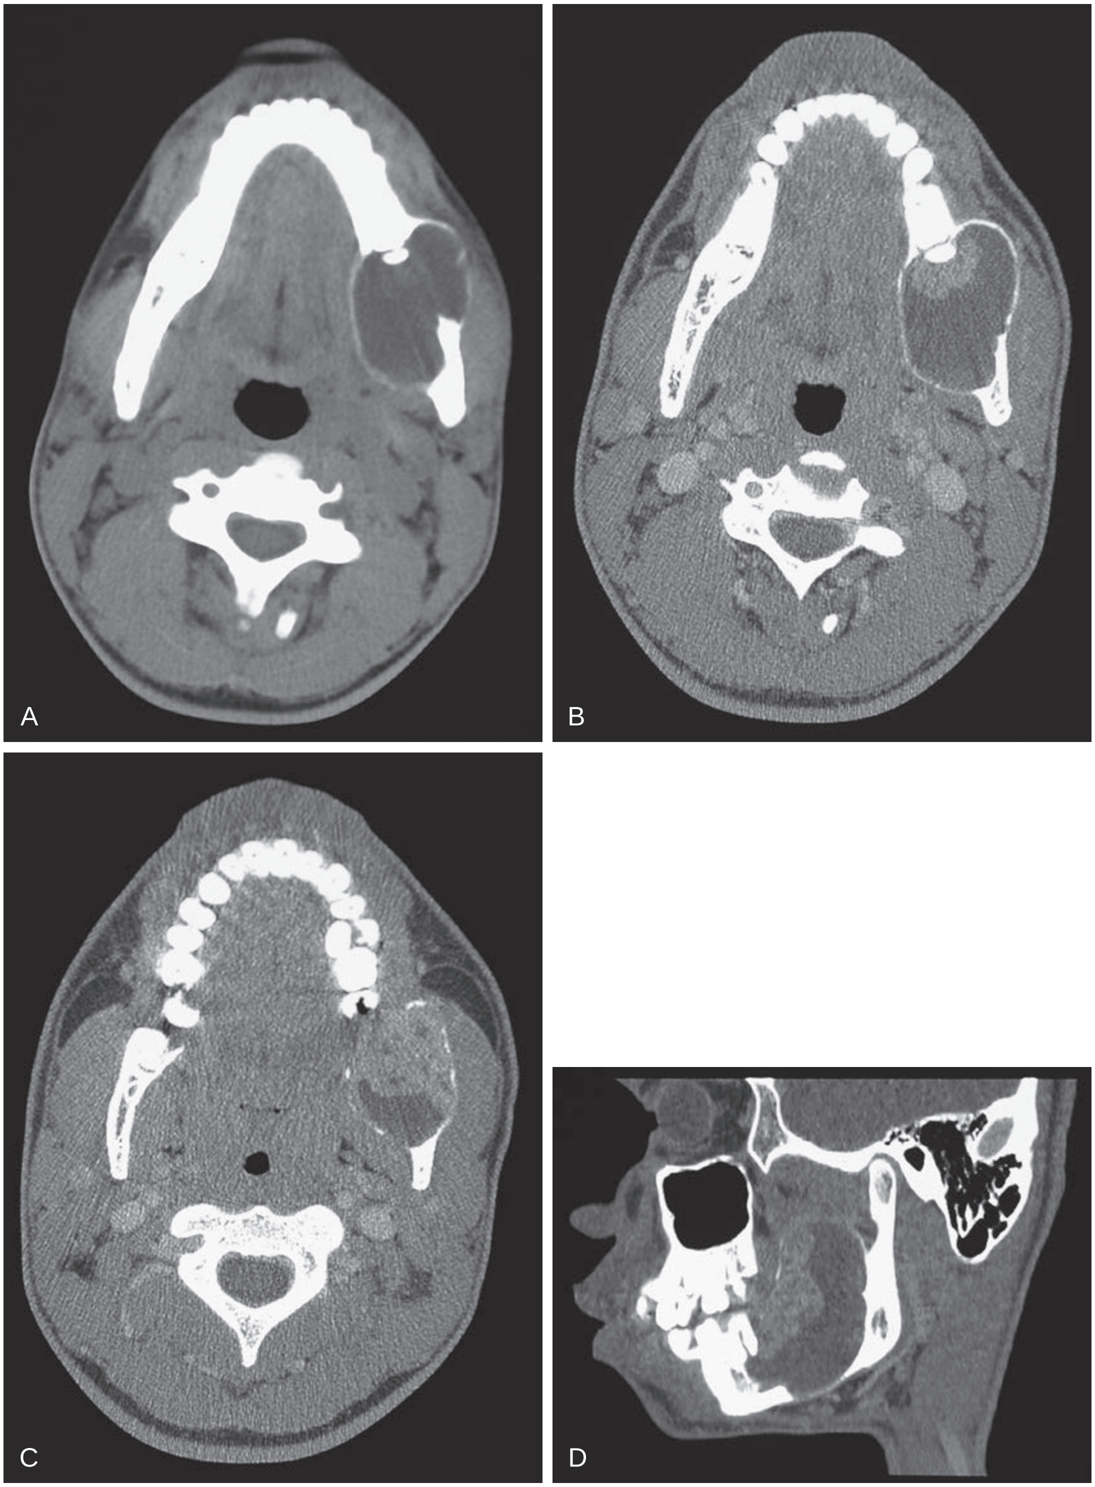

**Figure 22.19.** A 4-year-old patient with ameloblastoma of the left mandible. (A) An axial computed tomography (CT) scan shows the large destructive lesion of the left mandible. (B) Contrast-enhanced axial CT. With further windowing, the two components of the lesion are demonstrated: a more solid component anteriorly and a more cystic component posteriorly. (C) An image slightly inferior to that shown in (B) reveals the solid component. (D) The sagittal reconstruction shows the effect on the mandible; solid and cystic components of the lesion are seen.

Langerhans cell histiocytosis (LCH), the radiographic appearance of "floating teeth" has been observed in the context of other tumors that destroy the alveolar ridge (Figs. 22.22 and 22.23).[20]

In pediatric patients in whom there is ongoing mandibular growth and odontogenesis, surgical techniques, especially for large cystic lesions, aim to spare tissue, maintain continuity, and preserve function.[21]

## Cherubism

Cherubism is a benign condition characterized by progressive painless cheek swelling due to bilateral symmetric mandibular and maxillary multilocular giant cell-containing cystic lesions. Lesions tend to extend from the region of the molar teeth toward the anterior midline. Stretching of the skin as a result of maxillary involvement tends to pull the lower eyelids down, revealing a band of white sclerae between the eyelid and the iris (e-Fig. 22.24). This cherubic "eyes raised to heaven" expression has led to the term "cherubism." Once thought to be exclusively familial and dubbed "familial fibrosis of jaws," we now know cherubism can be nonfamilial. Once thought to be a subtype of craniofacial fibrous dysplasia, genetic analysis reveals that cherubism and craniofacial fibrous dysplasia are distinct entities despite their radiologic mimicry. Cherubism usually presents before age 5, most often between 12

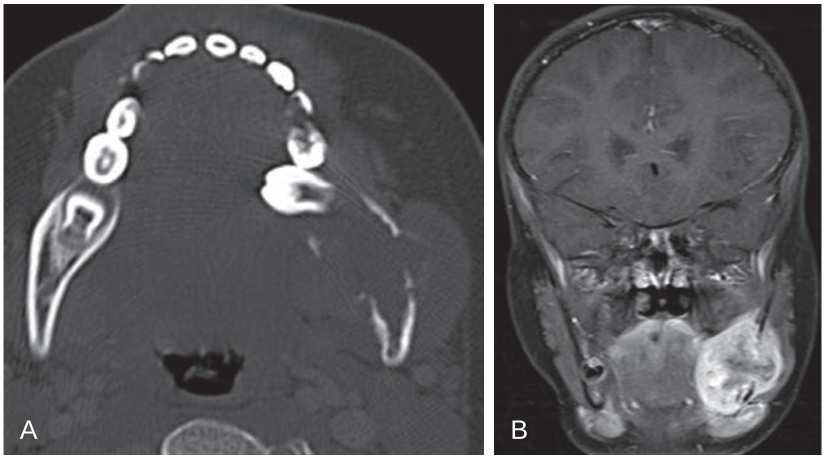

**Figure 22.21. Left mandibular rhabdomyosarcoma.** A 5-year-old female evaluated by her dentist for left mandibular swelling. (A) Contrast-enhanced axial CT image through the mandible demonstrates a destructive and deforming lytic mass in the left posterior mandible. (B) T1-weighted contrast-enhanced fat-saturated coronal MR image demonstrates a bulky, avidly-enhancing, aggressive left mandibular mass encroaching on the oral cavity with the very large extraosseous soft tissue component perhaps underestimated by CT.

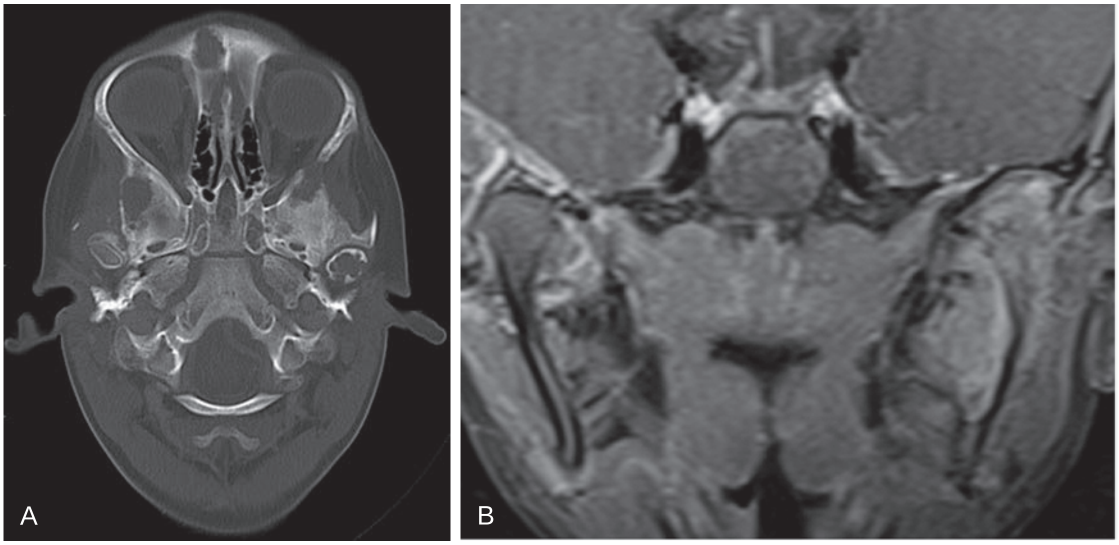

**Figure 22.22. Langerhans cell histiocytosis (LCH).** A 4-year-old male with facial swelling. (A) Axial unenhanced CT image shows multiple destructive lytic lesions at the skull base and left temporomandibular joint. (As in 25% of children with LCH involving the facial bones or anterior or middle cranial fossae, this child went on to develop CNS involvement with infiltration of the posterior pituitary and resultant diabetes insipidus.) (B) T1-weighted contrast-enhanced fat-saturated coronal MR image shows a destructive heterogeneously enhancing mandibular mass centered in the left condylar neck and vertical ramus breaking through the buccal and lingual cortices and also extending to the condylar articular surface.

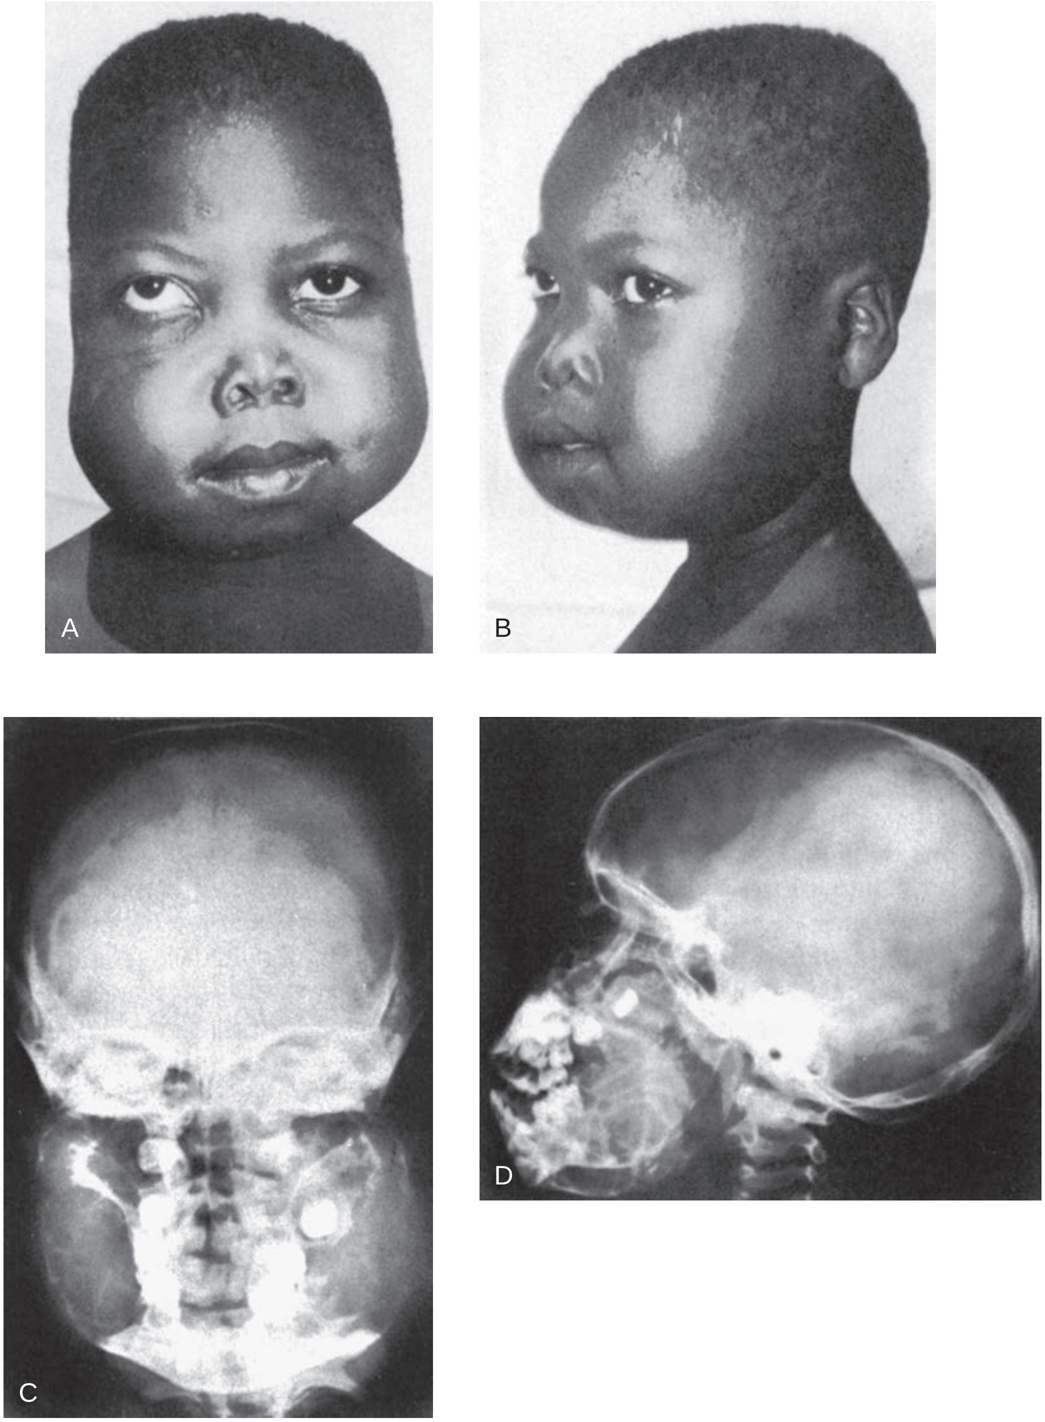

**e-Figure 22.24.** Familial fibrosis of the jaws (cherubism) in a 6-year-old boy whose two siblings and father were affected. (A and B) Clinical photographs. Massive painless swelling extends to the preauricular level and obscures the normal external ears in the frontal view. The downward displacement of the lower lids explains the term cherubism ("eyes raised to heaven"). (C and D) Frontal (C) and lateral (D) skull projections show cystic swelling of the mandible and, to a lesser degree, the maxilla. The teeth are displaced medially except for the unerupted left maxillary molar. The unerupted right molar and the swollen maxilla impinge on the right maxillary sinus, partially obliterating its cavity. The clouding of the left maxillary sinus extends to the left ethmoid, indicating bony involvement or ostial occlusion. *(From Shuler RK, Silverman FN. Familial fibrous dysplasia of the jaws of "cherubism" in a Haitian family.* Ann Radiol. *1965;8:45–52.)*

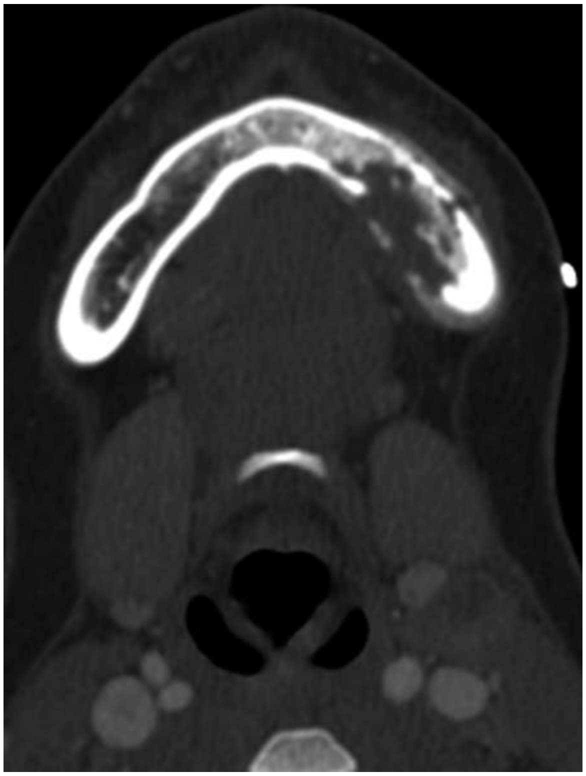

**Figure 22.23. Langerhans cell histiocytosis (LCH) mimicking chronic osteomyelitis.** A 10-year-old female with left jaw pain and swelling for 6+ weeks with clinical concern for osteomyelitis. Lesion in left mandible debrided by an oral surgeon. Histopathology compatible with LCH. Contrast-enhanced axial CT image through the mandible predebridement shows a destructive mixed lytic and sclerotic lesion in the body of the left mandible with cortical breakthrough, cloaking periosteal reaction, and periosseous soft tissue fullness.

and 36 months, and progresses until puberty, after which there is a partial to complete spontaneous involution. Nondevelopment, maldevelopment, displacement, and/or premature loss of both deciduous and permanent teeth are commonly present. Not all patients have the typical features and course.

Cherubism is rare. There is no active disease treatment. Surgical interventions are reserved for functional impairment or cosmesis.[22]

With the molecular basis of diseases being derived, what we now know about cherubism, initially described in 1933, will continue to evolve. Already various clinical and radiologic mimics that are genetically distinct, like craniofacial fibrous dysplasia and SOS-1-related Noonan syndrome, exist (Fig. 22.25).

## Other Generalized Diseases of the Skeleton Involving the Mandible

Monoostotic fibrous dysplasia is far more common than the polyostotic form of the disease. There is craniofacial involvement with both forms.

Infantile cortical hyperostosis (Caffey disease) is an asymmetric polyostotic process. Acute inflammation in periosseous soft tissues and periosteal bone causes localized thickening of adjacent bone cortex. The infant mandible is involved in 80% of cases.

Metabolic bone disorders may cause lesions in the mandible that are similar to lesions occurring elsewhere in the body. For example, renal osteodystrophy is a skeletal response to longstanding kidney disease. As in other parts of the skeleton, early renal osteodystrophy of the jaw is characterized by diffuse ground-glass attenuation replacing normal trabeculation with the blurring of cortical lines, a mimic of diffuse fibrous dysplasia of the jaw. Deforming osteosclerosis is seen in more advanced stages of renal osteodystrophy. Brown tumors of the jaw can also be seen.

Bisphosphonates are medications that inhibit pathologic bone loss and have become widely accepted in the treatment of pediatric bone disorders such as osteogenesis imperfecta. In adult patients, bisphosphonate use has been linked to osteonecrosis of the jaw. Thus far, bisphophonate-related osteonecrosis of the jaw has not been reported in children.[23]

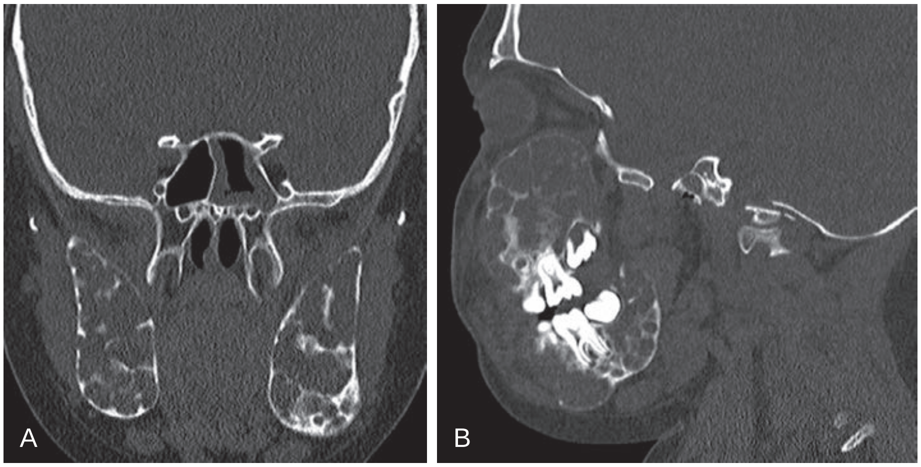

**Figure 22.25. Noonan syndrome with multiple giant cell lesions.** A 9-year-old female with Noonan syndrome and cherubic facies. (A) Coronal CT image of vertical rami of the mandible and (B) sagittal CT of the infraorbital maxilla show massive honeycomb-like expansion of the bone, diffusely thinned and eroded cortex, and blunted dental roots due to root tip resorption. There is bulging of the bilateral orbital floors contributing to the “eyes raised to heaven”/cherubic facies. These biopsy-proven giant cell-containing lesions are seen with a rare molecular variant of Noonan syndrome.

## KEY POINTS

- Abnormal development of the first and second branchial pairs can result in isolated mandibular anomalies or syndromes such as the otomandibular dysplasias.
- Mandibular development is increasingly assessed in utero using fetal MRI as an adjunct to screening US.
- TMJ involvement in JIA is well known but often asymptomatic and clinically undetectable. MRI is important for initial diagnosis and assessing response to therapy.
- The condyle is the most common site of pediatric mandibular fracture.
- Most primary mandibular lesions are benign and odontogenic in origin with cysts more prevalent than tumors.
- Malignant tumors of the mandible are usually not primary. Neuroblastoma is the most common metastatic disease to the pediatric mandible.

# Traumatic Lesions of the Skull and Face*

*Erin K. Opfer and Thomas L. Slovis*

## CONGENITAL DEPRESSIONS

Congenital depressions of the calvaria result from mechanical factors that occur before or during birth.[1] During labor, calvarial depressions are caused by excessive localized pressure on the head by the bony prominences in the maternal pelvis, including the sacral promontory, pubic symphysis, and sciatic spines (e-Fig. 23.1). Application of forceps to the fetal head and traction with excessive force is another less common cause of congenital depressions.

Deformities also may develop from sustained abnormal fetal positions (e-Fig. 23.2). Grooves in the calvarium and face may be caused by excessive pressure of an ectopic limb and represent restrictions of the usual active movements of the fetus. Deformities also may arise as a result of pressure from amniotic bands. Depressions due to long-standing fetal position are present at birth and are not associated with edema or hemorrhage.

These calvarial depressions are usually visible by direct inspection, but radiographs often are obtained to search for associated fractures. Spontaneous elevation of prenatal depressions during the first year after birth without adverse residual effects have been reported.[1] Acute depressions as a result of the application of forceps, often called "ping-pong ball depressions," have been elevated by simple tangential digital pressure on opposite sides of the depression and by suction with a vacuum extractor.[2,3]

## HEMORRHAGE

Hemorrhage in the neonatal scalp has an increased incidence with difficult or traumatic deliveries. It may occur at three different levels: subcutaneous (caput succedaneum), subaponeurotic (subgaleal), and subperiosteal (cephalhematoma). More superficial bleeds cross suture lines and may extend widely into the face ventrally, onto the neck dorsally, and onto the zygomatic arches and mastoid processes laterally.

## CAPUT SUCCEDANEUM

Caput succedaneum is a local subcutaneous swelling of the scalp that contains edema and blood and can extend across suture lines (Fig. 23.3). It is usually a result of pressure on the presenting head. The swelling is recognized at birth and disappears after a few days. Local scalp swelling casts a shadow of water density on skull radiographs that disappears without residual bone changes. Rarely, the hemorrhage can be so massive that hypovolemic shock occurs. In such cases, intracranial hemorrhage often is present.

## SUBGALEAL HEMATOMAS/HYGROMA

Subgaleal hemorrhages, also known as cephalhematoceles, result from an accumulation of cerebrospinal fluid (CSF) and blood beneath the epicranial aponeurosis caused by the rupture of emissary veins. The abnormal fluid extends across the sutures into a potential space that can develop slowly postdelivery.[4] Clinically, they present as a fluctuant mass and may simulate a cephalhematoma or caput succedaneum. Radiographically, the swellings are usually in the parietal regions and can have associated fractures (Fig. 23.4). Trauma from use of obstetric forceps or vacuum extraction is a common cause of subgaleal hematomas. In older children, a subgaleal hygroma may result from hair-pulling in cases of child abuse or accidental entrapment of long hair in mechanical equipment. A subgaleal hematoma may occur without trauma in patients with coagulation abnormalities.

## CEPHALHEMATOMA

Subperiosteal hemorrhages are known as cephalhematomas. Cephalhematomas are confined by sutures, and shells of bone form over them during resolution, arising from the elevated periosteum that covers them (Fig. 23.5). The usual cause of cephalhematomas is trauma to the fetal head during labor, and the incidence is higher in instrument-assisted delivery.[5,6] The incidence of neonatal cephalhematomas in two large series was found to be 1.5% to 2.5%.[5,6] Associated fractures were found in 25% of the cephalhematomas studied radiographically and generally are of no clinical significance.[5]

Clinically, subperiosteal cephalhematomas are localized swellings, usually over the parietal and occipital bone (Fig. 23.6). Fresh

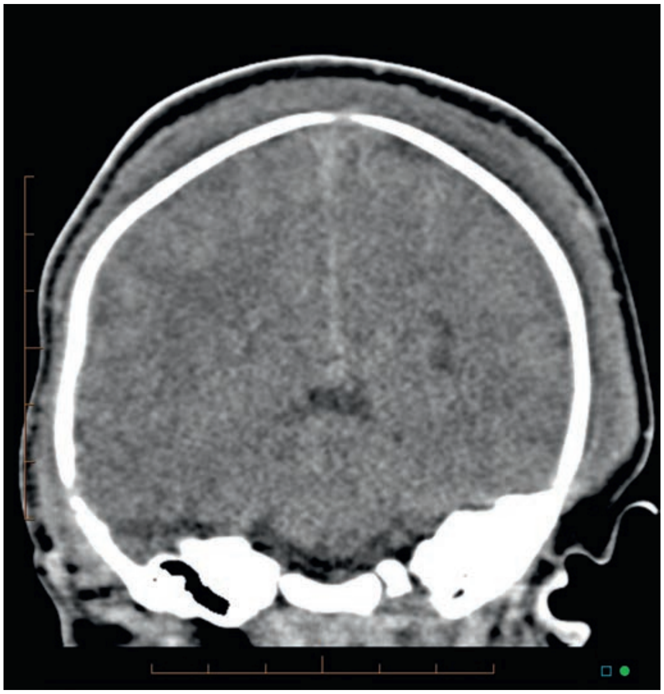

**Figure 23.3. Caput succedaneum in a 14-hour-old neonate with seizures after prolonged labor.** Coronal reconstructed CT image shows soft tissue scalp swelling/hematoma surrounding the calvarium and extending across the sagittal and lamboidal *(not shown)* sutures.

*This chapter originally was written by Dr. John Caffey and revised by Dr. Frederic Silverman. Although some of the images in this chapter appeared in the first edition in 1945, they are still excellent examples of clinical and radiographic imaging.

## Abstract:

Imaging of traumatic lesions of the pediatric skull can be helpful in the assessment and management of pediatric cranial skull fractures and soft tissue scalp injury. Deformities of the neonatal skull can be secondary to congenital depressions or post traumatic fractures during delivery. Other post traumatic injuries may include soft tissue scalp injuries such as caput succedaneum, subgaleal hematoma and cephalhematoma which are most commonly seen with traumatic delivery. The imaging features on plain film and cross sectional imaging can help differentiate level of the hemorrhage. Cranial fractures can occur in all pediatric age groups and usually nonabusive fractures of the pediatric skull heal well with no sequela. Imaging may be helpful if there are clinical signs that warrant assessment for associated intracranial evaluation.

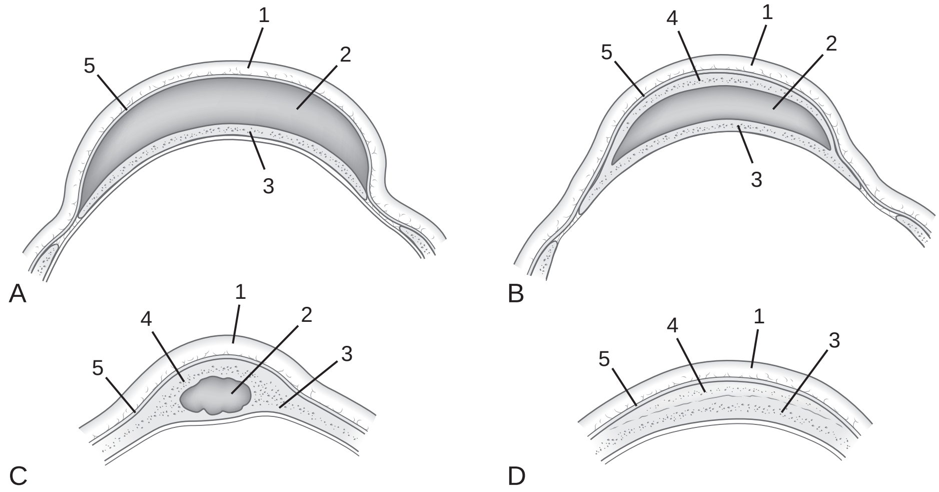

**Figure 23.5. Schematics of anatomic changes that occur in cephalhematoma.** (A) A fresh subperiosteal hematoma. (B) The healing phase, which shows a shell of subperiosteal bone over the hematoma. (C) Persistence of organized hematoma in the diploic space. (D) Residual external thickening of the outer table after complete resorption of subperiosteal blood. (C and D) represent late residuals that may persist into adult life. *1,* Scalp; *2,* hematoma; *3,* normal calvaria; *4,* new subperiosteal bone; *5,* periosteum.

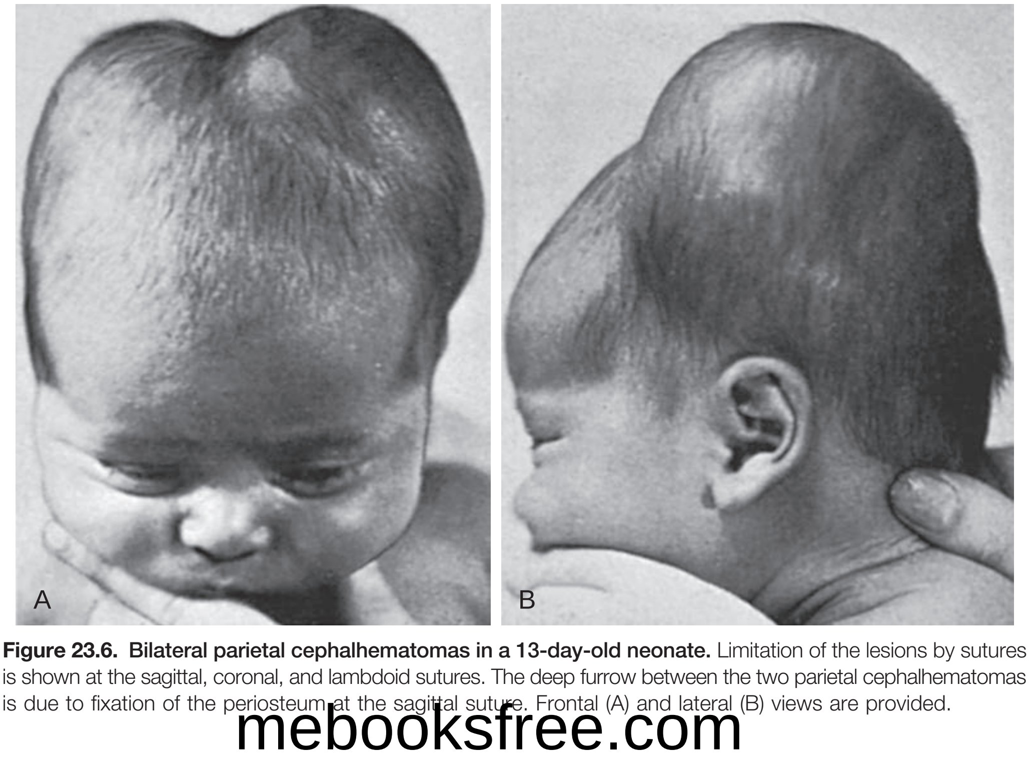

**Figure 23.6. Bilateral parietal cephalhematomas in a 13-day-old neonate.** Limitation of the lesions by sutures is shown at the sagittal, coronal, and lambdoid sutures. The deep furrow between the two parietal cephalhematomas is due to fixation of the periosteum at the sagittal suture. Frontal (A) and lateral (B) views are provided.

lesions often extend over the surface of the affected bone and are sharply limited by the tightly bound periosteum of the sutures. Occipital lesions are common and may be confused with occipital meningoceles during the first days of life. Frontal cephalhematomas are very rare.

The radiographic findings vary with the age of the cephalhematomas. During the first 2 weeks, the lesion is composed of fluid blood (Fig. 23.7). Near the end of the second week, bone begins to form under the elevated periosteum. It appears first at the margins, but soon the entire cephalohematoma is overlaid with a complete shell of bone (see Fig. 23.7; e-Fig. 23.8). Depending on their size, cephalhematomas are absorbed over 2 weeks to 3 months. The radiographic findings can persist long after the clinical signs have disappeared (e-Fig. 23.9). The outer table usually remains thickened as a flat, irregular hyperostosis for several months and is gradually resorbed (e-Fig. 23.10). Fresh cephalhematomas may become infected during bacteremia or needle aspiration.[7] Ultrasonography may be used for early diagnosis, thus avoiding radiation (Fig. 23.11).

In some cases, the space between a new shell of bone and the inner table remains widened for many years, and the space originally occupied by the hematoma becomes filled with normal diploic bone (Fig. 23.12). In other cases, large and small cystlike defects persist in the sites of cephalhematomas (e-Fig. 23.13).[8] Infantile cephalhematoma occasionally persists into adult life, when symptomless large segments of bone production and destruction still may be visible in the calvarium (cephalhematoma deformans) (e-Fig. 23.14).[9] The possibility of a prior neonatal cephalhematoma

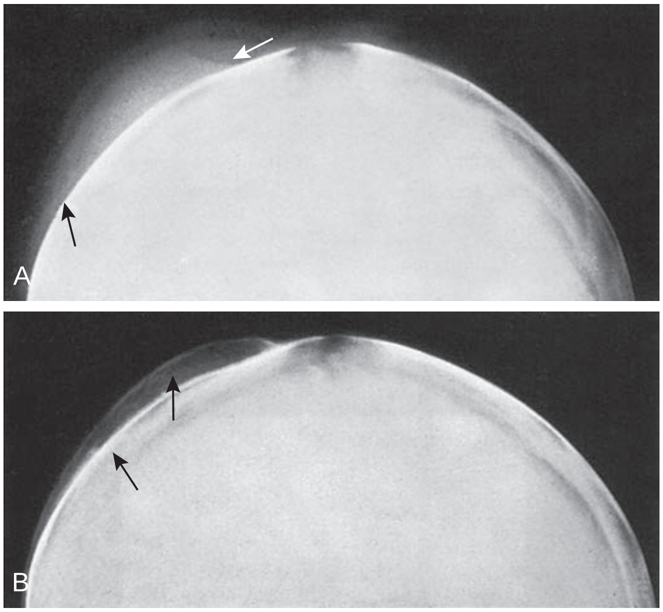

**Figure 23.7. Cephalhematoma in a newborn with scalp deformity.** (A) Rounded soft tissue swelling *(arrows)* of water density over the left parietal bone at age 7 days. (B) The same skull at age 32 days shows a thin shell of newly formed subperiosteal bone *(upper arrow)* overlying the margin of the partially resorbed hematoma *(lower arrow)*.

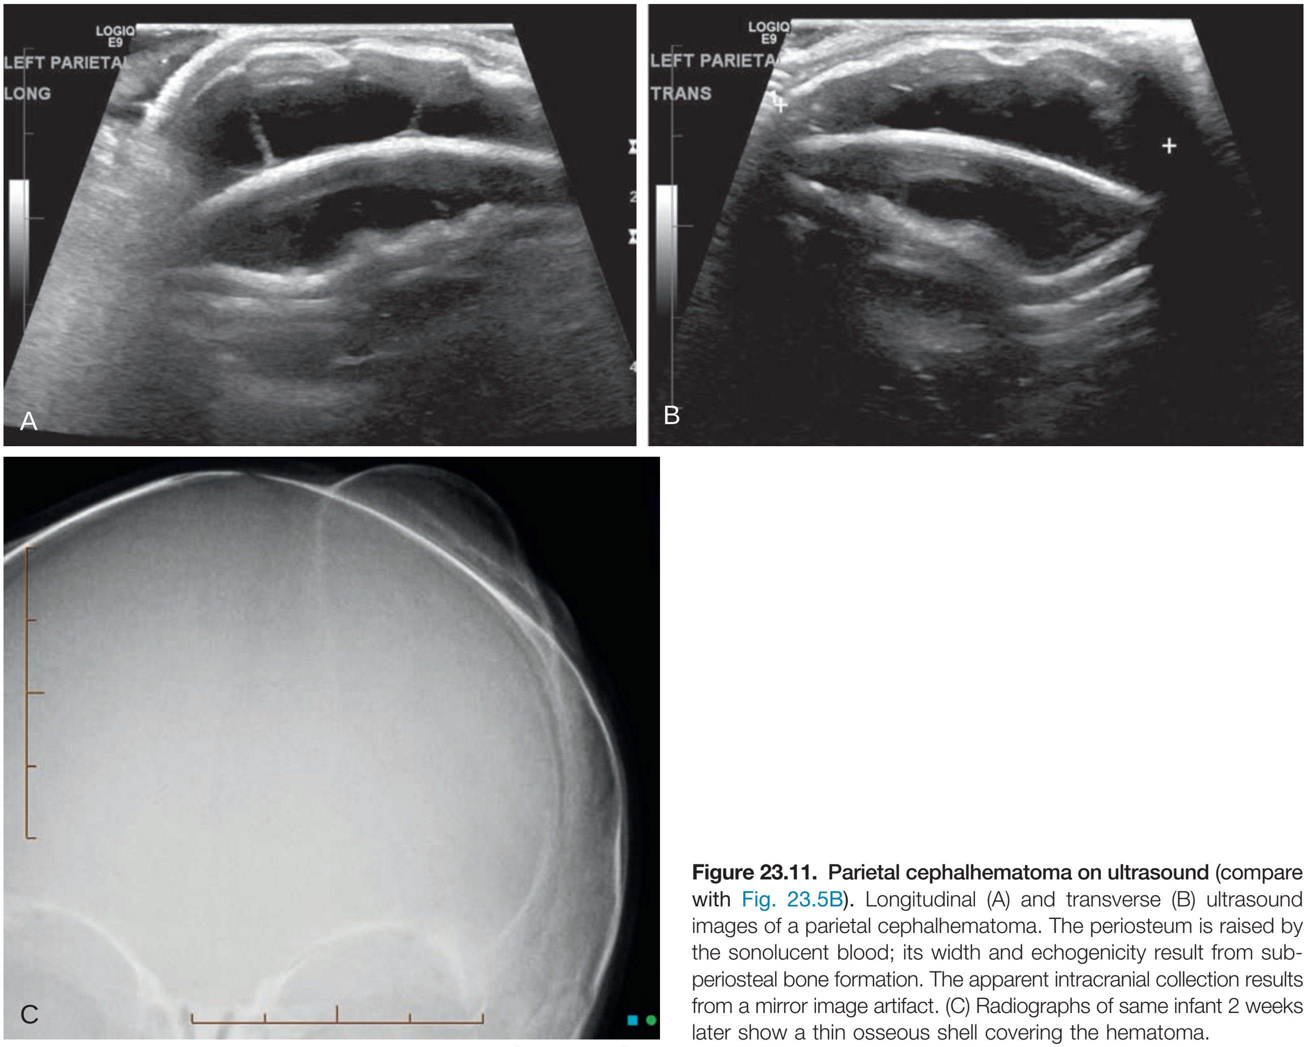

**Figure 23.11. Parietal cephalhematoma on ultrasound** (compare with Fig. 23.5B). Longitudinal (A) and transverse (B) ultrasound images of a parietal cephalhematoma. The periosteum is raised by the sonolucent blood; its width and echogenicity result from subperiosteal bone formation. The apparent intracranial collection results from a mirror image artifact. (C) Radiographs of same infant 2 weeks later show a thin osseous shell covering the hematoma.

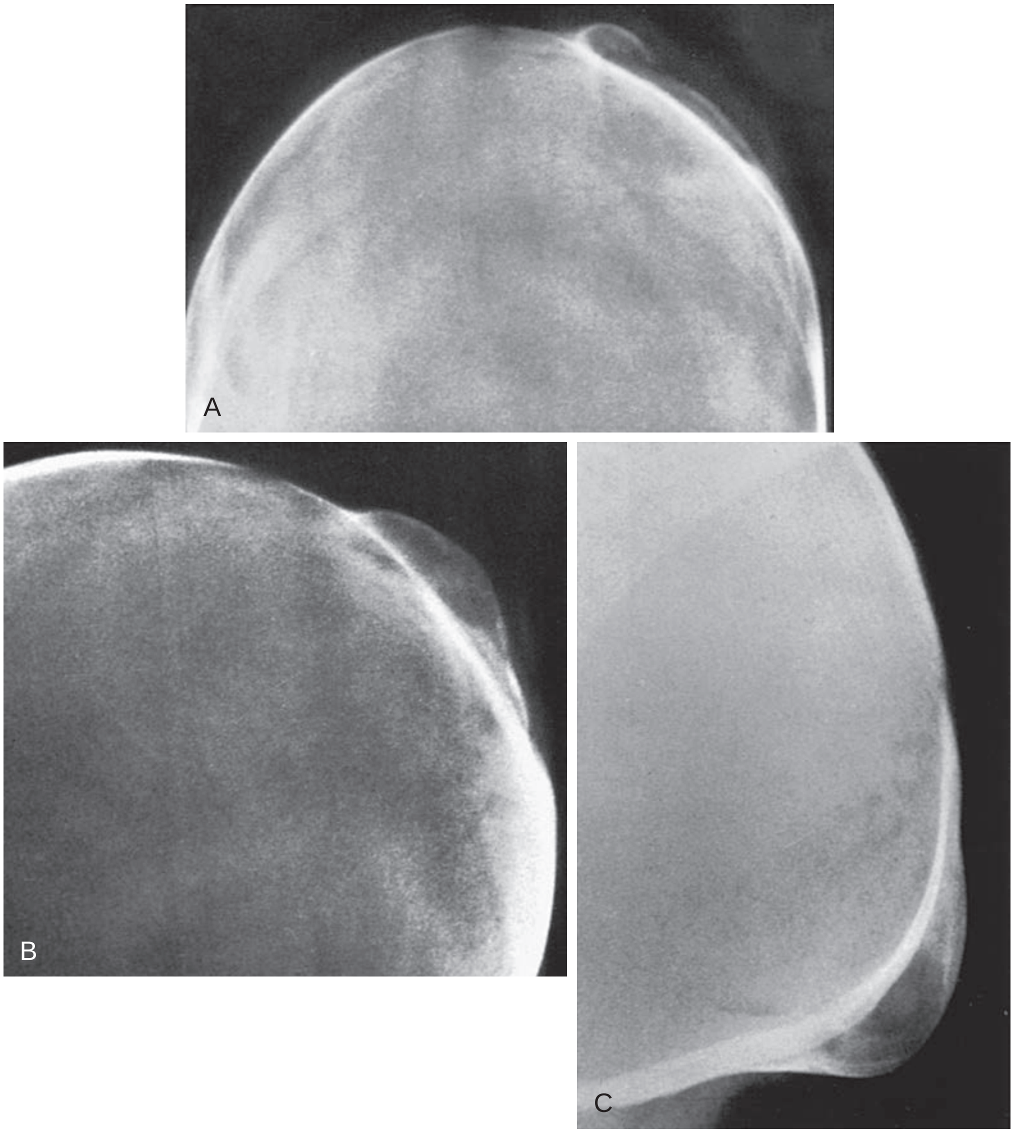
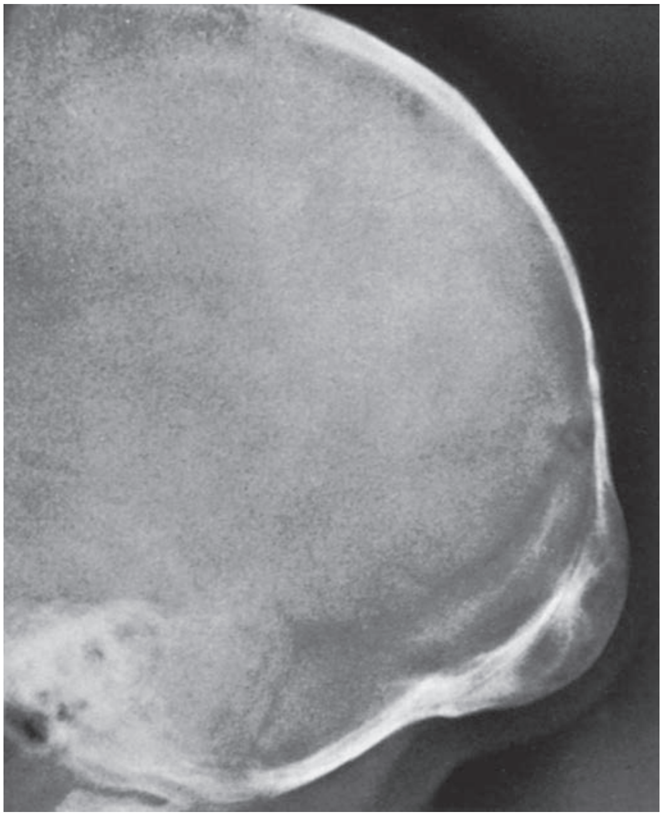
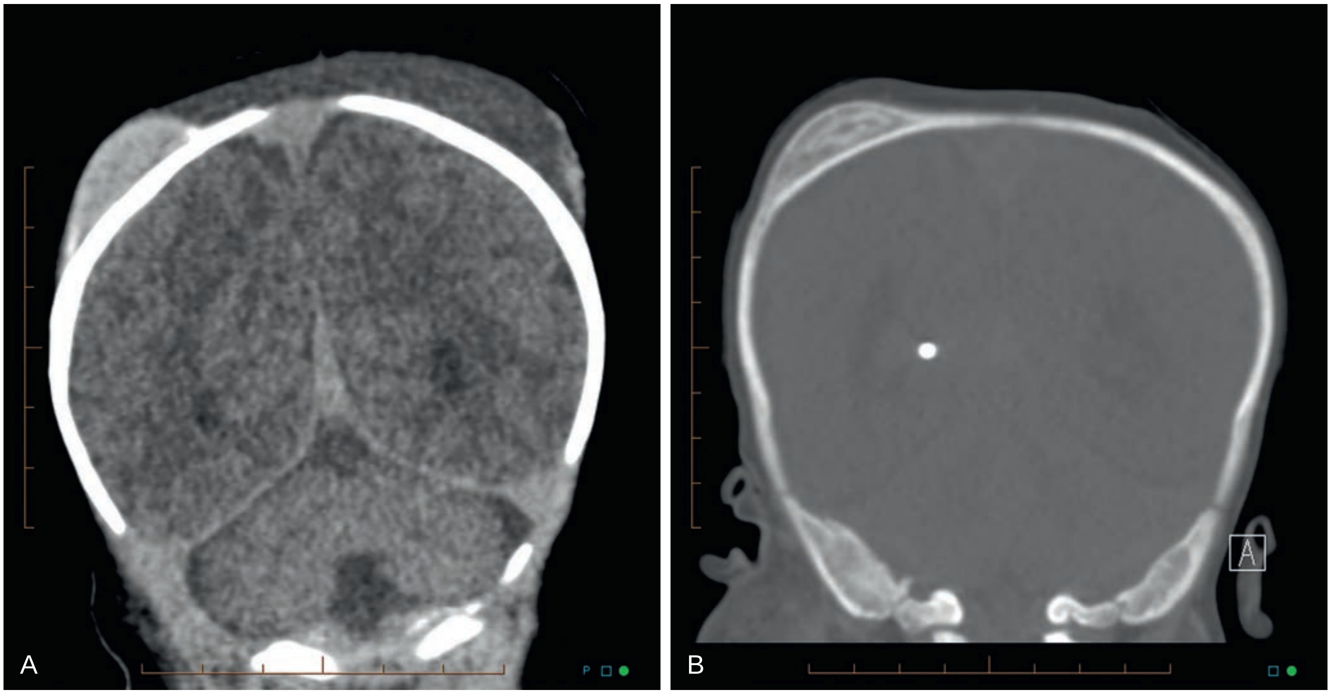


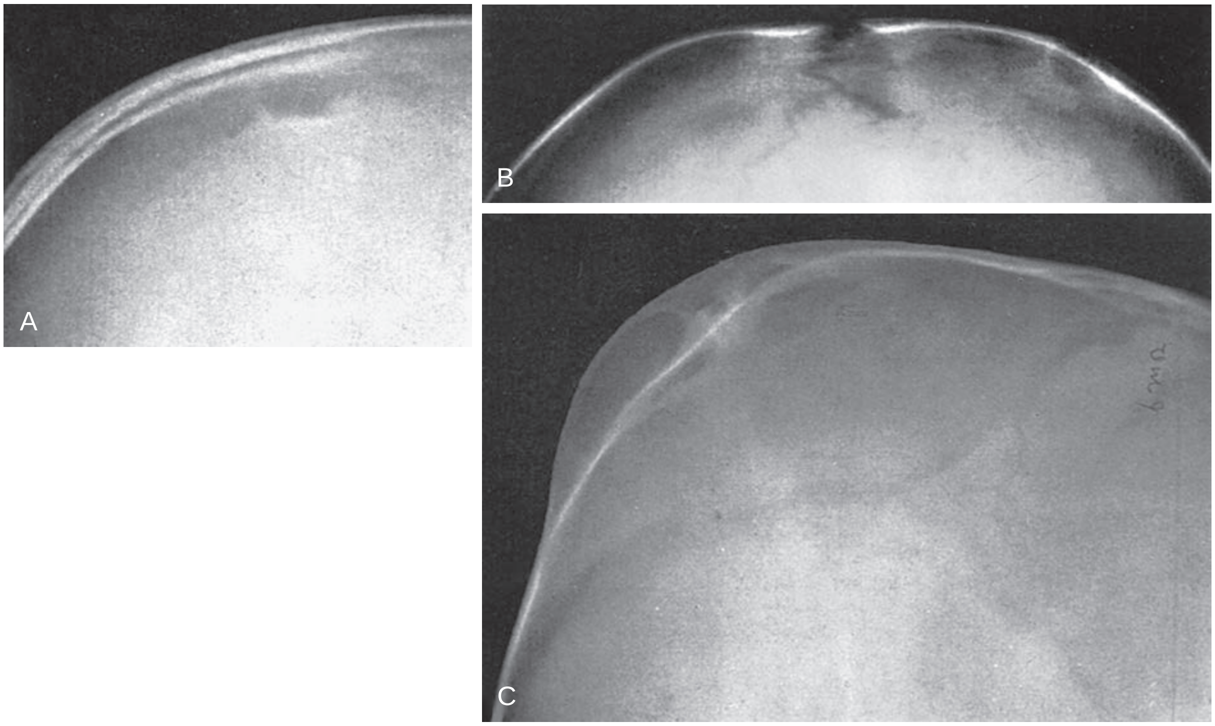
**e-Figure 23.8. Ossifying subperiosteal hematoma in a 6-week-old infant delivered by forceps.** Frontal (A) and lateral (B) projections demonstrate a thin, but incomplete, shell of bone covering the hematoma. (C) An occipital subperiosteal cephalhematoma with a complete, thicker shell of bone over the radiolucent hematoma, which is limited by the mendosal suture.



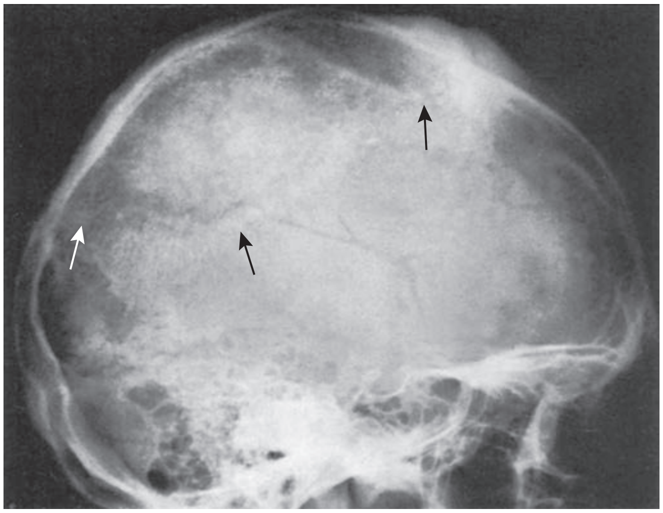
**e-Figure 23.9. An ossifying occipital subperiosteal cephalhematoma in a 4-month-old infant.** The cephalhematoma extends from the lambdoid suture above to the level of the mendosal suture below, which is already fused. The large radiolucent patches beneath the subperiosteal shell of newly formed bone are cast by masses of blood in varying degrees of organization and resorption.



**e-Figure 23.10. Right parietal cephalhematoma and caput succedaneum in a 15-day-old infant with seizures.** (A) Coronal reconstructed CT in soft tissue windows shows a hyperdense right parietal cephalhematoma with bone forming at the margins of the hematoma. (B) Follow up CT 5 months of age after placement of VP shunt reveals diploic bone filling in hematoma with small cystic area.



**e-Figure 23.13. Cephalhematoma with cystlike residuals in an 11-month-old infant.** (A) Lateral and (B) frontal projections show a parietal defect with residual thickening. (C) Residual parietal thickening in a different 6-month-old infant reveals large cystlike defects in the area of thickening.



**e-Figure 23.14. Cephalhematoma deformans parietalis in a 20-year-old patient whose cranium was injured when he was 2 years old.** A large segment of one parietal bone is irregularly dense and rarefied *(arrows)*, with a heavy peripheral rim of sclerosis and thickening. *(Courtesy of Juan M. Taveras, MD.)*

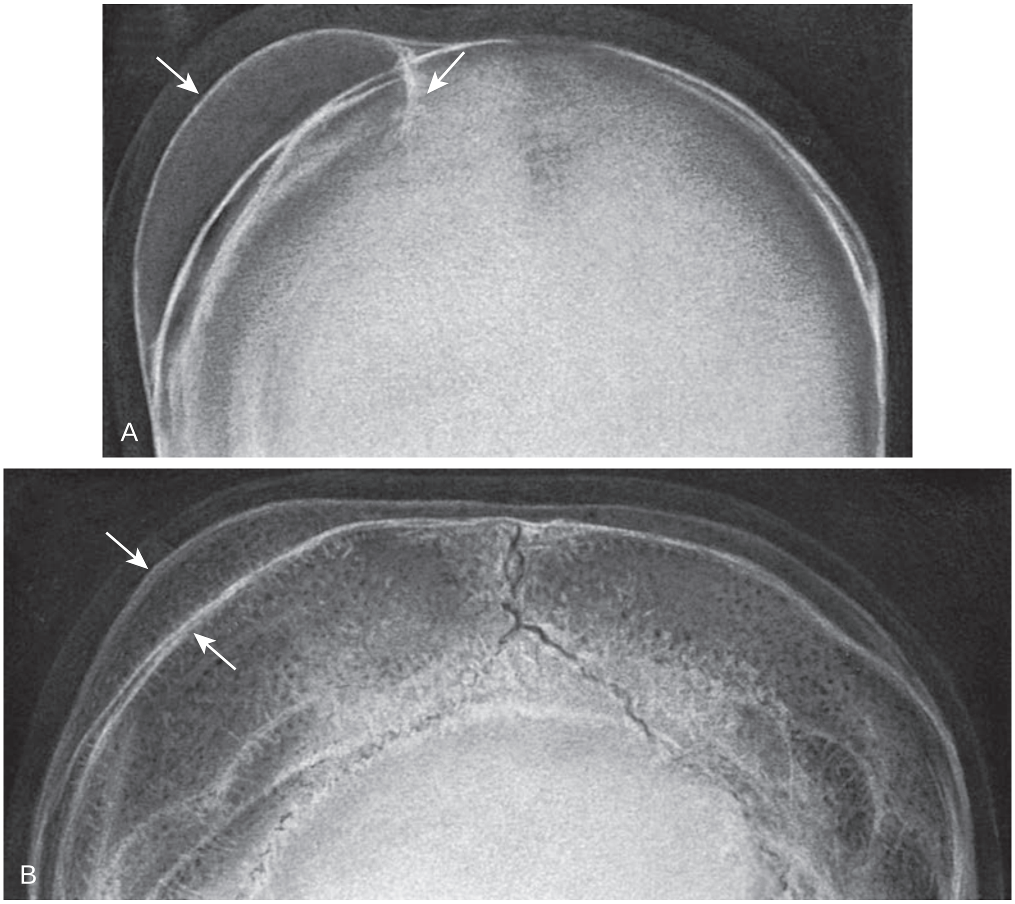


**Figure 23.12. Radiographs show late residual thickening of the calvaria resulting from neonatal cephalhematoma.** (A) At 7 weeks of age, a large right parietal hematoma *(arrows)* is covered by a thin osseous shell. (B) At 3 years and 11 months of age, a widening of the diploic space *(arrows)* is seen where the neonatal hematoma was located.

should be considered in lesions of parietal and occipital bones. To avoid unneeded radiation, history should be obtained before radiographic evaluation.

## CRANIAL FRACTURES

### Neonates

Occasionally, the skull is fractured during delivery. Simple linear or fissure fractures occur commonly and are seen as linear lucencies on radiographs. Basilar fractures are rare. A 12% incidence of skull fractures, all depressed, was reported in a large series of birth-related head injuries.[10] Forceps were used in most of these deliveries, and the fractures were almost all in the parietal and occipital bones. When clinical signs warrant intracranial evaluation, computed tomography (CT) may be used in emergent situations, but magnetic resonance imaging (MRI) will provide more detailed brain evaluation.

### Infants and Children

Skull radiographs have little to offer in nonabusive head trauma. The presence or absence of a fracture has no impact on management.[11–16] In a series of 256 children younger than 5 years who fell out of bed at home or in the hospital, only three skull fractures were found, and clinically these fractures were insignificant.[16] Serious injuries attributed to falls from a bed must be evaluated very carefully for possible child abuse factors.

The major indication for skull radiographs is suspected abuse. A prospective study including more than 7,000 patients suggests that, if certain clinical criteria are present singly or in combination, CT or MRI examination is warranted to evaluate for intracranial injury.[17–23] The selection criteria are (1) unconsciousness or a documented decreasing level of consciousness; (2) a history of a craniotomy with a shunt in place; (3) the probability of a skull depression or identification of a skull depression by probing through a laceration or a puncture wound; (4) blood in the ear or fluid discharge from the ear; (5) CSF discharge from the nose; (6) ecchymosis behind the ear (Battle sign); (7) bilateral orbital ecchymoses; and (8) unexplained focal neurologic signs. If cephalhematoma, drowsiness, and age less than 1 year were added as criteria, no fractures would have been missed.

In a multi-institutional study in which more than 42,000 children with head trauma and a Glasgow Coma Scale score of 14 or 15 were evaluated, a negative predictive value of almost 100% and a sensitivity of greater than 96.8% were found when the criteria in Box 23.1 were absent.

Depressed skull fractures occur most frequently when strong forces are involved, as in vehicular accidents or direct local trauma or after forceps deliveries in the neonate. Many fractures are comminuted and/or complicated by associated lacerations or communication with the nasal or aural cavities. Dural tears are common with depressed fractures, whereas extradural and subdural hematomas are far less common.[10]

When examining young patients with open sutures for potential fractures, it is necessary to remember normal suture variability. Widened sutures may result from long-term prostaglandin $E_1$ administration and during recovery from nutritional deprivation.[24,25] Whether or not the fractures are depressed, they may result in dural sinus tears. The position of the bone edges after trauma may give no indication of how much displacement took place when the fracture occurred. In some cases, especially depressed fractures, the fracture fragments may overlap. CT is the optimal modality for evaluating the depressed fragments and their relation to the underlying brain (Fig. 23.15). Several radiographic features of cranial

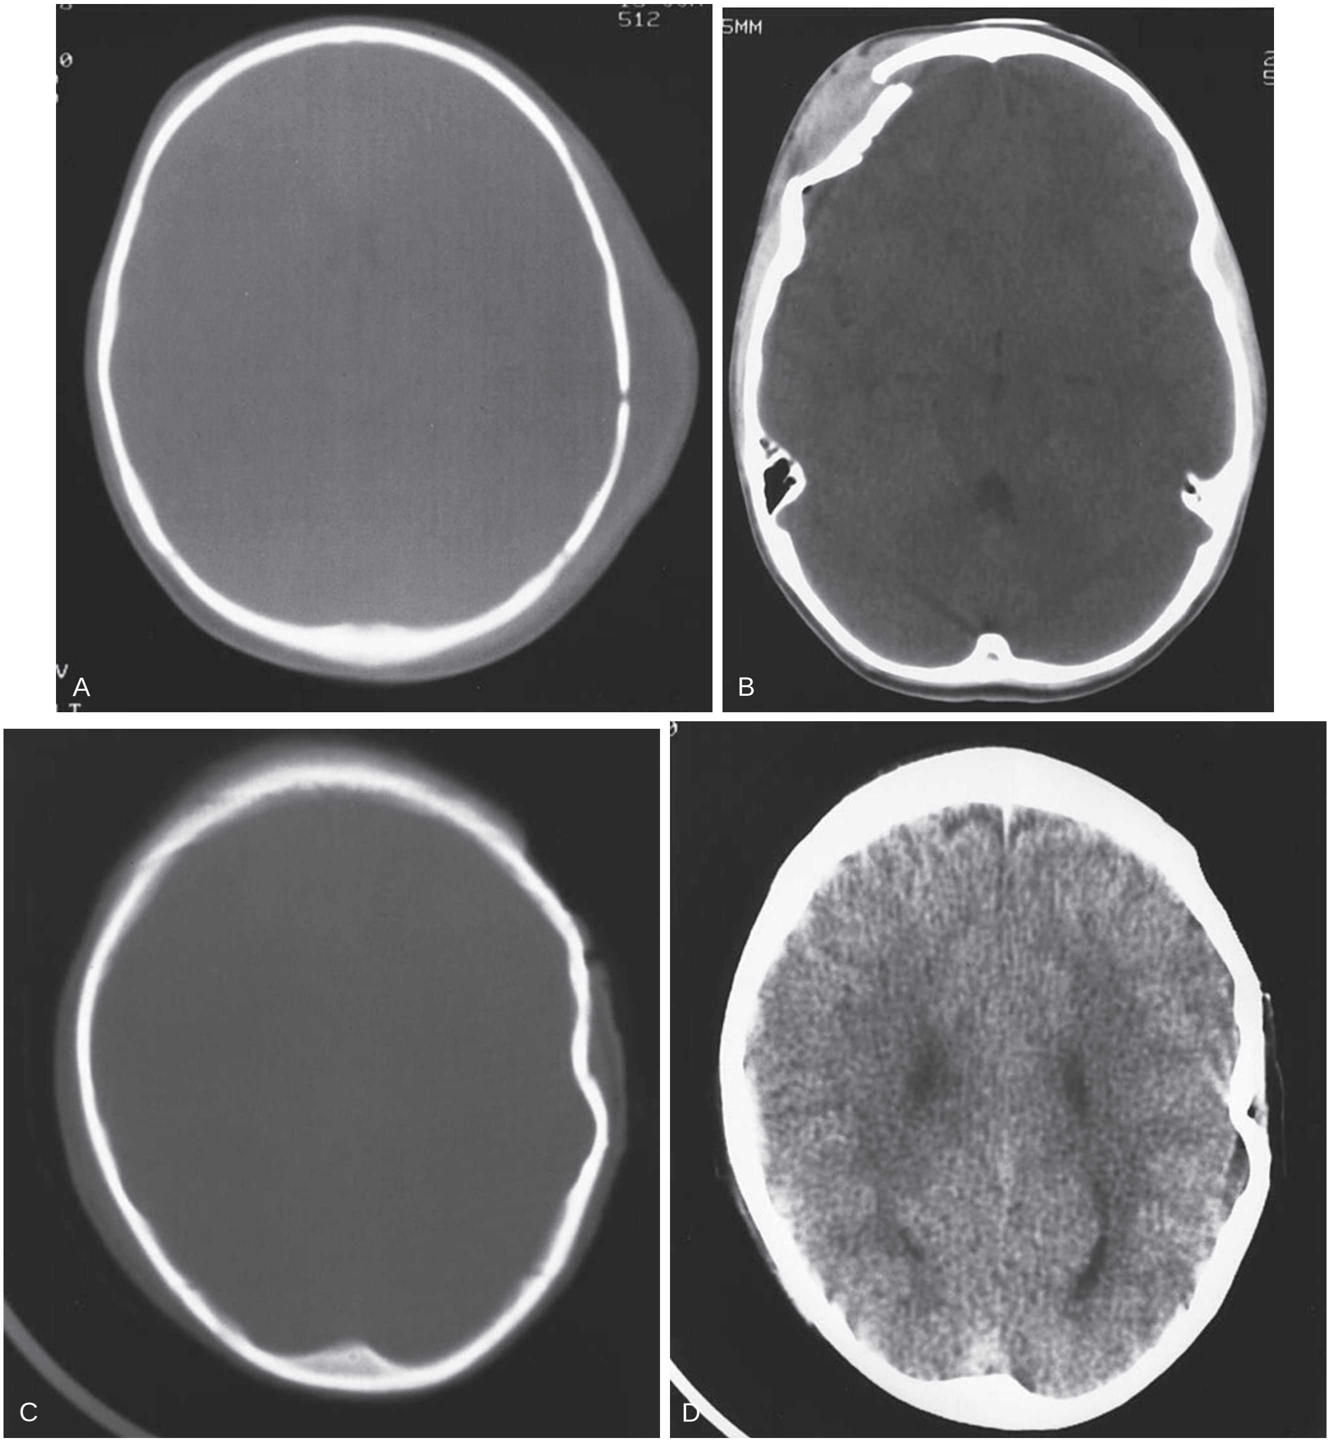

**Figure 23.15. Calvarial and intracranial trauma on CT.** (A) A CT scan with bone windows shows a large soft tissue hematoma and left linear parietal fracture. (B) CT image of another child shows a depressed right frontal fracture with a large external hematoma and a small epidural anteriorly. Bone (C) and brain (D) windows reveal lack of intracranial involvement, but the child has sustained a left parietal fracture and scalp lacerations.

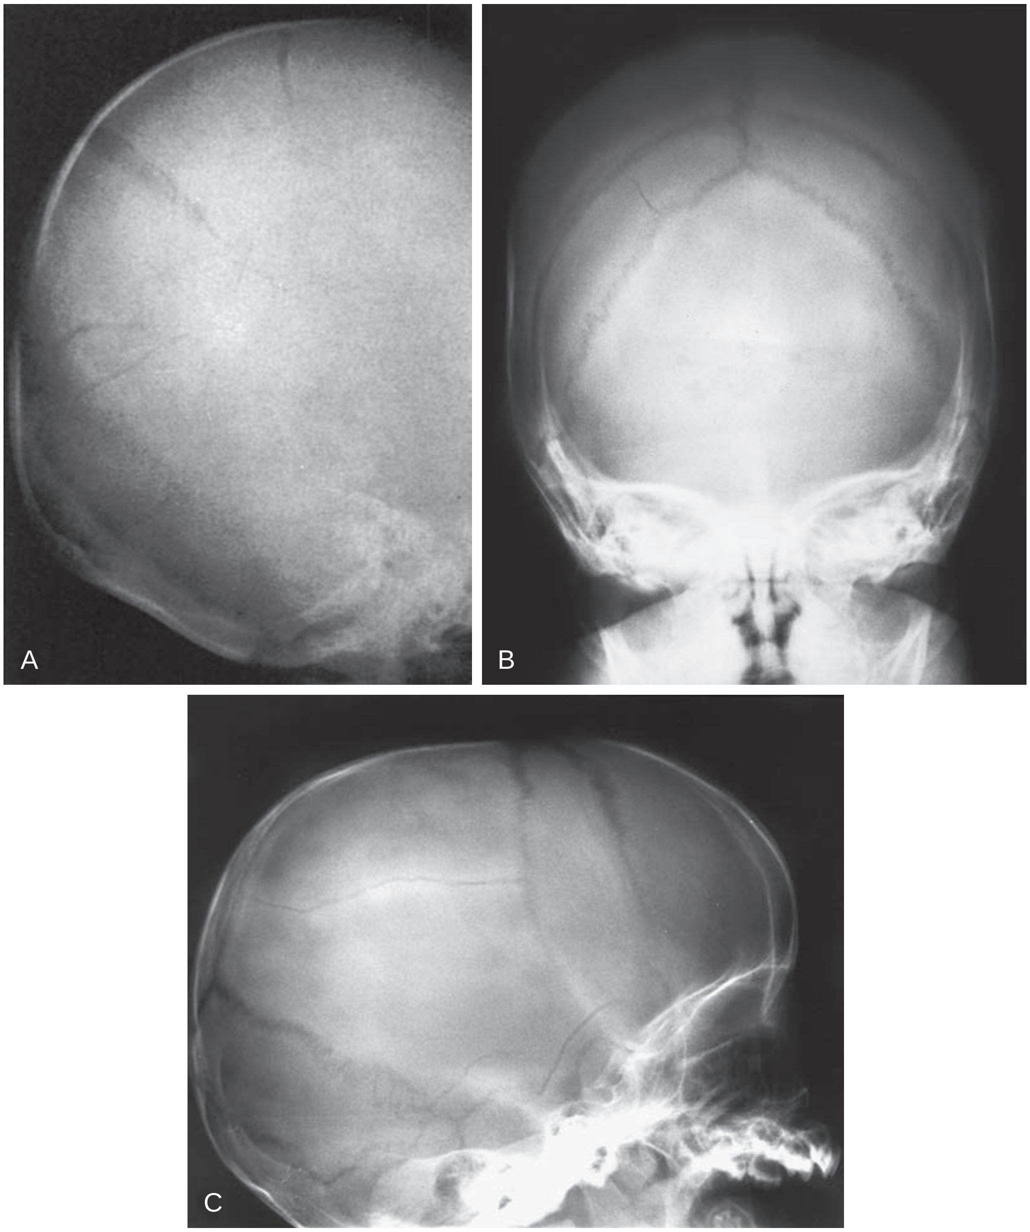

**Figure 23.17. Linear fractures alone and with signs of increased intracranial pressure.** (A) Multiple fractures of the right parietal bone in a 9-month-old infant. (B and C) Linear parietal fracture in another child, who also has diastatic sutures denoting increased intracranial pressure.

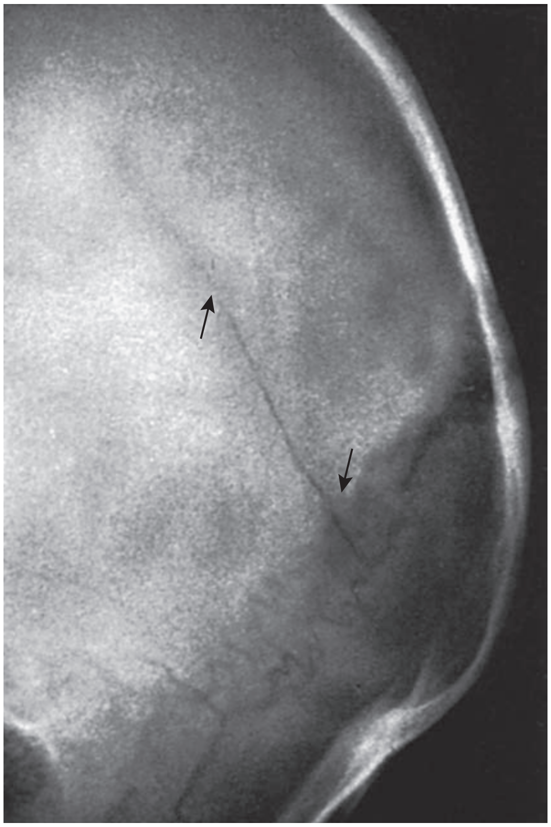
fractures are shown in e-Fig. 23.16, Figs. 23.17 through 23.19, and e-Fig. 23.20.

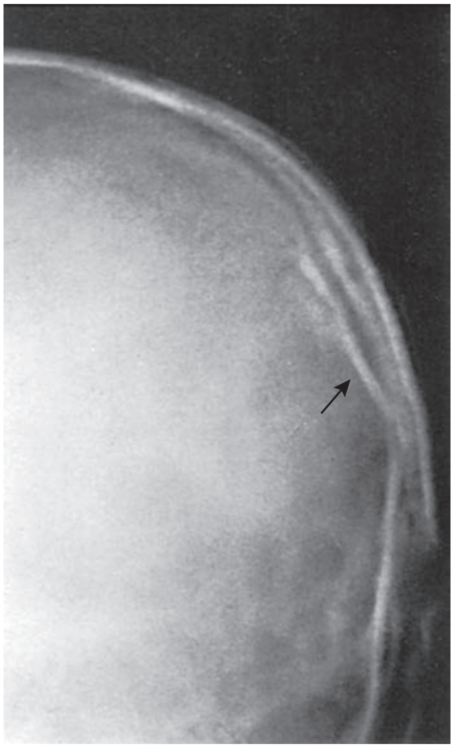
Linear fractures in infants and children generally heal with few or no sequelae. The fracture margins become hazy, and gradually disappear over several months. When comminution has occurred, bone may be resorbed locally, leaving a defect. If the dura has been disrupted at the time of the fracture, the edges of the fracture may separate allowing the local leakage of CSF and formation of a leptomeningeal cyst.[26,27] Cysts are thought to be most common in fractures involving sutures. Further, associated widening of one coronal suture has been reported after vacuum extraction when cup placement was too anterior.[28]

By transmitting the pulsations of the brain, the cyst causes pressure atrophy of bone unprotected by dura, and a large defect may develop after many months or years (Figs. 23.21 and 23.22). Progressive enlargement of the calvarial defect has given rise to the term "growing fracture." Scalloped defect margins results from differential erosion of inner and outer tables.

Gas may accumulate in scalp soft tissues contiguous to fractures, often through breaks in the paranasal sinuses or mastoid air cells. If air escapes from the sinuses into the subaponeurotic space of the scalp, the result is called extracranial traumatic pneumocephalus. Air also may leak into the cranial cavity, causing internal pneumocephalus.



**e-Figure 23.16.** A fine linear fracture of the parietal bone *(arrows)* in a 15-month-old infant who fell from a highchair.



**e-Figure 23.20. Depressed parietal fracture in a 7-year-old girl with plagiocephaly.** The left calvarium is smaller than the right due to a fracture that caused hypoplasia and flattening of the left producing a segment of inner table of the smaller parietal bone that is central to the larger right parietal bone.

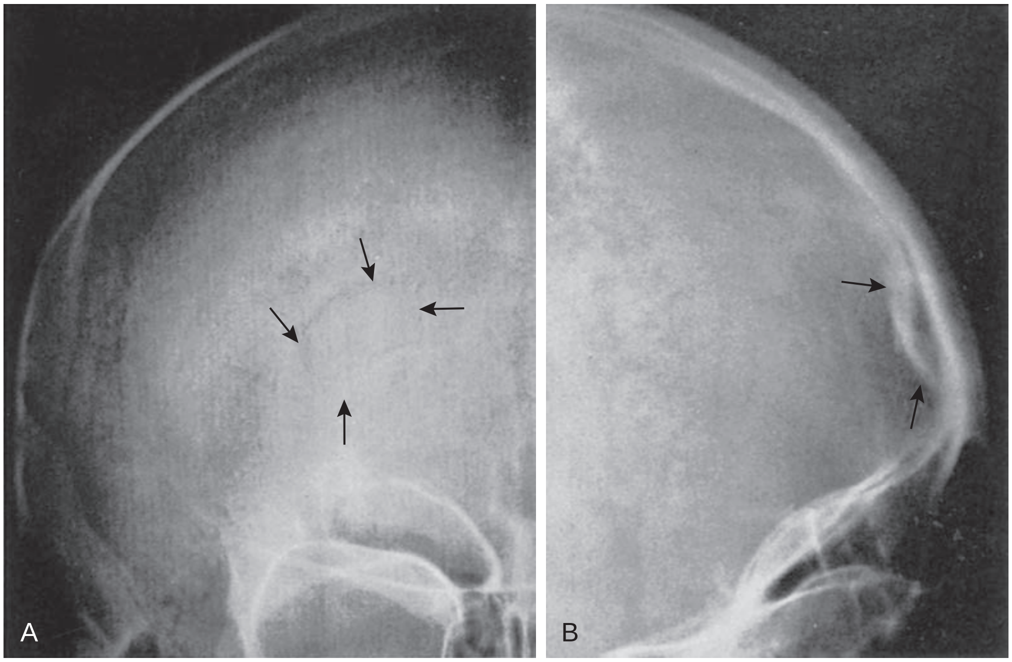


**Figure 23.18. Depressed fracture of the frontal bone in a 9-year-old child.** (A) A radiograph shows fracture *(arrows)*. In the medial inferior segment, the arcuate shadow of diminished density is replaced by a curved linear shadow of increased density that is caused by overlapping of bone fragments. (B) Lateral projection demonstrating the depression of the calvarial tables *(arrows)*.

**BOX 23.1** Criteria for Head Computed Tomography in Children With a Glasgow Coma Scale Score of 14

**A. <2 YEARS OLD**

1. Altered mental status
2. Palpable skull fracture
3. Occipital, parietal, or temporal scalp hematoma
4. Loss of consciousness >5 seconds
5. Severe mechanism of injury
6. Not acting normally, per parent

**B. >2 YEARS OLD**

1. Altered mental status
2. Signs of basilar skull fracture
3. Loss of consciousness
4. Vomiting
5. Severe mechanism of injury
6. Severe headache

*Modified from Kuppermann N, Holmes JF, Dayan PS, et al. Identification of children at very low risk of clinically important brain injuries after head trauma: a prospective cohort study.* Lancet. *2009;374:1160–1170.*

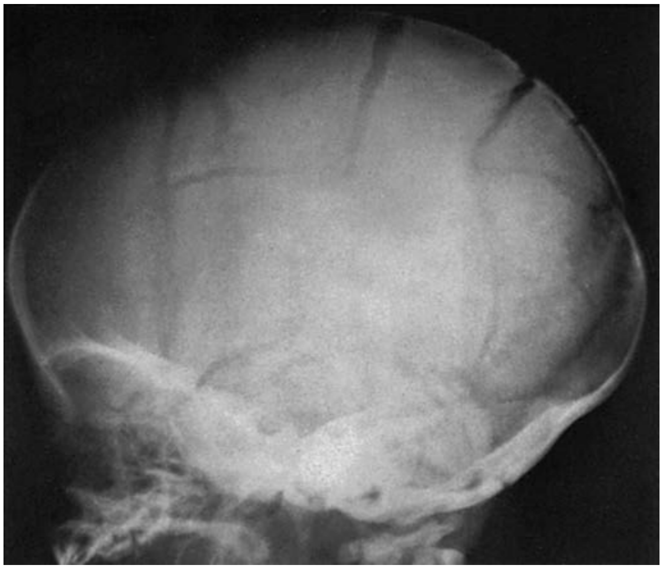

**Figure 23.19. Comminuted diastatic fractures in a 2-month-old infant due to nonaccidental trauma.** Comminuted diastatic fractures of the parietal bones are shown. Both ocular fundi contained retinal hemorrhages, and bilateral subdural hematomas were noted.

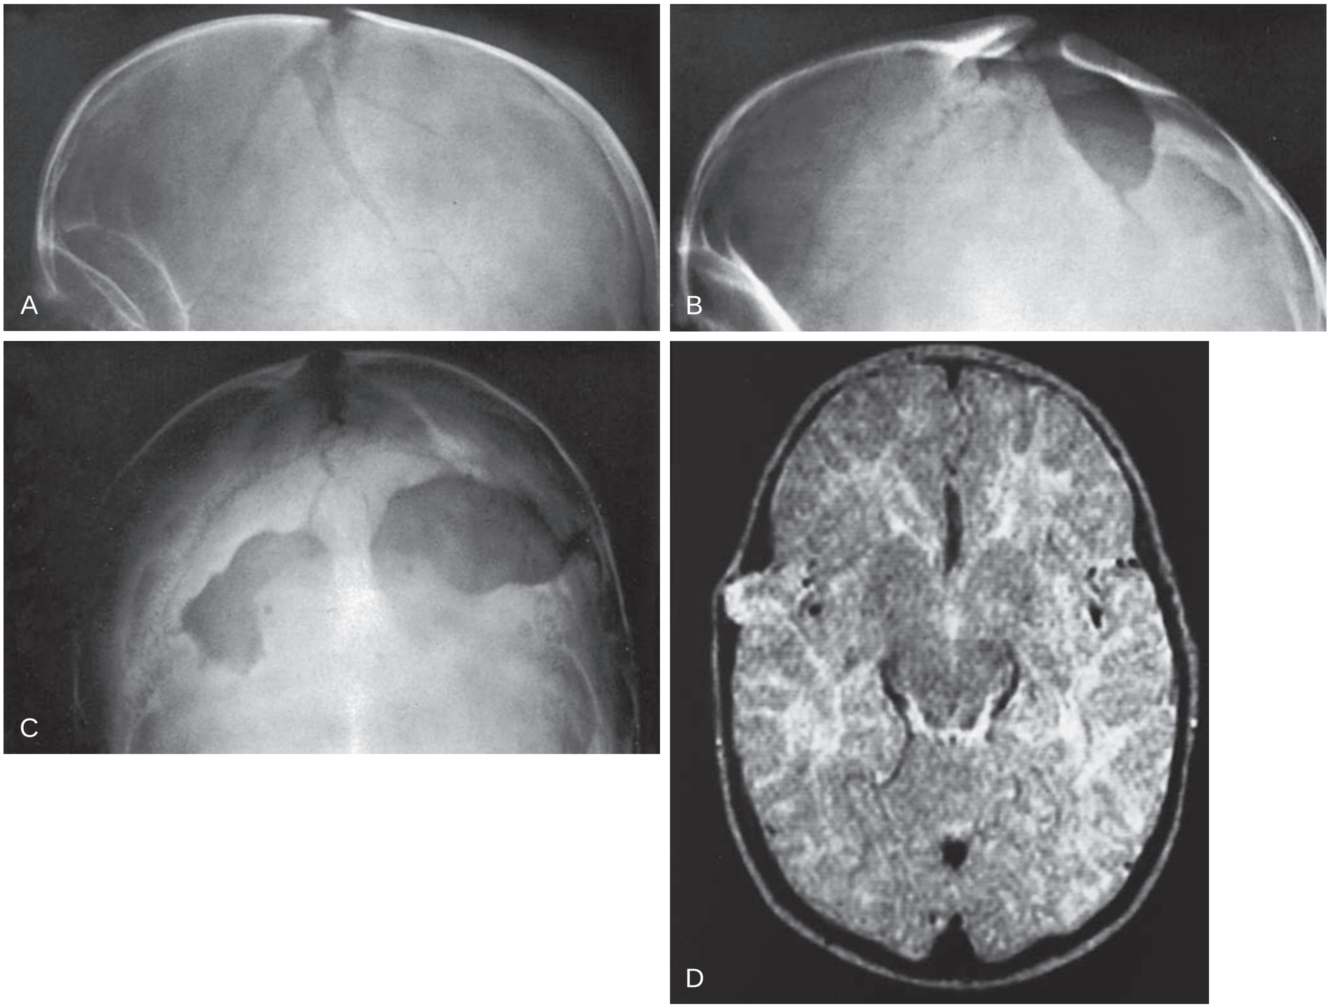

**Figure 23.21. A pulsating leptomeningeal cyst with residual bilateral large defects in the calvaria.** (A) Diastatic bilateral comminuted parietal fractures after a head injury during infancy. Lateral (B) and frontal (C) projections 5 years later show large bilateral defects in the sites of the earlier parietal fractures. At surgery, the dura beneath the fractures was torn. The bone on the margins of the defect is sclerotic and thickened. (D) Magnetic resonance imaging in another child with a leptomeningeal cyst reveals herniation of the brain outward in the right parietal region. *(A, B, and C, Courtesy of Walter E. Berdon, MD.)*

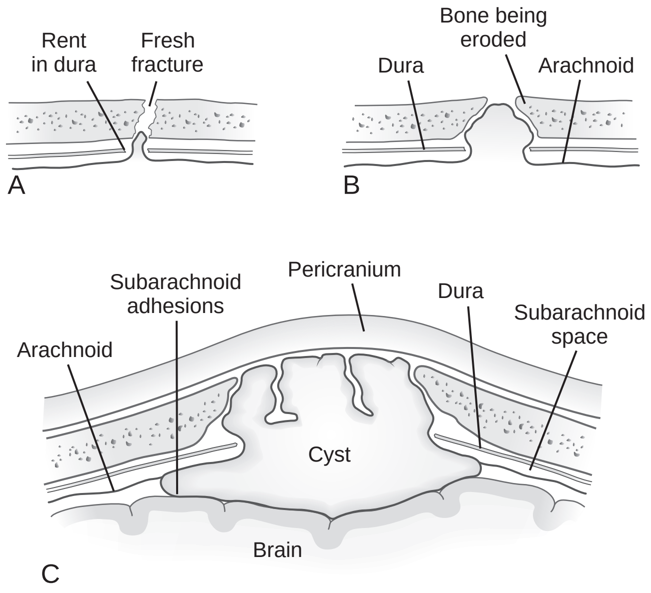

**Figure 23.22. Schematic representation of leptomeningeal cyst formation.** (A) Immediately after an injury occurs, fresh parietal bone fractures, fresh dural rents, and early protrusion of the arachnoid membrane through the fracture are seen. (B) Lateral marginal erosion of bone and widening of the dural defect. (C) Later incomplete cyst formation in the arachnoid due to adhesions, depression, and pressure atrophy of the underlying brain and leptomeninges and increases the defect. *(Courtesy of Juan M. Taveras, MD.)*

## KEY POINTS

- Cranial fractures seldom correlate with the clinical situation or management except in child abuse.
- Plain skull radiographs have little to offer in the management of pediatric nonabusive head trauma.
- Leptomeningeal cyst (i.e., a growing fracture of childhood) is uncommon after 5 years of age.

# 24

# Embryology and Brain Development

*Marvin D. Nelson Jr.*

The human brain undergoes four phases of development: (1) dorsal induction (primary and secondary neurulation), (2) ventral induction (patterning of the forebrain), (3) neuronal proliferation and migration, and (4) myelination. During the third week of embryogenesis, initiation of the central nervous system evolves with the development of the notochordal process. This derivative of ectoderm grows rapidly in length so that by 20 days it is converted from a hollow tube to a solid rod—the notochord (Fig. 24.1; e-Table 24.1). The notochord works with the axial mesoderm to induce the neural plate. The neuroepithelium of the neural plate begins the formation of the brain and spinal cord. It appears initially at the cranial end of the embryo and differentiates craniocaudally. At the beginning of the fourth week, the neural plate is composed of a broad cranial portion and a narrow caudal portion—the fetal brain and spinal cord.

## DORSAL INDUCTION

The process of neurulation or formation of the neural tube occurs when the lateral edges of the neural plate elongate to become neural folds and join together in the midline to form the neural tube (Fig. 24.2).[1] The process starts in the craniocervical region and proceeds superiorly and inferiorly. The space within the neural tube, the neural canal, initially is open at the cranial (or rostral) and caudal ends (cranial and caudal neuropores), which communicates with the amniotic cavity. The neuropores gradually decrease in size and close between the 24th and 26th day.[1] The lowest portion of the spinal cord, the inferior sacral and coccygeal levels, are formed by a different process called *secondary neurulation* (see Chapter 40). Pluripotent tissue within the caudal eminence forms a solid neural cord; this neural cord forms a lumen that fuses with the caudal end of the neural tube to form a portion of the conus medullaris and the filum terminale (e-Fig. 24.3). This secondary process is not completed until the eighth week after fertilization of the ovum.[1]

Some neural crest cells (the population of neural cells arising at the lateral edge of the neural plate during neural tube formation) detach during neurulation and form many different tissues (e.g., melanocytes and chromaffin cells of the adrenal medulla), including the major components of the peripheral and autonomic nervous system (e-Fig. 24.4).[1]

## VENTRAL INDUCTION

The prechordal plate cephalic to the neural tube and notochord induces this stage of development. The three major divisions of the brain—the prosencephalon or forebrain, mesencephalon or midbrain, and rhombencephalon or hind brain—are more clearly differentiated during the rostral expansion of the neural tube (the formation of the primary brain vesicles).[1,2] During the fourth and fifth weeks, a series of brain flexures occur in the midbrain, cervical, and later pontine regions so that by the end of the fifth week, five secondary brain vesicles are present (Fig. 24.5). With further development, the prosencephalon becomes subdivided into the telencephalon and the diencephalon. The rhombencephalon subdivides into the metencephalon and myelencephalon. The mesencephalon does not divide. Within each of these five vesicles, the neural canal expands into a primary ventricle. The central canal of the spinal cord is continuous with the brain ventricles. The fate of these structures is shown in Fig. 24.5. The cranial nerve nuclei appear in the brainstem during the fifth week (see the next section).[1,2]

## NEURONAL PROLIFERATION AND MIGRATION

During the period of morphologic development of the brain, cytodifferentiation occurs. Formation of the cerebral neocortex is a complex process with proliferation, migration, and differentiation varying in time from one site to another. Several patterns of neuronal migration occur, including (1) radial migration along the path of radial glial cells from the ventricles toward the surface and (2) tangential migration along transverse surfaces (e-Fig. 24.6).[1–3]

Although details of the migration process vary for each region of the brain, general principles include the following: (1) the ultimate migration is from deep (ventricle) to superficial regardless of trajectory differences; (2) the migration establishes layers of the cortex (Figs. 24.7 and 24.8); and (3) neurons of each later wave of migration pass through the preceding layers to form a more superficial layer.[4]

During the 10th to 20th weeks of gestation, neuronal genesis occurs. The proliferative cells of the ventricular zone (also known as *germinal matrix*) form waves of migrating neuroblasts that pass through the intermediate zone to form the cortical subplate. Each new layer migrates through the preceding layer to become more superficial. The mature cortex has six layers, and neuronal migration concludes between 20 and 24 weeks' gestation.

The subplate and cortical plate form the cortex, whereas the intermediate zone becomes white matter (see Fig. 24.7). The germinal matrix also produces the glial cells, that is, astrocytes and oligodendrocytes.[4] The microglial cells are of mesodermal origin and are the resting tissue histiocytes of the brain. In contrast to cortical migration, glial cell migration and differentiation continues for more than 1 year after birth.[4]

Excessive cells of the fetal neurosystem ranging from 30% to 70% are produced when compared with the number of mature cells. These "surplus" cells undergo programmed death or apoptosis if they are not utilized.

The steps of neurulation, cell proliferation, and migration are induced by multiple neurotransmitters, and genes controlling these transmitters have been identified.[5]

The brainstem and spinal cord are similar in development. Two basal (ventral) columns and two alar (dorsal) columns are formed. These columns form a dorsal sensory and ventral motor configuration and are found in both the brainstem and spinal cord. The cranial nerves IX through XII come from the myelencephalon (medulla) and cranial nerves IV through VII from the metencephalon (pons) (see Fig. 24.5). The pons is largely composed of white matter tracts of the cerebellum. The cerebellum is also derived from the metencephalon (see Fig. 24.5).

## Abstract:

This chapter reviews what we know about the process of normal development of the human brain.

New York: Churchill Livingstone; 1997.)*

## FETAL DEVELOPMENT IN THE PRETERM INFANT

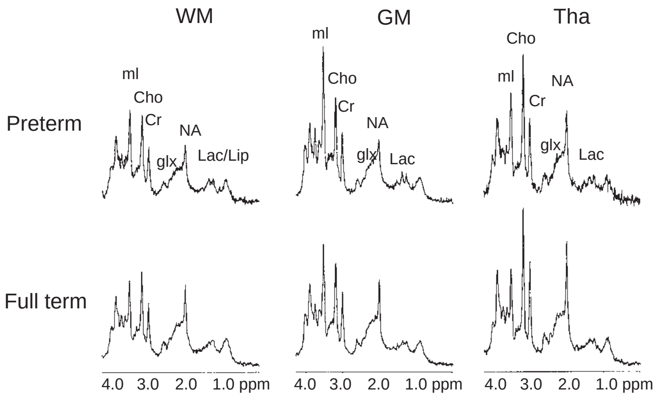
The normal brain anatomy of the fetus is in many ways quite different from the normal anatomy of the term infant. The following differences are noted:

1. The fetal ventricles are large relative to the size of the brain and have a posterior (occipital) predominance that decreases after 25 weeks.
2. The fluid-filled spaces of the brain are large; subarachnoid spaces are increased in size relative to size of the brain, and the cisterna magna is larger than at term.
3. The germinal matrix, for aforementioned reasons, is quite large, peaks at 26 weeks then regresses and is grossly gone by 34 weeks.
4. Primary and secondary sulcation and gyration follow a predictable course (Figs. 24.9 and 24.10).[6]

The normal biochemical profile follows the type and amount of cells present in any given stage of development. This can be seen through the normal but different spectrographic patterns (e-Fig. 24.11).[3] Normal myelination occurs via a defined order from the third trimester onward through adolescence (Table 24.2).[7,8] Generally, myelination proceeds caudal to rostral and posterior to anterior.

## NORMAL ANATOMY

The result of these complex processes result in the mature brain and spinal cord. Neuroanatomic descriptions in detail are beyond the scope of this text, but many atlases of anatomy and imaging are available. Comparison of normal development with pathologic development will be discussed in Chapter 31.



**e-Figure 24.11. Spectra during human functional development in different regions of the brain.** Metabolites identified are lactate *(Lac)*, lactate/lipid *(Lac/lip)*, N-acetyl aspartate *(NA)*, glutamine and glutamate *(Glx)*, creatine and phosphocreatine *(Cr)*, choline *(Cho)*, and myo-inositol *(mI)*. Spectra are all scaled identically. Developmental changes in metabolic concentrations are illustrated by different peak heights comparing spectra from preterm and full-term newborns. *GM,* Gray matter; *Tha,* thalamus; *WM,* white matter. *(Spectra analyzed by Roland Kreis, MR Center, Inelspital, University of Berne, Berne, Switzerland.) ## KEY POINTS

- The neural tube differentiates into the brain and spinal cord. The neural crest gives rise to the peripheral and autonomic nervous system.
- Neuronal migration proceeds from the ventricular zone to the superficial regions of the brain along radial glial cells.
- In general, myelination proceeds caudal to rostral and posterior to anterior.

# Magnetic Resonance Spectroscopy and Positron Emission Tomography

*Andre Dietz Furtado, Celso Hygino da Cruz Jr., Wael Abdalla, Stefan Bluml, and Ashok Panigrahy*

Magnetic resonance spectroscopy (MRS) capability is available in most clinical magnetic resonance (MR) scanners. The additional information from MRS allows the assessment of cellular metabolism noninvasively. For the brain in particular, it has been proved that MRS of protons or hydrogen (1H MRS) provides additional clinically relevant information for several disease processes such as brain tumors, metabolic disorders, and systemic diseases, and it is the most accessible method for studying and monitoring patients with neurometabolic disorders (Table 25.1).

## THEORETICAL BACKGROUND OF MAGNETIC RESONANCE SPECTROSCOPY

In MR imaging (MRI), the signal from hydrogen nuclei in water molecules is used to create images or anatomic maps. In contrast, 1H MRS analyzes the signal of protons attached to other molecules. The output of MRS is a collection of peaks at different radiofrequencies representing proton nuclei in different chemical environments, that is, the spectrum (typical MR spectra of normal occipital gray matter is shown in Fig. 25.1). MRS can measure a variety of metabolites (Table 25.2). The $x$ axis, or chemical shift axis, is a measure of the frequency shift of a proton relative to a universally fixed reference substance (tetramethylsilane at 0 parts per million [ppm]). In spectra in vivo, the protons of water (usually not shown) resonate at 4.7 ppm. The ppm scale has been selected instead of Hertz ($\text{Hz} = \text{sec}^{-1}$) because it is independent of the magnetic field strength. The $y$ axis is a measure of the signal intensity, which is proportional to the concentration of the metabolite or chemical.

## MAIN METABOLITES OF THE IN VIVO PROTON SPECTRUM

### N-Acetylaspartate

The most prominent peak of the 1H spectrum is the resonance at 2.0 ppm from three equivalent protons of the acetyl group of the N-acetylaspartate (NAA) molecule (see Fig. 25.1). The role of NAA and its regulation in vivo are not well understood. In the normal brain, NAA is synthesized in neurons, diffuses along axons, and is broken down in oligodendrocytes. NAA is present in high concentrations only in normal neurons and axons,[1,2] and from an MRS perspective, it is a marker of viability for mature neurons and axons. The concentrations of NAA increase after birth, becoming the dominant peak around 6 months.[3–5] Proton spectra of any disease associated with neuronal or axonal loss will exhibit a reduction of NAA. Brain NAA increases rapidly as the brain matures, peaks at approximately 10 to 15 years, and then decreases slightly over time as the number of neurons and axons declines even in the normal brain.[4]

### Total Choline

The next prominent peak at 3.2 ppm is commonly referred to as *choline* or *trimethylamines*. Choline is a complex peak comprising several metabolites that contain choline, and therefore the term total choline (tCho) is used in this chapter. Compounds that contain choline are involved in the synthesis and breakdown of phosphatidylcholine (lecithin). Phosphatidylcholine is the major phospholipid component of eukaryotic cells, accounting for approximately 60% of total cellular phospholipids.

### Creatine

The second tallest peak in occipital gray matter spectra is creatine (Cr) at 3.0 ppm. For normal brain tissue, the Cr peak comprises contributions from free Cr and phosphocreatine in approximately equal proportions. Phosphocreatine is in rapid chemical exchange with free Cr and is used to replenish adenosine triphosphate (ATP) levels, if required. Like NAA, Cr levels also are low in the newborn.

### Myo-inositol

tCho, Cr, and NAA can be detected readily and quantified in long echo time (TE) MRS. Short TE acquisition methods are necessary for reliable quantitation of myo-inositol (mI), which is a sugar-like molecule that resonates at 3.6 ppm in the proton spectrum. It has been identified as a marker for astrocytes and is an osmolyte.[6,7] mI also is involved in the metabolism of phosphatidyl inositol, a membrane phospholipid. Similar to choline, mI is altered in response to alteration of membrane metabolism or membrane damage. Both tCho and mI are high in the newborn brain but decrease rapidly to normal levels within the first 12 to 24 months after birth.

### Lactate

Lactate (1.33 ppm) indicates anaerobic metabolism. Lactate is the product of anaerobic glycolysis and increases when subsequent oxidation of lactate in the tricarboxylic acid cycle is impaired (for example, by lack of oxygen or mitochondrial disorders). With the exception of healthy-term neonates who may have trace amounts of lactate in the brain in the first days of life (lactate/choline <0.15),[8] significantly elevated lactate concentrations is indicative of pathologic tissue. Lactate is typically elevated in brain infarcts, contusions, infections, tumor necrosis, metabolic disorders, and cysts. Lactate (1.33 ppm) can be differentiated from other lipids and macromolecules (0.9–1.3 ppm) using TE = 144 ms that causes the lactate peak to reverse (Fig. 25.2).

### Lipids and Macromolecules

The protons of the methyl groups ($\text{-CH}_3$) of lipid molecules resonate at 0.9 ppm, whereas protons of the methylene groups ($\text{-CH}_2\text{-}$) resonate at 1.3 ppm in the $^1$H spectrum. Both resonances are broad and also may comprise contributions from other macromolecules. In normal tissue, the concentration of free lipids is small, and very little signal should be present in this part of the spectrum. Lipid signals increase upon breakdown of cell membranes and release of fatty acids, therefore lipids are marker of severity of brain imaging. NAA and lactate can be detected using either short echo (35 ms) or long echo (144 or 288 ms) time. MI, glutamate/

## Abstract:

Magnetic resonance spectroscopy allows the assessment of cellular metabolism noninvasively. In MR imaging, the signal from hydrogen nuclei in water molecules is used to create images or anatomic maps. In contrast, MRS of hydrogen protons (1H MRS) analyzes the signal of protons attached to other molecules, expressed as parts per million. N-acetylaspartate is present in high concentrations only in normal neurons and axons and is a marker of viability and maturation of neurons and axons. Choline compounds are involved in the synthesis and breakdown of phosphatidylcholine (lecithin), a major component of the cellular membranes and is typically elevated in regions with high cellularity and high mitoses. Lactate is the product of anaerobic glycolysis and indicates anaerobic metabolism. For the brain in particular, it has been proved that 1H MRS provides additional clinically relevant information in several disease processes such as neonatal hypoxic-ischemic encephalopathy, metabolic diseases and white matter disorders, pediatric brain tumors, hepatic encephalopathy and pediatric brain trauma. Additional metabolic information may be obtained with positron emission tomography (PET). PET is able to quantify the intracellular concentration of the compounds. PET using F18-fluorodeoxyglucose is a well-established biomarker of cellular metabolism, particularly in pediatric brain tumors and epilepsy. 68Gallium-labeled somatostatin analogues has been recently introduced for clinical use. Uptake 68Gallium-labeled somatostatin analogues have been reported in glioma, medulloblastoma, meningioma, and pituitary macroadenoma.

glutamine, and lipids can be detected only during use of the short echo technique (see Fig. 25.2).

## MAGNETIC RESONANCE SPECTROSCOPY METHODS

### Data Acquisition Techniques

#### Localized Single-Voxel Spectroscopy

Single-voxel MRS measures the MR signal of a single selected region of interest, whereas signal outside this area is suppressed. For single-voxel MRS, the magnetic field and other parameters are optimized to get the best possible spectrum from a relatively small region of the brain. Manufacturers generally provide point-resolved spectroscopy,[9,10] stimulated echo acquisition mode,[11] and image-selected in vivo spectroscopy.[12] These sequences differ in how radiofrequency pulses and so-called gradient pulses are arranged to achieve localization. It is beyond the scope of this review to discuss details about localization methods; the interested reader is referred to the aforementioned publications.

**TABLE 25.1** Common Indications for Pediatric Magnetic Resonance Spectroscopy

| | |
|---|---|
| Tumors | New tumor |
| | Evaluate progression |
| | Tumor vs. encephalitis/other lesions |
| Hypoxic ischemic injury | Patients at risk for cerebral malperfusion (congenital heart defects—status, postoperative) |
| | Status, postoperative cardiac arrest, apneic episodes |
| | Trauma, nonaccidental trauma |
| | Birth asphyxia |
| Other | New seizures, worsening seizures |
| | Unknown neurologic condition, altered mental state, developmental delay, global hypotonia |
| | Metabolic disorders, phenylketonuria |
| | Leukodystrophies—monitoring |
| | Liver problems/failure—preliver transplant |

#### Two-Dimensional or Three-Dimensional Chemical Shift Imaging

With chemical shift imaging (CSI) approaches, multiple spatially arrayed spectra (typically more than 100 spectra per slice) from slices or volumes are acquired simultaneously. Slice selection can be achieved with a selective radiofrequency pulse, as for MRI

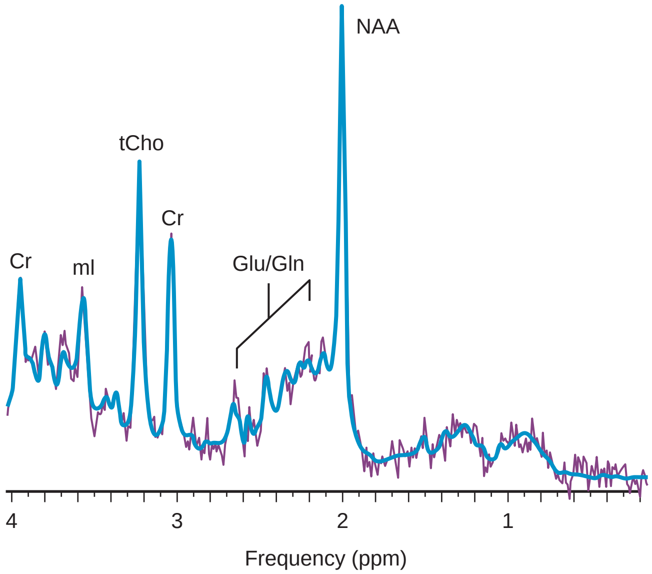

**Figure 25.1. $^1$H spectra of occipital gray matter acquired in a control subject.** Magnetic resonance imaging uses the signal provided by the protons of water to generate an anatomic map of the brain. In contrast, $^1$H magnetic resonance spectroscopy uses the signal from the protons of chemicals to generate a biochemical fingerprint of a "region of interest." Spectra were acquired using a point resolved spectroscopy sequence with echo time of 35 ms. *Cr,* creatine; *Glu,* glutamate; *Gln,* glutamine; *mI,* myo-inositol; *NAA,* N-acetylaspartate; *ppm,* parts per million; *tCho,* choline containing metabolites.

**TABLE 25.2** Summary of Chemicals Detectable With In Vivo Hydrogen Magnetic Resonance Spectroscopy

| | Long Name | Role, Regulation, Location | Altered in Magnetic Resonance Spectrum When: |
|---|---|---|---|
| NAA | N-acetylaspartate | Synthesized in neurons, diffuses along axons, broken down in oligodendrocytes, high in neurons and axons | Nonspecific but quantitative marker for neuronal/axonal damage |
| Cr | Creatine (creatine + phosphocreatine) | Synthesized in liver; functions as "battery" to replenish adenosine triphosphate levels | Abnormal in diseases of creatine synthesis, absent in cells that lack creatine kinase |
| tCho | Choline-containing metabolites | Involved in membrane synthesis and breakdown, osmolyte (GPC) | High in proliferative tumors, gliosis, leukodystrophies, low in hypoosmotic conditions, after radiation therapy |
| mI | Myo-inositol | High in astrocytes, osmolyte, sugar-like molecule, involved with phosphatidyl inositol (membrane lipid) metabolism | High in glial-based tumors (but low in glioblastoma multiforme), adrenoleukodystrophy, depleted in hepatic encephalopathy, low in other encephalitis (infections), liver disease |
| Glu | Glutamate | Excitatory neurotransmitter, high in neurons | High in seizures? Low in hepatic encephalopathy |
| Gln | Glutamine | Glutamate detoxification, osmolyte, high in glial cells, ammonia detoxification | High in hepatic encephalopathy, encephalitis (infections), ischemic-hypoxic injury |
| Lac | Lactate | End product of glycolysis, accumulates in cystic necrotic tissue, anaerobic metabolism indicator | Often high in tumors, (secondary) hypoxic-ischemic injury, mitochondrial disorders |
| Lip | Lipids | Membrane degeneration marker, necrosis marker | Aggressive tumors, infections, diseases associated with membrane breakdown |
| Glc | Glucose | Principle substrate for energy metabolism | Diabetes, disrupted energy metabolism |
| Tau | Taurine | Membrane stabilization | Elevated in medulloblastoma and possibly other primitive tumors |

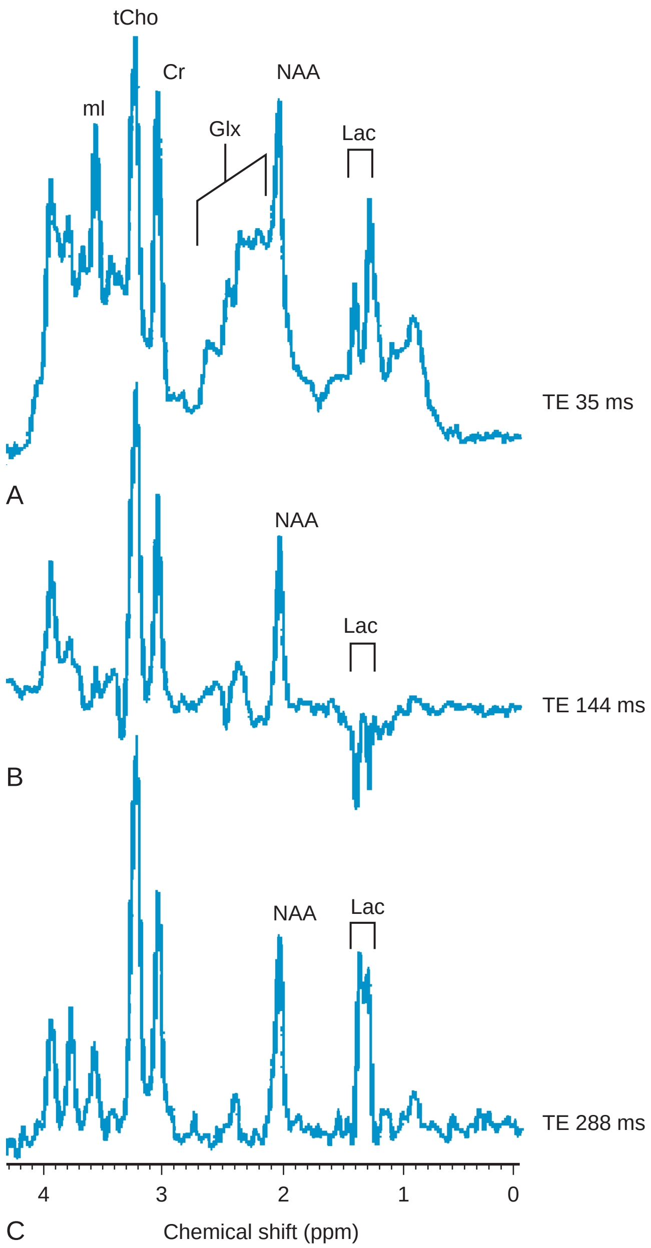

**Figure 25.2. Comparison of magnetic resonance spectroscopy (MRS) of neonatal hypoxic-ishemic encephalopathy (acquired at multiple echo times [TEs]) with neonatal metabolic disease.** (A–C) Single-voxel MRS at three different echo times in the basal ganglia of a hypoxic-ischemic term infant. Note the characteristic modulation of lactate *(Lac)*. (A) A spectrum acquired using short TE (35 ms), which shows a myo-inositol *(mI)* peak (left side of the spectrum), an elevated glutamine/glutamine *(Glx)* peak next to a reduced N-acetylaspartate *(NAA)* peak (middle spectrum), and an elevated lactate doublet next to a lipid peak (right side of the spectrum). (B) A spectrum acquired using long TE (144 ms) that shows a lactate doublet peak inverted and reduced NAA, but nonvisualization of myo-inositol, glutamate, and lipids. (C) A spectrum acquired using longer TE (288 ms) that is similar to 144 ms, except that the lactate doublet reverts to the other side of the spectrum.

(Fig. 25.3). When it is desired that the region of interest be limited to a smaller volume, for example, to avoid bone and fat from the skull, CSI is usually combined with point-resolved spectroscopy, stimulated echo acquisition mode, or image-selected in vivo spectroscopy but with a significantly larger volume selected than for single-voxel MRS. CSI is a very efficient method for acquiring information from different parts of the brain. An important feature is that, within the examined volume of interest, any region of interest can be selected retrospectively by a process termed *voxel shifting*.

### Parameters

The most important parameter is the TE. Indeed, MRS can be separated into long TE (typically >135 ms) and short TE (≈30 ms) methods. Long TE has been easier to use in clinical practice because of a flat baseline and because three peaks (NAA, Cr, and tCho) can be unequivocally separated. Short TE MRS allows the detection of an increased number of metabolites and has a signal-to-noise advantage over long TE.

## CLINICAL APPLICATIONS

### Neonatal Hypoxic-Ischemic Encephalopathy

MRS can detect neonates with acute hypotensive injury even when diffusion imaging and conventional imaging are negative.[13–24] The lactate from the acute event is rapidly cleared within the first 24 hours after resuscitation. The lactate/NAA peak ratio, measured in deep gray matter, is an accurate prognosticator for neonatal hypoxic-ischemic encephalopathy.[13,19,25–32] A generalized elevation of lactate would indicate global disruption or impairment of perfusion consistent with hypoxia and eventual poor outcome.[16]

### Metabolic Diseases and White Matter Disorders

Metabolic disease may be classified as acquired metabolic disorders or inborn errors of metabolism. Inborn errors of metabolism can present in the neonatal period.[33] Some examples of acquired metabolic disorders include hyperbilirubinemia and hypoglycemia, both of which may result in brain injury. Inborn errors of metabolism can be classified broadly into organic acidemias, disorders of amino acid oxidation, disorders of fatty acid oxidation, primary lactic acidosis, mitochondria function, lysosomal storage disorders, and peroxisomal disorders.[34–37]

Examples of organic acid disorders include methylmalonic acidemia and propionic aciduria, in which enzymatic defects occur in the conversion of valine, isoleucine, threonine, and methionine to propionic acid, succinic acid, and methylmalonic acid. Conventional MR findings include abnormal signal change corresponding to edema in both myelinated and unmyelinated structures. The edema in the myelinated structures is characterized by a vacuolating (or spongiform) myelinopathy, which can be seen in amino acid and organic acid disorders. In vacuolating myelinopathy, water is trapped within vacuoles that can be found within the myelin sheath layers, resulting in restricted diffusion of water. MRS of these organic acid disorders detects reduction in mI and NAA levels and elevation of glutamine and lactate levels as a result of hyperammonia, ketoacidosis, and mitochondrial dysfunction.[34–38]

The classic phenotype of maple syrup urine disease is a disturbance in the metabolism of the essential amino acids leucine, isoleucine, and valine. Symptoms occur by the first week of life and include seizures, vomiting and dystonia, fluctuating ophthalmoplegia, and coma. Conventional MR findings include abnormal edema in the deep cerebellar white matter, brainstem tegmentum, posterior limb of the internal capsule, perirolandic white matter, and pre- and postcentral gyrus. The accumulation of abnormal branched-chain amino acids and branched-chain α-keto acids results in a peak at 0.9 ppm. Both the changes detected by diffusion imaging and MRS may normalize after treatment is started.[39,40]

Urea cycle defects are characterized by a total of five disorders that involve different defects in the biosynthesis of enzymes of the urea cycle, including ornithine carbamyl transferase deficiency,

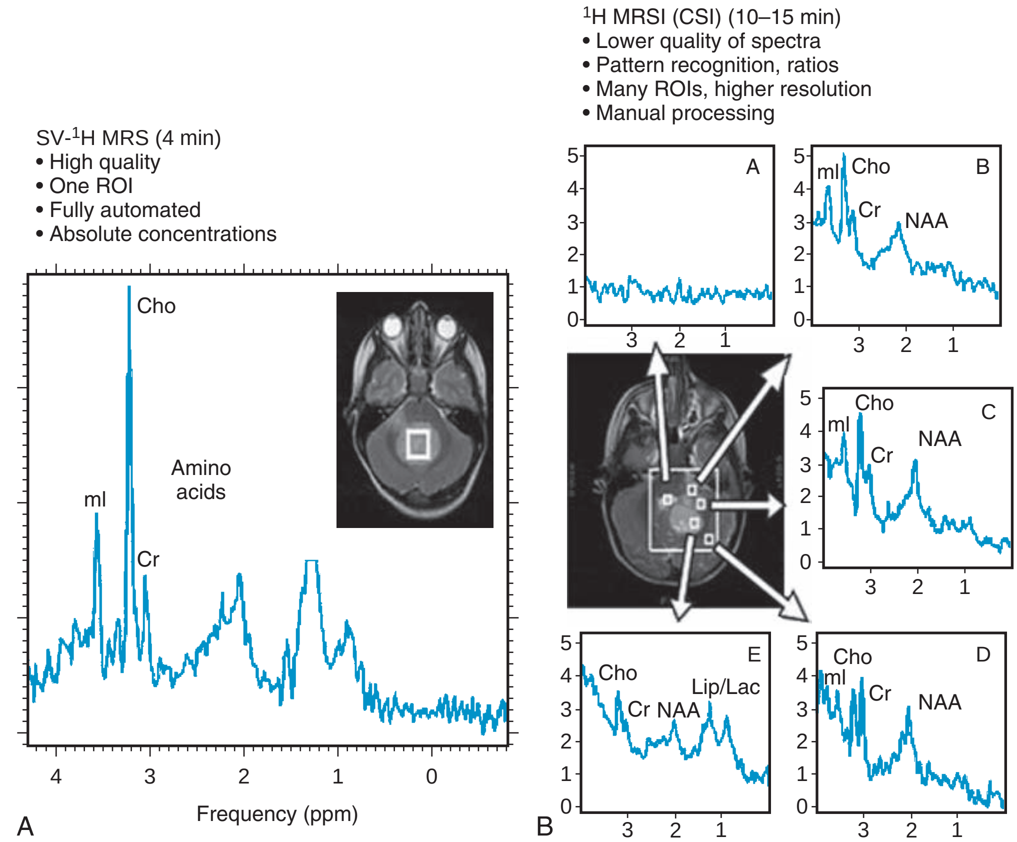

**Figure 25.3.** Differences between single-voxel (A) and multivoxel (B) acquisition. *Cho,* Choline; *Cr,* creatine; *CSI,* chemical shift imaging; *Lip/Lac,* lipid/lactate; *MRS,* magnetic resonance spectroscopy; *MRSI,* magnetic resonance spectroscopy imaging; *NAA,* N-acetylaspartate; *ppm,* parts per million; *ROI,* region of interest.

carbamyl phosphate synthetase deficiency, argininosuccinic aciduria, citrullinemia, and hyperargininemia.[41,42] In patients with these disorders, MRS can detect elevated glutamine levels resulting from hyperammonemia, which can be reversed with treatment.

Mitochondrial disorders are caused by defects of intracellular energy metabolism and result in decreased ATP production.[43–45] Leigh disease is a multisystem disorder in which the defect may be at different enzymatic mitochondrial levels, including the pyruvate dehydrogenase complex, cytochrome c oxidase, or ATP synthase. Conventional and diffusion imaging shows abnormalities in signal intensity and mean diffusivity in the brainstem (pons, periaqueductal gray, substantia nigra, and medulla), the subthalamic nucleus, and the globus pallidus. MRS is used to detect lactate in these disorders. It should be noted, however, that an elevated lactate level is not specific for a mitochondrial disorder. Similarly, failure to detect lactate does not exclude the possibility of a mitochondrial abnormality.

Leukoencephalopathies include a broad spectrum of inherited and acquired diseases that affect white matter that are associated with genetic enzyme defects leading to myelin dysfunction and breakdown. These disease processes tend to present in infancy or childhood. Leukoencephalopathies can be classified in multiple ways, including (1) involvement of the primary cellular organelle; (2) biochemistry; and (3) location of primary involvement (periventricular, subcortical, white matter only, and gray and white matter). The MRS correlate of these white-matter disorders have been reviewed extensively.[33] One of the most exclusive pathognomonic MRS diagnoses is that of Canavan disease. Canavan disease is an autosomal-recessive disorder arising from a deficiency of the enzyme aspartoacyclase[46] that results in an accumulation of NAA in the brain. MRS shows marked elevation of the NAA peak (Fig. 25.4).

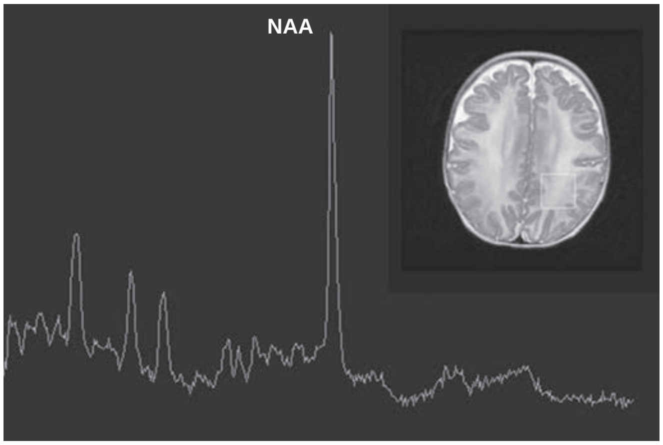

**Figure 25.4.** Elevated N-acetylaspartate *(NAA)* in a patient with Canavan disease.

## Pediatric Brain Tumors

### Posterior Fossa Lesions

Approximately 60% of all pediatric tumors arise from the posterior fossa. In most cases, these tumors are grade IV medulloblastoma or grade I pilocytic astrocytoma; grade II or III ependymoma are

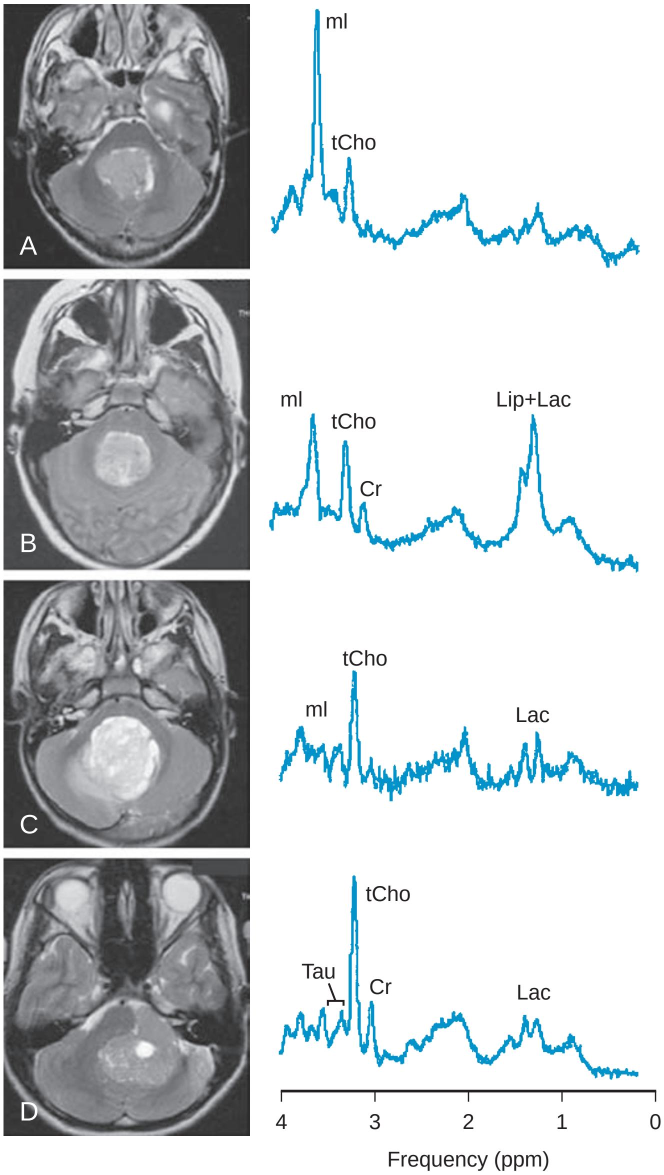

**Figure 25.5. T2-weighted MR images and MR spectra of posterior fossa tumors.** (A) Choroid plexus papilloma. (B) Ependymoma (grade II). (C) Pilocytic astrocytoma. (D) Classic medulloblastoma. All spectra were acquired from lesions with no partial volume of surrounding tissue using a single-voxel point resolved spectroscopy sequence with a short echo time of 35 ms. Shown are the original unfiltered spectra *(thin line)* and the LCModel fits to the data *(thick line)* (Stephen Provencher Inc., version 6.1-G4). In all four cases presented, MR spectroscopy provided clues to the correct diagnosis, which was different from the impression of the routine anatomic MR image. *Cr,* Creatine; *Lac,* lactate; *Lip,* lipid; *mI,* myo-inositol; *tCho,* total choline; *Tau,* taurine.

less common. Occasionally, a cystic/necrotic medulloblastoma may have imaging characteristics that overlap with posterior fossa pilocytic astrocytoma (Fig. 25.5). Grade I pilocytic astrocytomas may have high Cho/Cr and elevated lactate, similarly to high grade tumors. Taurine (Tau) elevation has been observed in medulloblastomas[47–50] and is an important differentiator of medulloblastoma from other tumors of the posterior fossa. Medulloblastomas also have higher levels of choline than other posterior fossa tumors.[51,52] The hallmark of pilocytic astrocytomas is very low Cr concentrations, low mI, and low tCho concentrations, consistent with their low cellularity. Lipids also are low in pilocytic astrocytomas, but mean lactate levels are higher than in other tumors. Ependymomas have higher mI levels than medulloblastomas or pilocytic astrocytomas; their choline levels are variable but generally fall between that of medulloblastomas and pilocytic astrocytomas.

### Supratentorial Tumors

Approximately 40% of all pediatric brain tumors arise outside the posterior fossa. Embryonal tumors outside the posterior fossa are central nervous system primitive neuroectodermal tumors (PNETs) or atypical teratoid/rhabdoid tumors (AT/RT). Supratentorial PNETs have metabolic profiles comparable to that of posterior fossa medulloblastomas, with prominent choline levels and presence of taurine. Atypical teratoid/rhabdoid tumors may have more moderate choline levels and typically no detectable taurine. A pilocytic astrocytoma outside the posterior fossa may show a slightly more prominent mI signal, but the metabolic pattern otherwise is quite comparable with that of cerebellar pilocytic lesions.

### Treatment Response

Conventional imaging does not reliably distinguish between recurrent/residual disease and postoperative changes or necrosis after radiation. Postradiation changes sometimes occur many months after therapy, and the correct diagnosis is a major challenge for patient management. Spectroscopy is an important tool to assess response to therapy in pediatric and adult brain tumors.[53–59] Effective therapy causing cell death will result in generally reduced metabolite concentrations (including tCho) and increased lipids because of the release of fatty acids from cell membranes. On the other hand, increasing levels of tCho (or tCho/NAA) are indicators for failed therapy and high risk for progressing disease.

## Neoplasia Versus Encephalitis

Accurate initial diagnoses are needed not only to distinguish different types of tumors but also to separate neoplastic from nonneoplastic disease. Acute encephalitis (mostly viral) can mimic conventional MRI characteristics of primary brain tumors. Accurate noninvasive diagnosis of encephalitis is important because it may prevent the risks of a more invasive procedure. Brain lesions resulting from acute encephalitis (mostly viral) can have reduced levels of mI compared with neoplastic processes.[60]

## Hepatic Encephalopathy

Hepatic encephalopathy refers to a broad spectrum of neurologic derangements associated with liver disease. MRS of hepatic encephalopathy typically demonstrates decreased levels of mI and choline and increased concentration of glutamate/glutamine (Glx) (Fig. 25.6). More recently, it has been demonstrated that MRS metabolites are correlated with plasma ammonia levels and the ratio of branched-chain to aromatic amino acids and can be useful to help establish a diagnosis of minimal hepatic encephalopathy in pediatric patients.[61]

## Pediatric Brain Trauma

Traumatic brain injury is the leading cause of morbidity and mortality in children and adolescents in the United States. Two age groups are at greatest risk: ages 0 to 4 years and 15 to 19 years. MRS may improve detection of parenchymal brain injury in children with severe head trauma and infants with suspected

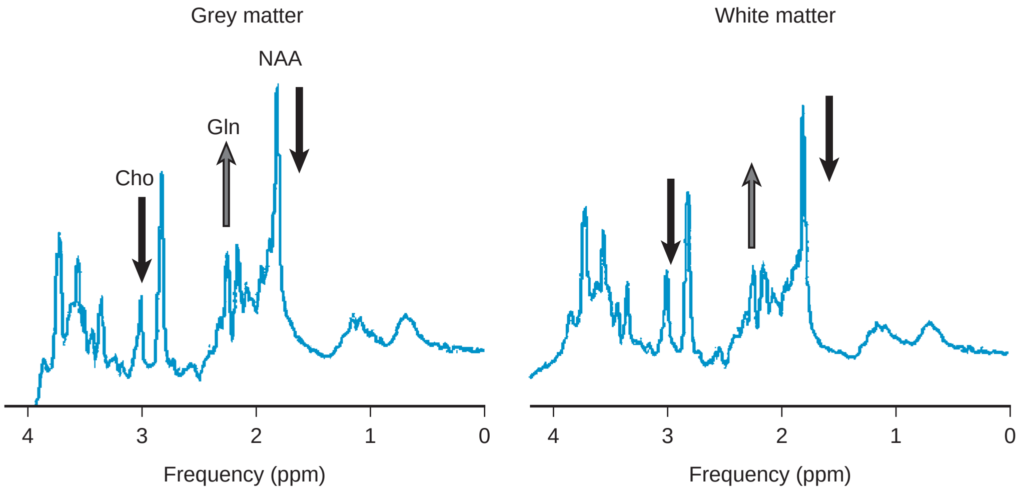

**Figure 25.6. Hepatic encephalopathy in a pediatric patient with iron intoxication and acute liver failure.** Magnetic resonance spectroscopy performed at 3T with point resolved spectroscopy and a time echo of 35 ms. Three voxel locations show an elevated glutamine *(Gln)* level, a reduced choline level, and a reduced myo-inositol level, indicating poor liver function. N-acetylaspartate *(NAA)* also is reduced, which may indicate neuronal/axonal loss/damage. Conventional magnetic resonance imaging was within normal limits. *ppm,* Parts per million.

inflicted head trauma. In pediatric head trauma, reduced NAA/Cr level and presence of lipid/lactate predicted poor outcome with high sensitivity and specificity.[62,63]

## QUANTIFICATION IN POSITRON EMISSION TOMOGRAPHY IMAGING

Positron emission tomography (PET) is able to quantify radioactivity concentration within a given region of interest. Analysis of tracer activity and its distribution can provide meaningful information on available receptor binding sites or biochemical processes. Three categories of methods in analyzing data are available: (1) qualitative analysis (visual assessment), (2) semiquantitative assessment such as standardized uptake value (SUV) and lesion-to-background ratio, and (3) absolute quantitative analysis using nonlinear regression, Patlak graphical analysis, and simplified quantitative methods.[64] Qualitative analysis requires minimal effort but has the least accuracy, whereas an absolute quantification method requires more complex procedures such as compartmental kinetic modeling to measure the individual rate constant based on data from dynamic image acquisition and serial blood sampling. Because of its complexity and time-consuming nature, this method is impractical in most clinical settings.

In clinical fluorodeoxyglucose (FDG)-PET studies, SUV is the most commonly used semiquantitative parameter. SUV is defined by lesion concentration of tracer per injected dose of normalized patient body weight multiplied by a decay factor:

$$\begin{aligned}\text{SUV} = {} & \text{Tissue activity concentration (MBq/mL)} \\ & \text{(Injected dose [MBq/mL]/Body weight [g]} \\ & \times \text{Decay factor of 18 F)}\end{aligned}$$

Compared with kinetic modeling, the SUV calculation is simple (without any need for arterial blood sampling) and faster (without dynamic image acquisition). Tissue SUV is known to have a highly correlative linear relationship with the rate of glucose metabolism measured by kinetic modeling.[65,66]

## POSITRON EMISSION TOMOGRAPHY AND BRAIN DEVELOPMENT

The FDG-PET metabolic pattern of a developing brain follows the order of anatomic, evolutional, and behavioral development.[67] Increased glucose metabolism demonstrated in the visual cortex, sensorimotor cortex, and cerebellum is correlated with early visuospatial and sensorimotor function and primitive reflexes. It also is known that hypermetabolism in the basal ganglia is associated with developing movement and sensorimotor function.

The degree of glucose metabolism of infants is known to be significantly lower than that of adults based on the quantitative analysis of brain FDG-PET. The current hypothesis is that increased metabolism is associated with increased metabolic demands from neuronal plasticity development. The metabolic level of the neonatal brains is about 30% that of adults, and it continues to increase with age. By the age of 3 years, the degree of metabolic activity exceeds that of adults, reaching its plateau between ages 4 and 9 years, with a value 1.3 times higher than that of healthy adults.[68] After this period, the metabolic activity continues to decrease to adult levels by the end of the second decade.[67] The overall degree of cortical metabolism significantly decreases with age, a consistent finding related to normal aging.[69]

The distribution of glucose metabolism of a pediatric brain becomes similar to that of young adults by the age of 1 year. The frontal lobe demonstrates more significant age-related metabolic changes compared with other parts of the brain. For the first 4 months of life, the frontal lobe has relatively low glucose levels, and the metabolic levels in this area gradually increase as frontal lobe–mediated cognitive function and complicated social interaction develops.

The remaining cortical areas such as the parietal, occipital, and temporal lobes have significant variations within and across age groups. The metabolic activity in the basal ganglia, thalami, hippocampi, cerebellum, visual cortices, and posterior cingulate gyrus is shown to remain stable at different ages, whereas the metabolic activity in the brainstem increases with age.[69]

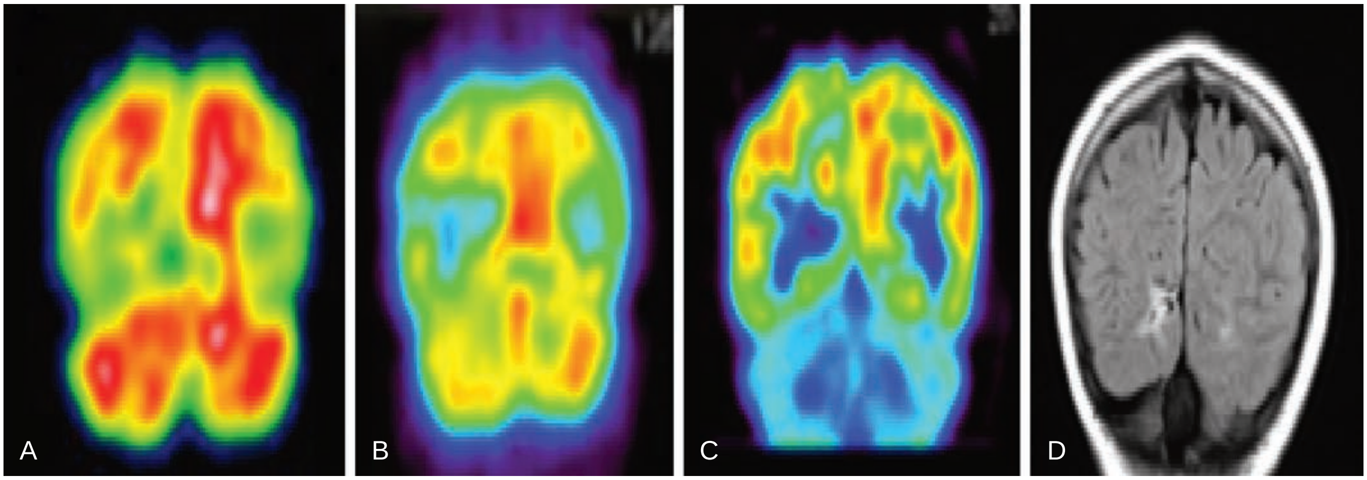

**Figure 25.7. Extratemporal lobe (right occipital) epilepsy in a 13-year-old girl with with localizing epileptogenic focus shown in interictal single photon emission computed tomography (SPECT), positron emission tomography (PET), magnetic resonance imaging (MRI), and nonlocalizing ictal SPECT.** (A) Ictal SPECT scan demonstrates an asymmetric perfusion pattern with relative hypoperfusion in the right occipital lobe. No focal hyperperfusion is noted. (B) Interictal SPECT scan demonstrates hypoperfusion in the right occipital lobe with an epileptogenic focus. (C) Fluorodeoxyglucose-PET scan demonstrates hypometabolism in the right occipital lobe with an epileptogenic focus. (D) Fluid attenuated inversion recovery MR image demonstrates hyperintensity in the right occipital lobe, suggesting an epileptogenic focus.

## POSITRON EMISSION TOMOGRAPHY IN PEDIATRIC EPILEPSY

The PET tracer most widely used in clinical practice for evaluation of brain glucose metabolism to localize epileptogenic focus is fluorine-18-deoxyglucose ($^{18}$F-FDG). FDG-PET is better suited for capturing the interictal state of epilepsy rather than the ictal state because of its long uptake period (40–60 minutes). The typical pattern of PET glucose metabolism of an epileptic focus is hypometabolism of the ipsilateral temporal lobe with or without less severe hypometabolism in the extratemporal structures such as the frontal lobe, parietal lobe, and contralateral temporal lobe. When anatomic lesions are associated with epilepsy, the extent of hypometabolism is known to be greater than the size of the structural lesion.[70]

The pathophysiology of regional hypometabolism in interictal FDG-PET is not clearly known, although several hypotheses have been proposed, including neuronal cell loss, neuronal inhibition, and diaschisis associated with hippocampal neuronal loss (Fig. 25.7).[71] However, conflicting evidence also exists, such as temporal hypometabolism without neuronal loss or gliosis[72] and a poor correlation between metabolic change in the temporal lobe and hippocampal cell count.[73]

Additional proposed hypotheses to explain interictal hypometabolism include an inhibitory process and reduction in synaptic density. Findings of several studies suggest that this secondary inhibition or neuronal loss in the area surrounding the epileptic zone can cause larger and more extensive hypometabolism in FDG-PET[71,74,75] and hypoperfusion in single photon emission computed tomography (SPECT)[76] than the area of involvement seen on electroencephalography or a pathologic correlate. Interictal FDG-PET is known to be more sensitive than MRI in localizing epileptogenic foci in cases of temporal and extratemporal epilepsy.[77]

About 29% of patients with partial or focal epilepsy have normal MRI findings.[78] Intracranial electroencephalography has limitations in this situation because of a lack of electrode targeting precision to the areas of suspected seizure origin. FDG-PET and ictal SPECT correctly localized epileptogenic zones in greater than 80% of patients in temporal lobe epilepsy.[79] In two studies, the localization rates by FDG-PET in patients with normal MRI findings were 57% and 32%.[80,81]

## PET/CT IMAGING OF PEDIATRIC BRAIN TUMORS

Recently, the use of PET for brain tumor imaging has increased. Currently the only radiotracer approved by the FDA is $^{18}$F-FDG, although other investigational agents show promise in specific situations.[82,83] In clinical practice, FDG-PET is being used as an adjunct tool in cases in which CT and MRI are unable to address a specific clinical question. The most common clinical indications of PET imaging include: (1) confirmation of the presence or absence of tumor; (2) help in establishing the grade of malignancy; (3) determination of the degree of treatment of the tumor or tumor response; and (4) distinguishing tumor recurrence from radiation necrosis (Figs. 25.8 and 25.9).[84] FDG-PET is known to be very sensitive in detecting high-grade gliomas. The high background uptake of FDG normally seen in the cortex results in less accurate detection of low-grade gliomas.[85]

## PET/MRI

Combined PET/MRI is a promising newer technology offering the potential application for novel molecular imaging with excellent soft tissue differentiation, lack of ionizing radiation from the MRI component, and simultaneous anatomic and functional data acquisition.

The first PET/MRI studies in humans demonstrated an excellent simultaneous performance of PET and MRI imaging without degrading image quality.[86] The diagnostic advantages of fused PET and MR images over PET/CT were shown by a 2006 study.[87] Moreover, PET/MRI is more beneficial to pediatric patients because it entails less radiation exposure compared with PET/CT. The ultimate role and utility of combined PET/MRI studies versus separately acquired and fused PET and MRI studies remain to be determined.

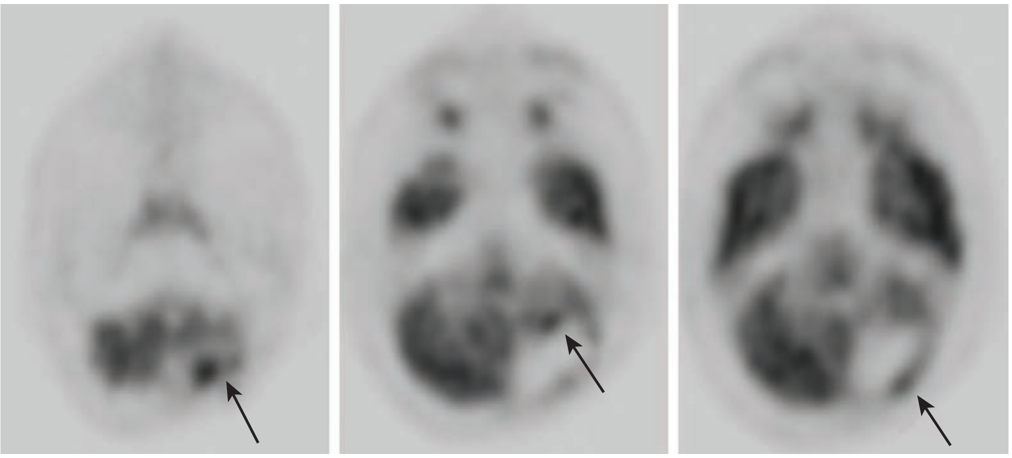

**Figure 25.8. An 18-year-old male with a history of anaplastic ependymoma in the left cerebellum, after having multiple surgeries.** FDG-PET brain scan demonstrates multiple areas of increased activity in the anterior and posterior resection margin consistent with malignant disease *(arrows)*.

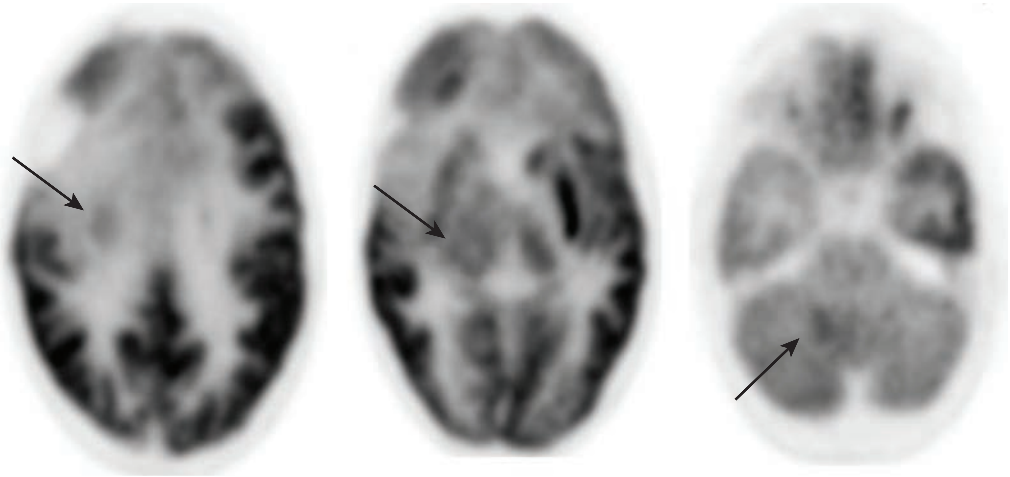

**Figure 25.9. A 9-year-old boy with an anaplastic astrocytoma after undergoing resection in the right frontal lobe.** Multiple areas of increased metabolic activity *(arrows)* are noted involving the right posterior medial frontal lobe, right basal ganglia, right thalamus, and the right cerebellum corresponding to areas of tumor infiltration seen with magnetic resonance imaging.

## KEY POINTS

- Proton magnetic resonance spectroscopy can provide metabolic information that can lead to more specific diagnoses of metabolic and neoplastic conditions.
- The presence of lactate indicates anaerobic metabolism.
- Long TE MRS is easier to use in clinical practice, although short TE MRS detects an increased number of metabolites and has a signal-to-noise advantage over long TE.
- Epileptic foci are typically hypometabolic at FDG-PET imaging. When anatomic lesions are present, the extent of hypometabolism is usually greater than the size of the structural lesion.

# Diffusion-Weighted Magnetic Resonance Imaging: Principles and Implementation in Clinical and Research Settings

*Jessica L. Wisnowski, Rafael C. Ceschin, and Vincent J. Schmithorst*

Of the advanced magnetic resonance imaging (MRI) modalities, diffusion-weighted (DW) MRI has probably garnered the most excitement in both clinical and research settings during the past decade. Standard now in nearly every neuroimaging MR protocol, DW-MRI has demonstrated substantial clinical utility in the detection of acute ischemia, the differential diagnosis of intracranial lesions, and the evaluation of white matter. Diffusion tensor imaging (DTI) and other high-angular resolution diffusion imaging (HARDI) models have been applied to the evaluation of normal developmental processes and pathology, particularly that which involves the white matter. Numerous postprocessing methods have been developed that not only allow for group level comparisons of the underlying "tissue microstructure" but also allow for estimation (and visual representation) of the underlying white matter "tracts." In this chapter, we will review (1) underlying principles of DW-MRI acquisitions; (2) basic diffusion-weighted imaging (DWI) acquisitions (its application in clinical settings); (3) DTI models and postprocessing methods, with emphasis on the strengths and potential pitfalls in both clinical and research settings; and (4) advanced diffusion imaging models.

## UNDERLYING PRINCIPLES OF DW-MRI ACQUISITION

At its core, DW-MRI involves the application of two additional pulses of magnetic field gradient (called "diffusion-encoding" or "diffusion-sensitizing" gradients) to a T2-weighted sequence after the excitation pulse but before the readout. During the first gradient pulse, spin precession is accelerated in accordance with the spatial position of the individual water molecules; spins associated with water molecules with a high Z coordinate, for example, will precess more quickly after administration of a gradient pulse along the Z direction, whereas spins associated with water molecules with a low Z coordinate will precess more slowly. Therefore the net effect of the first gradient pulse on the ensemble of spins is that the spins begin precessing at different rates and consequently "dephase," resulting in signal attenuation. The second gradient pulse is equal in direction, magnitude, and duration ($\delta$) to the first and is either of opposite polarity (in the case of a gradient echo acquisition) or of the same polarity (in the case of a spin echo acquisition) but placed after a 180-degree refocusing pulse. Assuming that the spins do not move from their original locations, the effect of the second gradient pulse will be to precisely undo the effect of the first and thus "rephase" the spins so there is no longer any signal attenuation due to spin dephasing. However, under physiologic conditions, water molecules possess thermal energy and therefore will move a finite distance away from their original locations during the time between gradient pulses ($\Delta$). Thus, the rephasing is incomplete and the signal will be attenuated compared with the signal with no diffusion-sensitizing gradients.

Assuming that the movement of water molecules is not hindered by any form of barrier (so-called "free diffusion"), the mean squared distance that the spins will move over a given period is described by the Einstein-Smoluchowsky equation and is linearly proportional to the time ($\Delta$) and to the self-diffusion coefficient $D$. The amount of attenuation is a function of the gradient strength $G$, gradient duration $\delta$, time between gradient pulses $\Delta$, and diffusion coefficient $D$. Typically $G$, $\delta$, and $\Delta$ are combined to derive the "b-value"; the higher the b-value, the greater the signal attenuation in the resultant DW images (Fig. 26.1). In fact, signal attenuation is exponential, where $S$ is the measured signal and $S_0$ is the signal in the absence of diffusion weighting. As a result, $D$ (measured in $mm^2/s$) can be estimated by obtaining DW images at different b-values or by obtaining images with and without diffusion weighting.

However, the diffusion of water molecules in the brain differs in two important respects from free diffusion. First, the diffusion of water is hindered by a variety of barriers, including axon sheaths and glial cell and astrocyte membranes. Hence the measured diffusion coefficient is not a self-diffusion coefficient and therefore is referred to as an *apparent* diffusion coefficient (ADC). Furthermore, the diffusion of water in the brain is not isotropic (i.e., independent of direction). For instance, diffusivity along an axon direction will be larger than diffusivity perpendicular to the axon. Hence, DW images often are obtained using a variety of gradient directions to infer information about the diffusivity of water molecules in different directions; the amount of attenuation in the DW images is dependent on the diffusion of water molecules only in the direction of the applied diffusion-encoding gradients.

It also is important to note that, because DW measurements reflect an *attenuation* of signal at a given spatial location, maintenance of sufficient signal to noise in the resultant data is an inherent challenge in DWI. Moreover, the time needed to acquire data sufficient for some of the most advanced postprocessing techniques, which require acquisitions at many different gradient direction and b-values, is often well outside of what is typically feasible in clinical settings and in many pediatric populations. Thus in practice, most pediatric DW-MRI studies generally are limited to the more basic DW-MRI models (i.e., DTI, described in a later section of this chapter), although recent developments provide hope that other techniques will become clinically feasible.

## DIFFUSION WEIGHTING, APPARENT DIFFUSIVITY, AND THEIR APPLICATION IN CLINICAL SETTINGS

Clinically relevant information is available even from a single DWI acquisition. For instance, diffusion is restricted in regions of cytotoxic edema after a stroke, and these regions therefore will be hyperintense on DW images. However, typical DWI acquisitions are strongly T2-weighted, because a long echo time is necessary as a result of the time needed to apply the diffusion-sensitizing gradients. Therefore it is important to distinguish hyperintensity on DWI that represents true diffusion restriction from hyperintensity that reflects tissue T2 prolongation (often termed "T2 shine-through"). This differentiation usually is performed by the additional acquisition of an image without diffusion weighting (e.g., $b = 0\ s/mm^2$) and quantifying ADC on a pixel-by-pixel basis, which subsequently can be represented in gray scale as an ADC map. Additionally, instead of a single DW acquisition, three DW

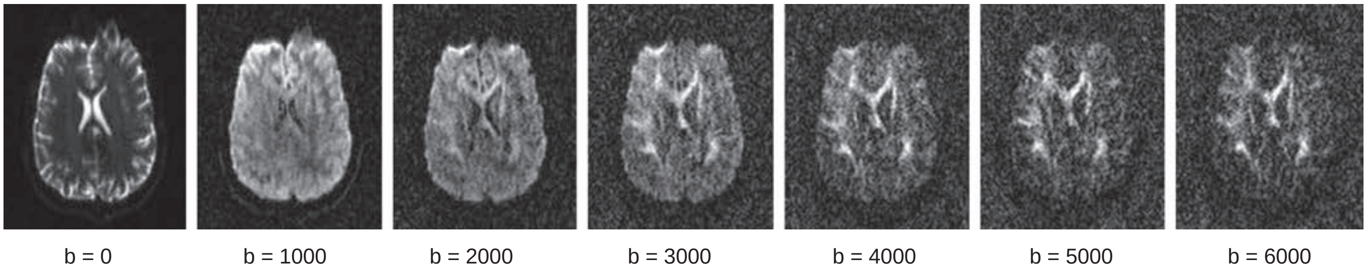

**Figure 26.1. Changing b-value.** Displayed are corresponding slices from a single subject imaged at multiple b-values. Notice how contrast between gray and white matter increases with the increasing b-value, whereas overall signal/noise ratio decreases. *(Author's Original.)*

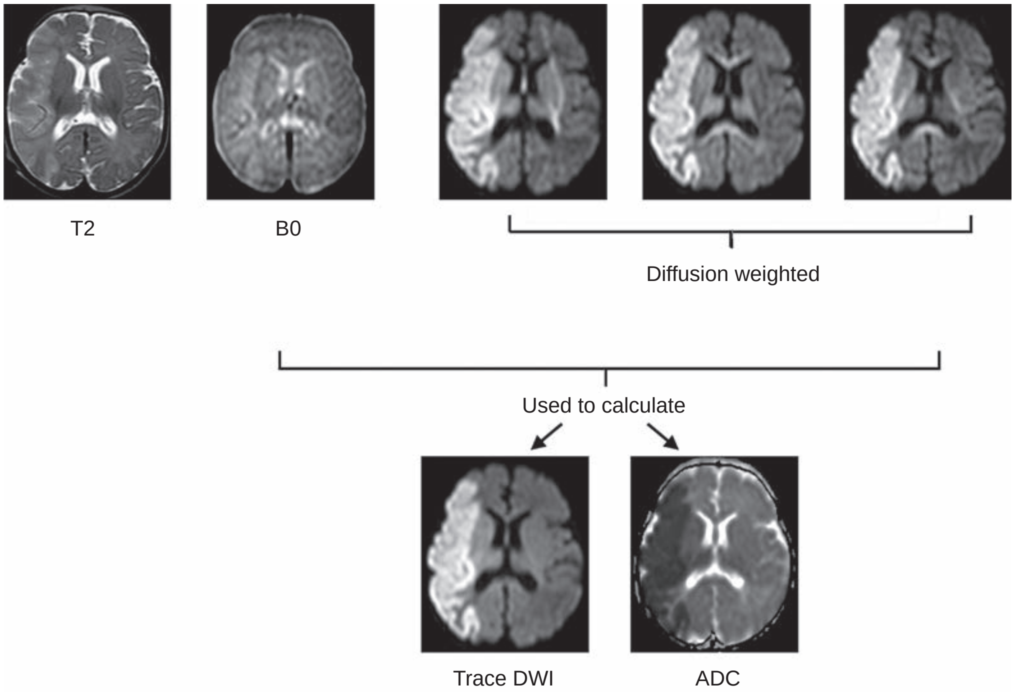

**Figure 26.2. Diffusion-weighted imaging demonstrated in a 3-week-old neonate with an acute stroke.** *(top row)* Corresponding slices from an axial T2-weighted and DW-MRI scan. In most protocols, three diffusion-encoding directions (rather than one) are acquired, averaged, and compared with the image without diffusion encoding (B0) to generate *(bottom row)* trace-weighted and apparent diffusivity maps that demonstrate areas of restricted diffusion as areas of high and low signal, respectively. Note that areas of directional anisotropy are visualized in each of the diffusion-encoding directions, but as a result of averaging, these areas are not apparent in the trace-weighted and ADC maps.

images typically are acquired using three orthogonal gradient directions, and the results are averaged to obtain *directionally averaged* DW images and ADC maps to minimize the effects of anisotropy. The directionally averaged ADC map is proportional to the trace of the diffusion tensor (described later), and thus the DWI images and ADC maps often are referred to as "trace-weighted DWI" and "trace diffusion tensor maps," respectively (Fig. 26.2).

As previously noted, in the past 2 decades, trace DW images with corresponding ADC values have demonstrated remarkable clinical utility in the detection of cerebral ischemia, before such injuries become apparent on T2-weighted MRI. Acutely, ischemia leads to energy failure, and more specifically, a failure of the Na+/K+–adenosine triphosphatase pumps in the cell membrane. This phenomenon, in turn, leads to an influx of sodium (and other ions) and water into the cell, resulting in cytotoxic edema and a concomitant decrease in ADC.

ADC values decrease within minutes after the onset of cerebral ischemia and reach a nadir around 3 days after onset, although this timing can be variable depending on the magnitude of initial insult, tissue reperfusion, and application of neuroprotective therapies (e.g., therapeutic hypothermia).[1–3] Subsequently, ADC values begin to rise, reaching "normal values" approximately 1 week after onset (i.e., pseudonormalization) and then continuing higher in the subacute/chronic phase, paralleling cell death and the resultant decrease in cell density.

Because ADC is not only sensitive to edema but also cell density, DWI is becoming the method of choice for imaging cancerous lesions. DWI has advantages over positron emission tomography

(PET) in that it does not use ionizing radiation or require injection of any radioactive tracer. Water diffusion decreases as cellularity increases; thus a low ADC is usually associated with a high degree of malignancy (Fig. 26.3). By contrast, high ADC values are typically observed in low-grade lesions or in association with a positive treatment response. Recent studies have now combined serial ADC measurements with quantitative postprocessing techniques (i.e., parametric response mapping), which not only allow treatment response to be characterized on a voxelwise basis but also provide quantitative biomarkers for use in clinical trials and in clinical practice.[4]

## DIFFUSION TENSOR IMAGING

Although three diffusion-sensitizing gradients are sufficient for calculating a directionally averaged ADC image, a minimum of six directions is needed to characterize diffusion anisotropy. Anisotropic diffusion is directionally dependent, as within white matter fiber bundles, and is distinguishable from isotropic diffusion, which is observed in free fluids (e.g., the lateral ventricles) (Fig. 26.4).

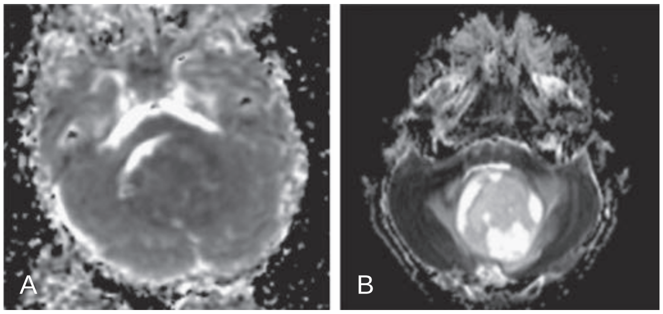

**Figure 26.3. Apparent diffusion coefficient and intracranial lesions.** (A) The ADC map demonstrates restricted diffusion in a tumor with high cellularity (a medulloblastoma). (B) The ADC map demonstrates increased diffusion in a tumor with low cellularity (a pilocytic astrocytoma).

To calculate anisotropy, DTI models diffusion as a tensor quantity (a 3 × 3 matrix) on a voxel-by-voxel basis. Typically, the matrix is rotated such that anisotropy may be described in terms of three coordinate axes ("eigenvectors"), with the principal axis (the one corresponding to the largest "eigenvalue" $\lambda_1$, also known as $\lambda_{\parallel}$, or axial diffusivity [AD]) being along the axis of preferred diffusion and the remaining two eigenvalues ($\lambda_2$ and $\lambda_3$) corresponding to vectors perpendicular to the principal axis. Eigenvalues $\lambda_2$ and $\lambda_3$ often are combined (averaged) to generate another metric referred to as radial diffusivity (RD) ($\lambda_{\perp}$). Importantly, although the 3 × 3 *diffusion tensor* may be ideal for estimating diffusion in a three-dimensional (3D) structure characterized by fiber bundles aligned in a single orientation, this model falls short if the underlying structure includes fiber bundles of different orientations (e.g., "crossing fibers"). Potential pitfalls associated with DTI will be discussed in further detail later.

The most common anisotropy metric derived from DTI data is fractional anisotropy (FA). FA is a scalar metric (rather than a vector) and represents the degree of anisotropy at a given voxel. It is calculated by comparing the estimated diffusion along each of the three eigenvalues in accordance with the following equation:

$$\mathrm{FA} = \frac{\sqrt{(\lambda_1-\lambda_2)^2+(\lambda_2-\lambda_3)^2+(\lambda_3-\lambda_1)^2}}{\sqrt{2(\lambda_1^2+\lambda_2^2+\lambda_3^2)}}$$

As can be determined from this equation, FA can range from 0 (when $\lambda_1 = \lambda_2 = \lambda_3$, i.e., isotropic diffusion) to 1 (when $\lambda_2 = \lambda_3 = 0$, i.e., fully anisotropic). In adults, typical white-matter values range between 0.9 and 0.4 depending on whether the measurement is obtained in a region where fiber bundles are heavily myelinated, tightly packed, and uniformly oriented (e.g., in the corpus callosum) or in a region where the organization deviates from that (such as in the vicinity of crossing fibers), respectively. FA values are much lower in neonates (ranging between 0.45 and 0.1) but rapidly increase toward the adult range in the first 2 years of life and then continue to increase at a much lower rate through adolescence into adulthood.[5–7]

Because of the higher water content in the neonatal brain and the fact that this increase in extracellular water is associated with increased diffusivity and increased signal attenuation in the setting

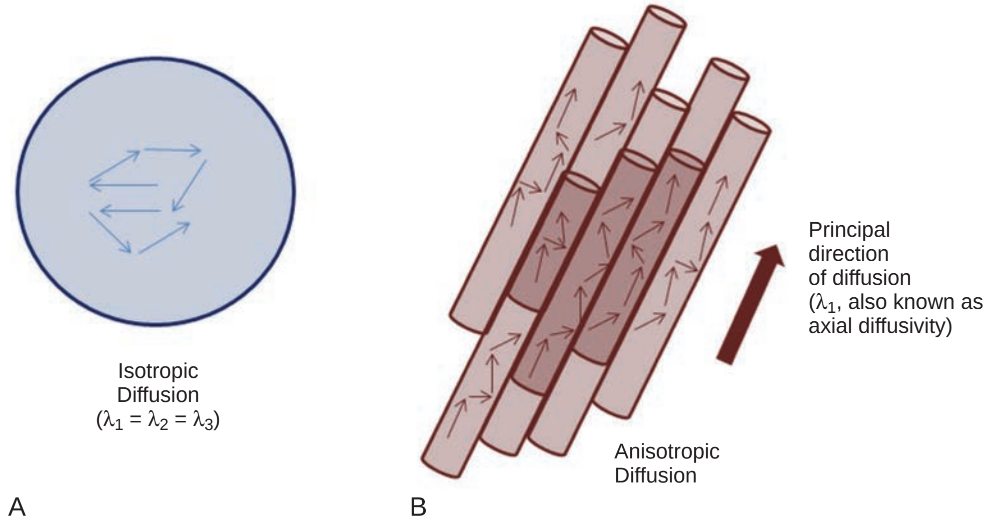

**Figure 26.4. Isotropic and anisotropic diffusion.** (A) Isotropic diffusion is exemplified by free diffusion such as in a large glass of water. (B) Anisotropic diffusion occurs when diffusion is greater in one direction compared with the others, such as in axons. By convention, the principal eigenvalue ($\lambda_1$) represents diffusion along the preferred axis.

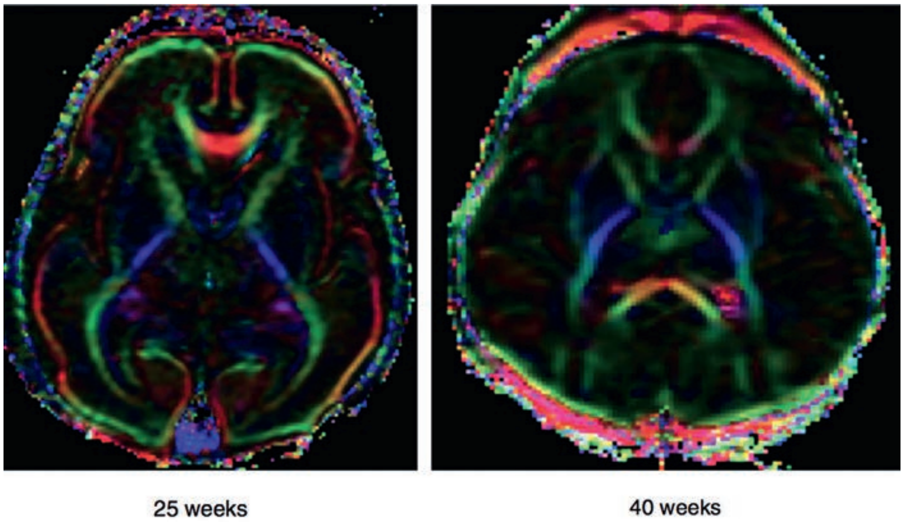

**Figure 26.5. Color fractional anisotropy maps reconstructed from diffusion tensor imaging data acquired from a preterm neonate at 25 weeks and a term neonate at 40 weeks.** By convention, voxels in which the principal eigenvector ($\lambda_1$) is in a left-right orientation (relative to the slice) are colored in *red,* voxels in which $\lambda_1$ is in an anterior-posterior orientation are colored *green,* and voxels in which $\lambda_1$ is in a superior-inferior orientation are colored *blue.* Note the presence of high anisotropy in the cortex of the neonate at 25 weeks and that, by term, the cortex has lower anisotropy than the adjacent white matter.

of diffusion encoding gradients, neonates often undergo imaging at a lower b-value (e.g., b = 700 s/mm$^2$).

To further enhance clinical utility, FA often is combined with information regarding the direction of the principal eigenvector, yielding a color FA map (Fig. 26.5). The typical convention is to color pixels red when the principal eigenvector is in the left-right direction relative to the 3D coordinate space, green when the principal eigenvector is anterior-posterior, and blue when the principal eigenvector is inferior-superior.

## Microstructural Integrity

The sensitivity of DTI to local (“microstructural”) tissue properties has rendered the technique a popular instrument for investigating the neuroanatomic underpinnings of various conditions (e.g., traumatic brain injury, multiple sclerosis, white-matter injury of prematurity, autism, and dyslexia, but also such areas as normal development, learning, and musical training) at the level of gray- and white-matter tissue microstructure. Moreover, DTI sequences are readily available in most commercial MRI scanners, with the acquisition time necessary for a typical 30- to 60-direction DTI sequence being between 5 minutes to less than 15 minutes. Accordingly, DTI is not only feasible in most pediatric patients but also is a potential key to understanding the neuroanatomic basis for a wide range of conditions, many of which are not associated with visible changes on conventional T1- and T2-weighted imaging.

However, the precise interpretation for many of the differences in DTI measures of microstructure remains to be determined. Pioneering laboratory work by Sheng-Kwei Song and colleagues in mouse models demonstrated that myelin loss alone (without loss or degeneration of axons) results in an increase in RD, leaving AD unchanged.[8] By contrast, direct axonal damage results in a decrease in AD.[9] Based on these findings, many researchers have drawn inverse conclusions on their own data—namely, that an increase in RD in a given white-matter region reflects primarily damage to myelin, whereas a decrease in AD reflects primarily damage to axons. Unfortunately, the inverse conclusion is not necessarily valid. First, most of the laboratory work supporting the interpretation of AD and RD in relation to axonal pathology versus myelin has been carried out in the optic nerve, spinal cord, or corpus callosum.[8–10] These structures are unique in the central nervous system in that they contain fiber bundles essentially aligned in parallel along a principal axis. By contrast, it has been estimated that as many as 90% of white-matter voxels in the cerebrum contain crossing fibers,[11] and it is not yet known how altering myelination or axonal integrity along a single fiber bundle, in the setting of multiple crossing fibers, would alter AD or RD. Accordingly, in the cerebrum, given available knowledge at this point, a more appropriate interpretation may be “altered microstructure,” with more specific conclusions being drawn from collateral information.

## Tractography

Some of the increasingly common—and most important—questions that researchers and neuroradiologists have aimed to address with use of DTI concerns anatomic connectivity (e.g., “Which cortical and subcortical regions are connected and by which fiber pathways?” “How strong are the connections between X and Y? … in this population compared with that one?”). To address these types of questions, most researchers and clinicians begin by constructing a visual representation of the white-matter fibers (or tracts). This task is carried out with the use of computer algorithms that regard fiber tracts as a continuous trajectory derived from local (voxel or pixel) estimates of fiber orientation (e.g., eigenvectors; Fig. 26.6). This technique is commonly known as tractography. It should be emphasized that no tractography method is capable of reconstructing axonal fibers or even fiber bundles. Rather, these methods compute trajectories or pathways represented by the data, which, it is hoped, parallel the predominant trajectories of the underlying axonal fiber bundles.

One of the most commonly used algorithms for tractography is known as fiber assignment by continuous tracking (FACT, also known as deterministic tractography).[12] This algorithm proceeds from an initially determined point (seed region) and propagates pixel by pixel in the direction of the principal eigenvector until a predetermined lower FA threshold or maximal turning angle is reached, at which point the fiber path is terminated (see Fig. 26.6). The result is a streamline, a visual representation of anisotropic diffusion, and importantly, not an actual visual representation of

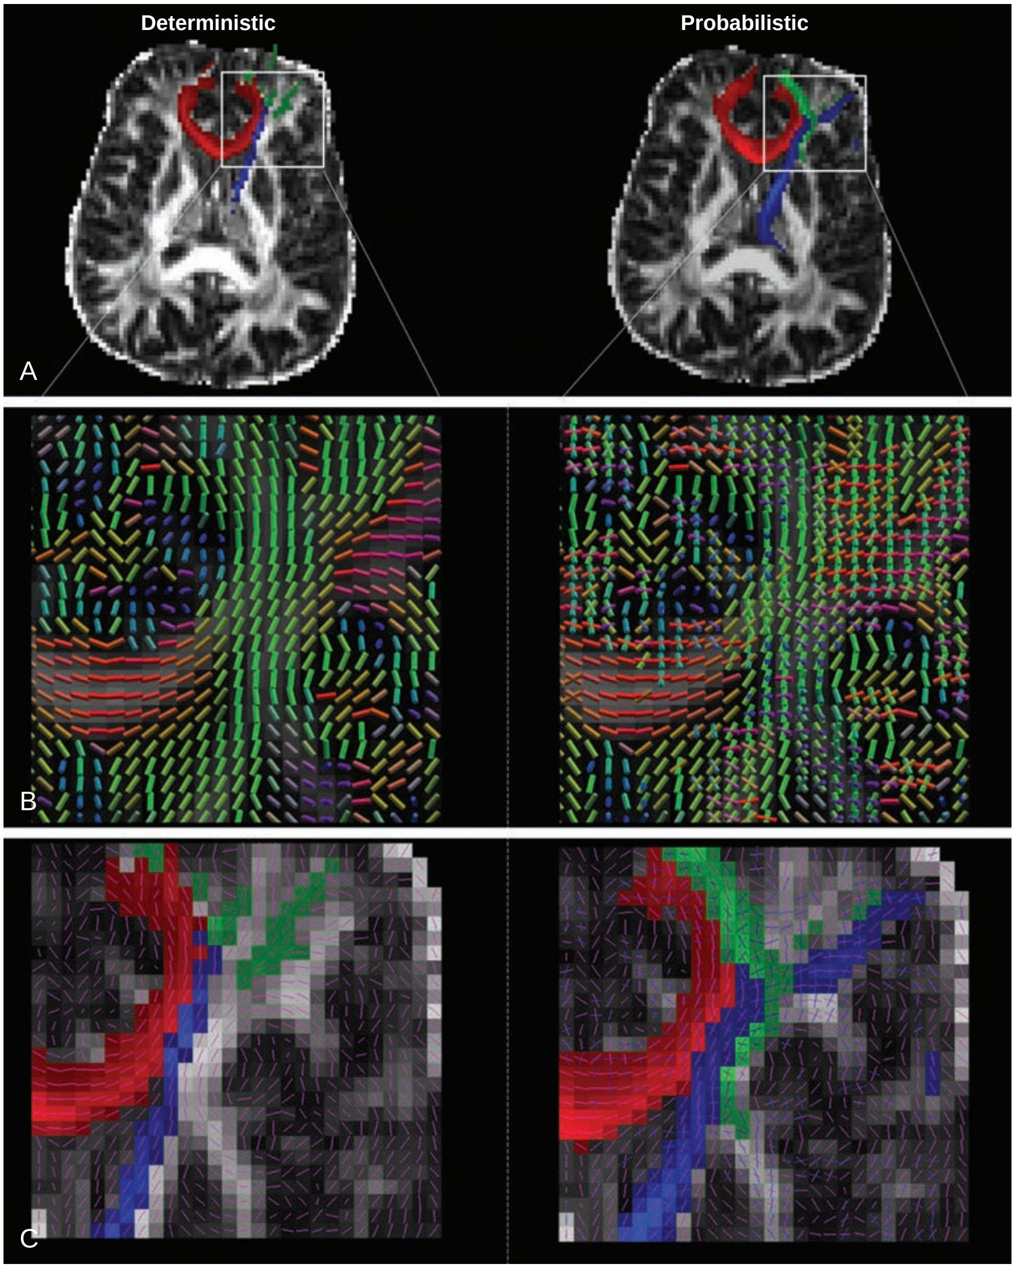

**Figure 26.6. Deterministic and probabilistic tractography.** (A) The same seed and waypoints were used to track anterior thalamic radiation *(blue),* genu of corpus callosum *(red),* and inferior frontooccipital fasciculus using deterministic *(left)* and probabilistic *(right)* algorithms on the same dataset acquired on a single subject. (B) In deterministic tractography, the direction of anisotropy is considered to be along the axis of a single, principal eigenvector, which is represented voxelwise in the image on the left. (Color convention is as described in Fig. 26.5.) In contrast, probabilistic tractography models anisotropy as a probability distribution and allows for a two-fiber solution, which is represented on the right, with the major axis being larger in scale compared with the minor axis. (C) The difference in output is clearly visualized in the region of the crossing fibers where, on the *left,* deterministic tractography (principal eigenvector overlaid as *pink lines*) fails to yield as many tracks as the output from the probabilistic algorithm on the *right* (again, principal and secondary eigenvectors are overlaid in *pink* and *blue,* respectively).

axons or fiber bundles. Moreover, the number of streamlines originating from a particular seed region is directly proportional to the number of seed points within a given voxel, and accordingly, not directly related to the underlying anatomic connectivity. However, assuming the same number of seed points per given voxel are used across populations of interest (which, in most software packages, is not a number that can be manipulated by the operator), the number of streamlines can be considered a proxy for the underlying tissue microstructure, and accordingly, may be used as a metric in group-level comparisons.

One of the key limitations in tractography is that the mathematical model used to reconstruct DTI data assumes that a single fiber population exists in each voxel. However, at the resolution of a typical DTI acquisition (≥2 mm in each dimension), many voxels contain populations of fibers oriented in some manner other than parallel (from one-third to 90%), including fibers that are crossing, fanning, branching, or bottlenecking.[11,13,14] This crossing fiber problem is a significant concern if one is trying to carry out tractography on DTI data. First, the main effect of crossing or other nonparallel fiber orientations on the principal eigenvectors is to decrease the principal eigenvalue. This effect, in turn, results in a decrease in FA, which can cause tractography algorithms to prematurely stop if the FA value has fallen below the predetermined threshold. Second, because the algorithm follows only the principal eigenvector, it may generate spurious streamlines (e.g., a streamline that propagates into a crossing region perpendicular to the principal eigenvector could be made to bend and then continue in the new direction).

One method to address limitations associated with using deterministic tractography and DTI parameters is to use the information derived from the diffusion tensor fit to generate a 3D probability distribution regarding the diffusion of water molecules instead of constraining the molecules to only move along the direction of the principal eigenvector.[13,15,16] In this way, probabilistic tractography algorithms allow water molecules to follow more than one orientation when passing through a voxel in a crossing region. Current probabilistic algorithms allow for the modeling of uncertainty of two (or more) fiber directions at each voxel. Tracking is done by launching a high number of streamlines from a seed region, and at each voxel—instead of deterministically following the principal eigenvector—drawing from the previously determined 3D probability distribution to propagate the tracts. Coherent fiber orientation is preserved by following the sampled direction most closely parallel to the previous location's direction, as opposed to only following an arbitrary angle threshold. After a sufficient number of samples, the output is a probabilistic mapping of the uncertainty of fiber tracts at each voxel, with the dominant streamline surfacing as most probable (see Fig. 26.6). Notably, this method does not resolve the crossing fiber problem with 100% certainty, but the resulting probabilistic map yields a much more robust estimate of the dominant fiber path when compared with deterministic approaches.[13,17] Moreover, it also shows improvements in the rendering of the lateral corticospinal and corticobulbar tracts and the medial portion of the superior longitudinal fasciculus, which typically are not visualized by deterministic tractography. Fig. 26.6 shows the comparison between deterministic and probabilistic algorithms in modeling fibers passing through a densely packed, high-fiber–crossing region of the brain. The probabilistic output shows significant improvement in delineating crossing fiber tracts, such as the inferior frontooccipital fasciculus and anterior thalamic radiation. Similar performance is noted in a single direction tract, as in the genu of the corpus callosum. Despite improved performance in modeling regions with crossing fiber tracts, probabilistic tractography still cannot completely overcome the limitation that the diffusion tensor model is not an adequate model for the underlying physiology in crossing fiber regions. This limitation requires more advanced approaches, as described in the next section.

## Advanced Diffusion Imaging Techniques

Advanced diffusion imaging techniques have been proposed to address the two major limitations of the DTI model: multiple/crossing fiber bundles and signal attenuation that deviates from an exponential decay with increasing b-value. Currently, these approaches have found limited clinical use because of their greater acquisition time and the greater computational resources needed for data analysis. However, with the increasing availability of multiband and other fast imaging techniques, higher order diffusion techniques will become possible in clinical settings.[18]

To address the problem of crossing fibers, HARDI methods (sometimes called "Q-ball")[16,17,19,20] sample a much larger number of diffusion directions (e.g., 64–256) than typical DTI acquisitions (e.g., ~30, although DTI analysis is possible with as few as 6). In addition to more directions, HARDI acquisitions utilize higher b-values (~3000 s/mm$^2$). As discussed earlier in this chapter, higher b-values allow for greater signal decay (see Fig. 26.1). At the same time, this signal decay will be most pronounced for the faster-diffusing extracellular water, thereby increasing the sensitivity toward slower-diffusing intracellular water (note the increased conspicuity of the white-matter tracks in the higher b-value images in Fig. 26.1). The HARDI sampling technique allows for modeling of orientation distribution functions (ODF) in lieu of simple tensors, in turn improving angular resolution and fiber detection. With these techniques, it is possible to model two, three, or even more crossing fiber bundles.

Higher b-values not only support better fiber detection, but also, when combined with additional b-weightings, further delineation of tissue microstructure due to the non-exponential nature of the signal decay. Biophysical models such as composite hindered and restricted model of diffusion (CHARMED) and neurite orientation dispersion and density imaging (NODDI) combine diffusion acquisitions at multiple high b-values (i.e., "multishelled" acquisitions) and advanced reconstruction techniques to model cellular geometry, diameter, and density/dispersion in grey and white matter.[21,22] Likewise, techniques such as diffusion kurtosis imaging (DKI) utilize multishelled acquisitions (albeit typically with fewer diffusion directions) to increase sensitivity toward pathologic changes, such as discriminating high and low grade glioma.[23,24]

The "ultimate" in DWI acquisition combines high directional resolution and multiple b-values, which allows for the most accurate specification of the water diffusion profiles, enabling the simultaneous modeling of crossing fiber bundles as well as nonexponential decay. This technique is called diffusion spectrum imaging (DSI) or Q-space imaging.[25,26] The acquisition demands are intense; a typical DSI protocol involves 512 separate DWI acquisitions, making the total acquisition time longer than 1 hour for a typical DWI acquisition protocol; however, ongoing efforts to optimize imaging parameters may soon make this feasible in clinical settings.[26]

### KEY POINTS

- The diffusion of water is hindered by a variety of barriers, including axon sheaths and glial cell and astrocyte membranes.
- The amount of attenuation in the DW images is dependent on the diffusion of water molecules only in the direction of the applied diffusion-encoding gradients.
- In addition to fluid homeostasis and intracellular water, DWI and ADC also are sensitive to the relative properties of water in the extracellular space.
- Because of the higher water content in the neonatal brain and because of the fact that this increase in extracellular water is associated with increased diffusivity and increased signal attenuation in the setting of diffusion encoding gradients, neonates often undergo imaging at a lower b-value (e.g., b = 700 s/mm$^2$).
- Tractography methods compute trajectories or pathways represented by the data, which, it is hoped, parallel the predominant trajectories of the underlying axonal fiber bundles.
- Advanced diffusion imaging techniques address the two major limitations of conventional tractography: multiple/crossing fiber bundles and signal attenuation that deviates from an exponential decay with increasing b-value.

# Functional Magnetic Resonance Imaging

James Leach

## PHYSIOLOGIC BASIS OF FUNCTIONAL MAGNETIC RESONANCE IMAGING

Functional magnetic resonance imaging (fMRI) is based on the blood oxygen level–dependent (BOLD) contrast effect and neuronal activity–cerebrovascular flow coupling. Oxygenated blood (oxyhemoglobin) is diamagnetic, producing little susceptibility-related dephasing on magnetic resonance (MR) signal. Deoxyhemoglobin is paramagnetic and elicits a more prominent effect on local field homogeneity and phase coherence, resulting in signal loss. Changes in the relative concentrations of oxyhemoglobin and deoxyhemoglobin in the vascular bed therefore result in changes in regional MR signal. The increase in cerebral blood flow that accompanies neuronal activity results in a relative increase in oxyhemoglobin concentration and a resultant localized increase in MR signal.[1] The actual physiology underlying the BOLD response is complex and is the subject of ongoing research.[2] Many anatomic and physiologic changes occur during brain development that have the potential to alter the BOLD response in children compared with adults.[3-6] Despite these physiologic differences, the basic BOLD response in children is generally similar to that in adults,[3,7] albeit with some task-related differences.[8] Neonates and infants may exhibit significantly different BOLD responses than do older children and adults, complicating interpretation in this age group.[9-11]

## TECHNICAL CONSIDERATIONS FOR FUNCTIONAL MAGNETIC RESONANCE IMAGING PERFORMANCE IN CHILDREN

The requirements for fMRI performance include an MRI scanner with gradient hardware capable of performing fMRI useable sequences, stimulation/presentation hardware and software linked to the scanner to allow for synchronization of stimuli and MR imaging, hardware and software for documenting patient responses, and postprocessing software for producing activation maps. The small BOLD effect changes in MR signal typically are detected by echo-planar imaging (EPI) T2*-sensitive gradient recalled echo techniques. Because of increased signal to noise and sensitivity for BOLD contrast effects, 3T scanners are preferred for fMRI studies.[12,13]

Performance of useful clinical fMRI examinations in children requires specialized preparation and resources. The patient is assessed for underlying neurologic deficits, developmental level, and ability to complete the fMRI paradigms. Explanation of the MR procedure and fMRI paradigms to the patient and parents in a calm, child-centered environment is critical. Practicing the fMRI paradigms is important to maximize performance and to adapt the tasks for the patient's clinical and developmental level. Video presentations and mock scanners are highly useful in preparing children for the fMRI environment.[14,15] Patient comfort should be maximized.

Patient motion can influence fMRI performance in children.[14,16] Despite some ability to retrospectively correct for head motion, gross head movement typically results in unusable fMRI data. Head coil bite bars, inflatable head cushions, and forehead and chin straps may be used but can be difficult to implement. Head motion is more pronounced in younger children and in boys.[16] Older children and girls have a higher rate of successfully completed examinations.[14] With care and adequate preparation, most children presenting for clinical fMRI studies can complete fMRI examinations with multiple administered paradigms.[17] The routine application of real-time fMRI processing can reduce the number of inadequate studies.[18]

For task-based fMRI examinations, repeated samplings of the brain (one brain volume scan during each repetition time period) while the subject alternates between active cognitive and control tasks typically is performed (the fMRI "paradigm"). Typical fMRI paradigms require 3 to 7 minutes of imaging time for acquisition of 100 or more image volumes during three to five cycles of alternating behavior. Although many approaches are possible, clinical fMRI is most commonly performed in a "blocked-periodic" design in which blocks of task and control (baseline) conditions are administered sequentially.[19] The fMRI paradigm that is used ideally will result in activation of brain regions involved with the sensory, motor, or cognitive task presented, without activation in other regions. The proper choice of control and task conditions is important to allow this distinction and must be carefully matched to elicit detectable BOLD signal and isolate the function of interest.[20,21] For successful performance of fMRI examinations in children, utilization of age and developmentally appropriate paradigms is mandatory.[14,21]

Imaging processing is required for fMRI and should involve the interpreting radiologist. After acquisition of images during the fMRI paradigm, the images typically are processed to diminish EPI artifacts, correct for susceptibility-related distortions, limit effects from patient movement during the paradigm, align and transform the T2* EPI images to a higher resolution anatomic dataset, and statistically analyze the images for BOLD signal changes between the task conditions on a voxel-by-voxel basis (the statistical map) (Fig. 27.1).[22,23] Increasingly, streamlined, clinically oriented options are being offered on most clinical MR systems or by a growing number of third-party vendors. The most common statistical tests used for clinical fMRI are the general linear model[22] and the cross-correlation method.[19] Determination of the optimum statistical threshold for use in individual clinical patients is a complex issue.[23,24] Evaluating fMRI studies at multiple different thresholds is important to maximize clinical effectiveness.

## CLINICAL APPLICATIONS OF FUNCTIONAL MAGNETIC RESONANCE IMAGING IN CHILDREN

Although many indications for pediatric fMRI are undergoing active research evaluation, the most common clinical use of fMRI in children is for presurgical assessment of language and memory function for patients with intractable epilepsy and evaluation of potentially eloquent cortex in patients with brain lesions (e.g., tumors and cavernous malformations).

### Limitations

Some fundamental concepts must be kept in mind when performing and interpreting fMRI studies in clinical patients.[25] For example, fMRI activation regions are not functionally specific, and lack of activation in a brain region does not indicate lack of critical brain function. The fMRI procedure is an indirect evaluation of neuronal function and relies on statistical mapping techniques that are not clinically standardized. The BOLD effect can be directly altered by pathologic states with changes in cerebrovascular autoregulation

## Abstract:

Clinical fMRI use in children primarily is used to assess eloquent brain regions before surgery relating to lesions or epilepsy. Clinical fMRI in children requires special preparation and resources, as well as developmentally appropriate fMRI paradigms. Somatosensory and language assessments are the most commonly performed fMRI examinations in clinical patients. Standardization of fMRI paradigms and interpretation, as well as better validation and outcome studies, are needed in pediatric patients. Newer techniques such as resting state fMRI hold promise to expand clinical fMRI applications to children who currently are unable to perform task-directed fMRI examinations.

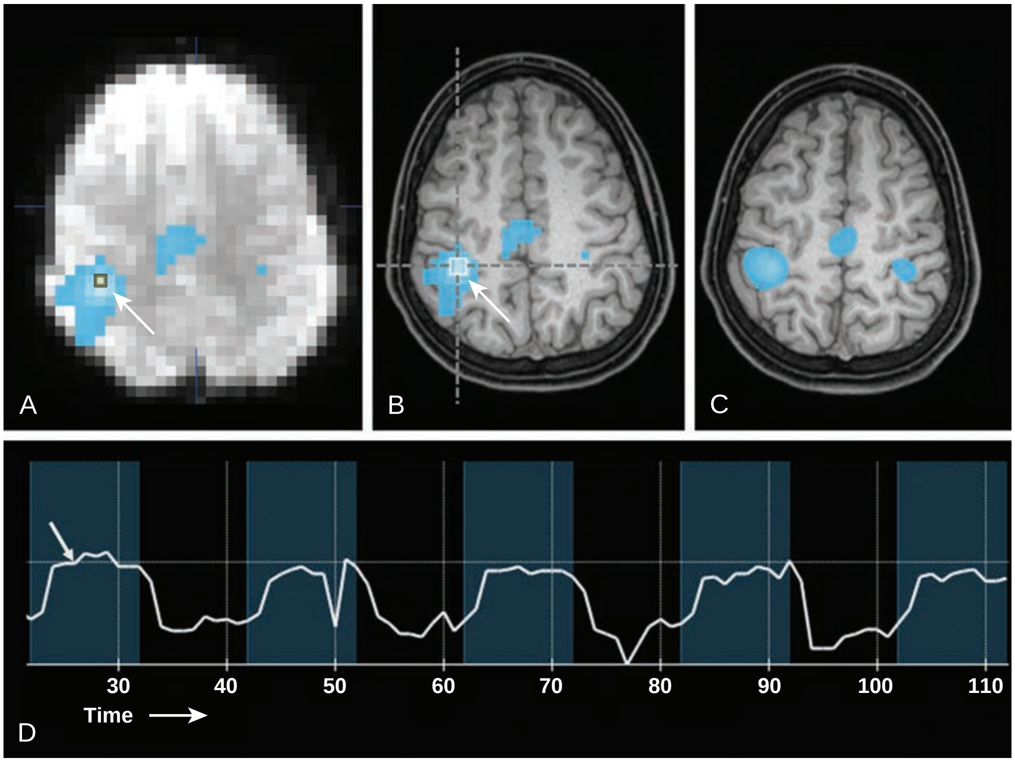

**Figure 27.1. Example of bilateral finger tapping functional magnetic resonance imaging (fMRI) and the effect of smoothing on the appearance of fMRI statistical maps.** (A) A source echo-planar image with an overlaid nonsmoothed statistical activation map. A single voxel region of interest *(arrow)* is located in the region of maximal statistical significance. (B) A nonsmoothed fMRI statistical activation map overlaid onto a 1-mm isotropic T1-weighted image shows activation overlying the right central sulcus in the hand motor region *(arrow).* Overlay onto anatomic MRI images allows the spatial relationships of the fMRI activation areas to be appreciated and related to anatomy and pathology. (C) An fMRI statistical activation map overlaid on a 1-mm isotropic T1-weighted image with smoothing applied to fMRI data. (D) Actual signal intensity within a voxel of interest (*arrow* in A) during the fMRI paradigm. Blue time periods are during finger tapping. Black periods are times of rest. Note the delay in the signal increase (hemodynamic response, *arrow*) after task initiation.

and neurovascular coupling,[26] including vascular steno-occlusion, tumors with high vascularity, and arteriovenous malformations.[26-28] Artifacts from regions of susceptibility effect (e.g., skull base, sinuses, hemorrhage, and prior surgery) may limit fMRI sensitivity. Sedation also can alter the BOLD response significantly.[29,30]

## Sensorimotor System Evaluation

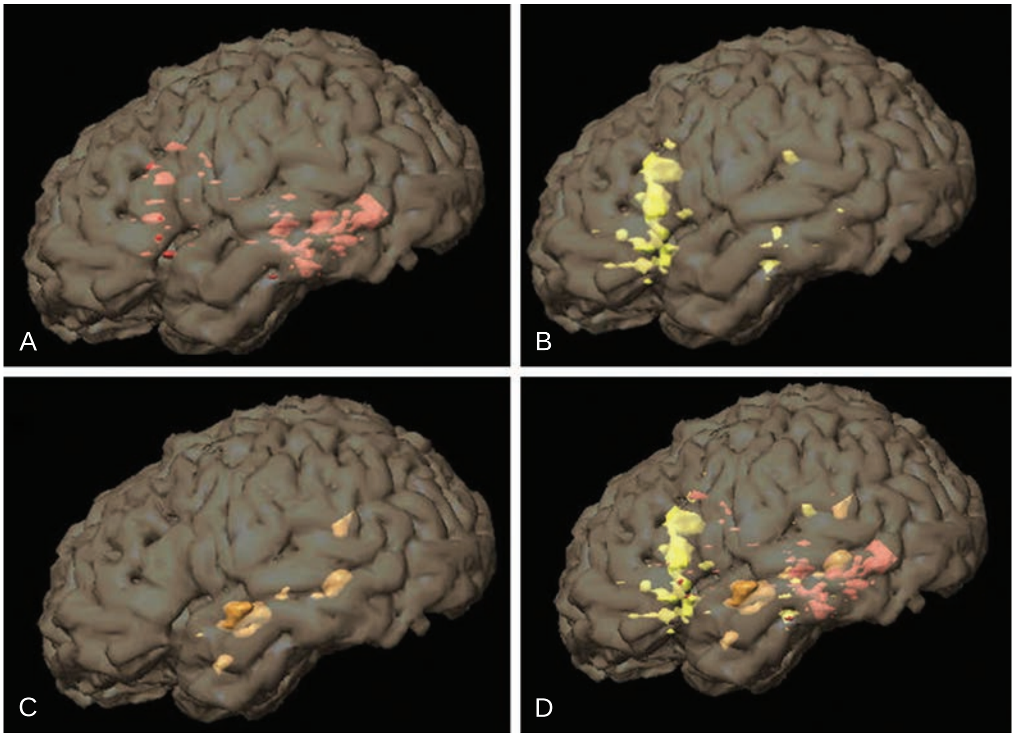
The most common and reproducible application of fMRI in clinical patients is assessment of the sensorimotor system (Fig. 27.2).[25,31] The fMRI activation areas are somatotopically arranged along the central sulcus. Secondary regions, including the supplementary motor area and premotor cortex, often are identified. Validation with direct electrocortical simulation (ECoS), the surgical gold standard, generally has been excellent,[32-35] with studies demonstrating nearly 100% concordance.[31] Sensorimotor fMRI evaluation is most useful when the normal anatomic relationships relating to the central sulcus are distorted by adjacent mass lesions; fMRI can help guide operative approaches in these cases (Fig. 27.3). High success rates of motor fMRI (93%) in children undergoing surgery for epilepsy have been documented.[36]

## Language Evaluation

Multiple clinical and fMRI studies have established that a left hemispheric dominance exists for semantic and phonologic language functions in most persons. Most fMRI studies of language lateralization in children have shown similar patterns of activation compared with adults, supporting the theory that language networks are established by early childhood. However, multiple cross-sectional and longitudinal fMRI studies have demonstrated changes in BOLD localization[21,37-41] with multiple language paradigms during development. In general, greater and more widespread activation is present in children compared with adults, which likely is related to differential brain maturation and performance differences. Hemispheric language dominance is related to handedness, with approximately 93% to 95% of normal right-handed adults and children being left hemispheric dominant for language, whereas approximately 15% to 20% of non–right-handed subjects (those who are ambidextrous or left handed) exhibit atypical (nonlateralizing or right-sided) hemispheric language dominance.[42,43] These findings should be kept in mind when interpreting language fMRI examinations in children.

### Paradigms for Language Assessment

Multiple fMRI paradigms have been created to assess different aspects of language function (Fig. 27.4 and e-Fig. 27.5). It is important to use multiple language tasks in clinical patients to more fully define language processing.[21,44-46] The use of multiple tasks reduces the likelihood of nondiagnostic findings, improves interrater reliability, and helps in the confirmation of language



**e-Figure 27.5.** Left hemispheric activation areas from language tasks in Fig. 27.4 are superimposed on three-dimensional (3D) segmented brain images, a very useful tool for presurgical mapping and understanding the 3D relationships between functional magnetic resonance imaging activation regions. (A) Verb generation. (B) Semantic decision. (C) Story processing (temporal lobe regions). (D) Combined activation regions.

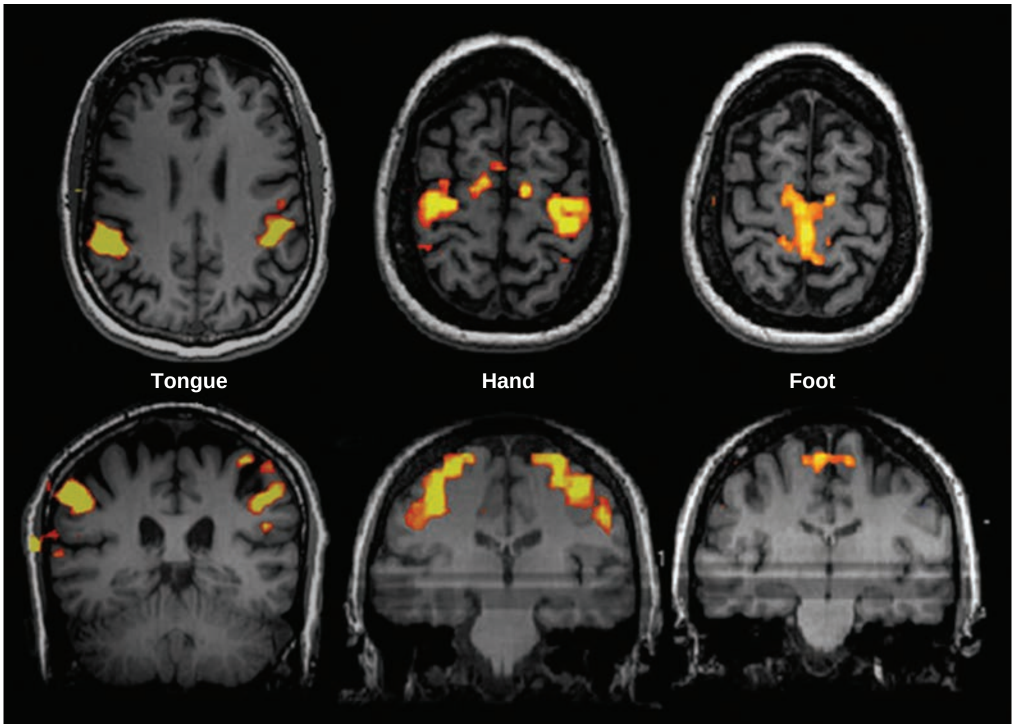


**Figure 27.2. Examples of different motor paradigms useful for clinical functional magnetic resonance imaging.** *Tongue:* Sequential tongue movement while the mouth is closed. *Hand:* Sequential bilateral finger tapping. *Foot:* Sequential bilateral foot flexion and extension. Typically performed clinical paradigms include sequential finger thumb opposition, hand grasping, wrist flexion and extension, foot flexion and extension, lip puckering, and tongue movement for motor strip assessment and tactile stimulation with brushes or air puffs for sensory component evaluation.

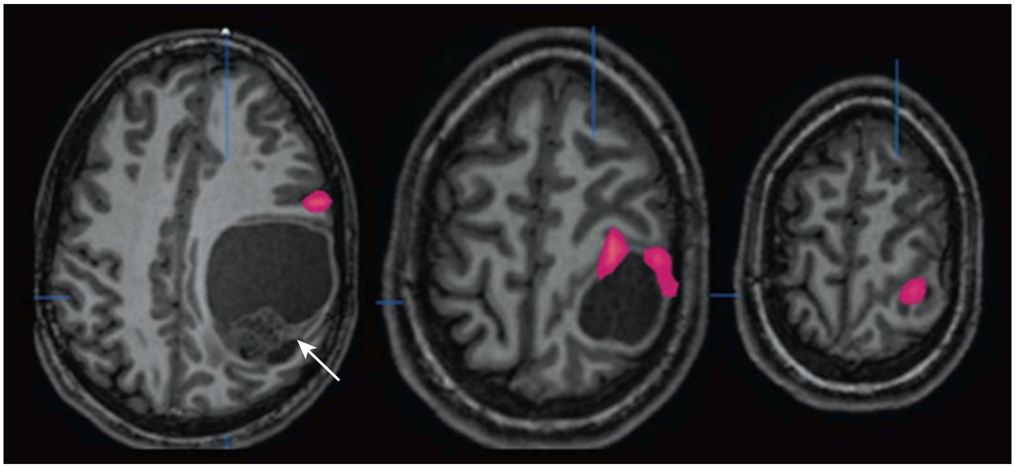

**Figure 27.3. A 15-year-old boy with progressive right-sided motor weakness.** Anatomic magnetic resonance imaging revealed a large cystic and solid mass within the left parietal lobe *(arrow)* that was markedly distorting normal anatomy; functional magnetic resonance imaging (fMRI) was requested to outline the location of the motor strip more definitively. An fMRI image obtained during right-sided sequential finger tapping demonstrates activation along the superior and anterior aspects of the mass. A posterior surgical approach was performed with gross total resection and no new deficit. Pathology revealed that the mass was an anaplastic ependymoma.

laterality.[46] Three of the most studied paradigms in children are verb generation, semantic decision, and story processing (see Fig. 27.2).

The verb generation task[37] (see Fig. 27.4A) involves the auditory presentation of a series of concrete nouns. The patient covertly (silently) generates as many verbs associated with the noun as possible. Control tasks include rest or bilateral sequential finger tapping.[37,38,47] The semantic decision task has been modified for children and involves the auditory presentation of single words (animal names)[44,48] (see Fig. 27.4B). The child makes a button press if the animal fits a target semantic property (e.g., “Does the

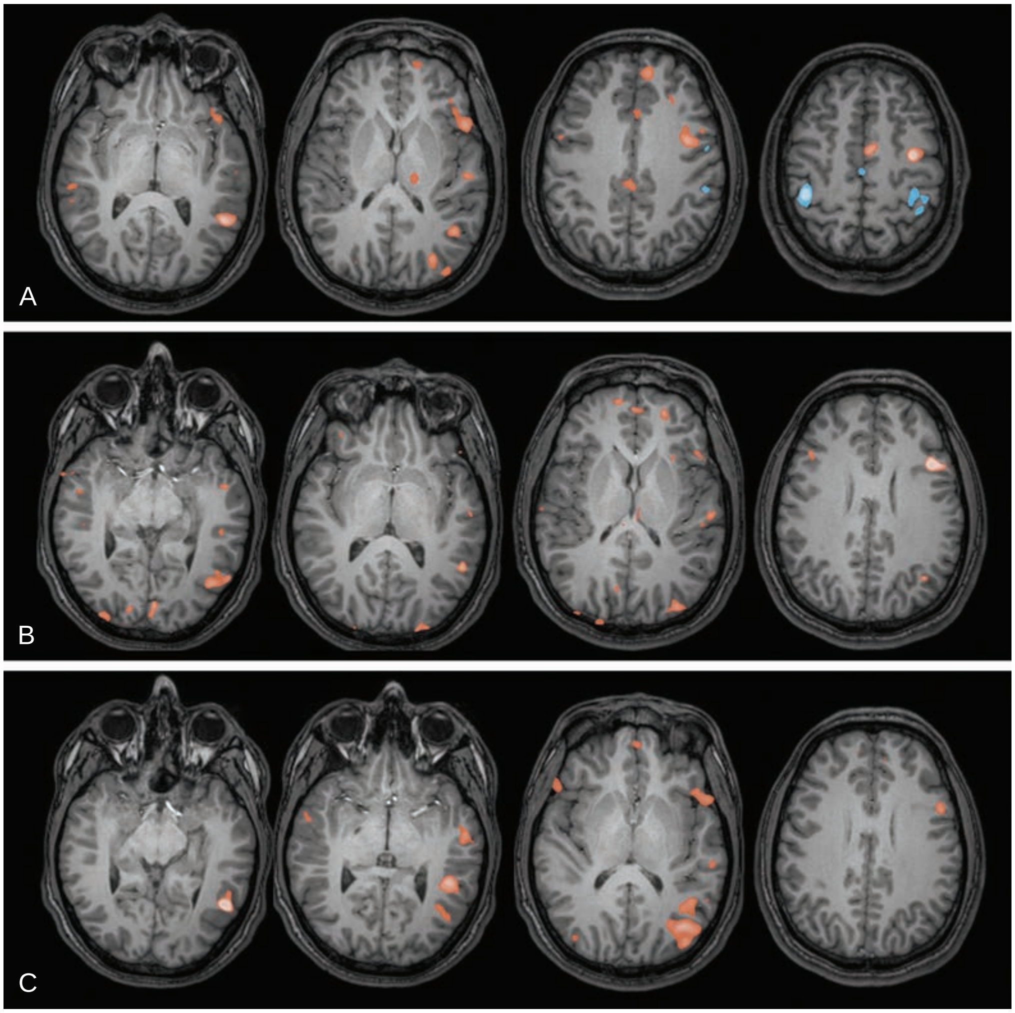

**Figure 27.4. Examples of language functional magnetic resonance imaging (fMRI) paradigms in a 12-year-old right-handed girl with intractable epilepsy.** (A) Verb generation (control task: finger tapping). A statistical map of fMRI activation during verb generation *(orange areas)* demonstrates left lateralization, particularly in the left inferior frontal lobe and left temporal lobe, which is typical for this paradigm. Activation during finger tapping is noted along both central sulci in the hand motor regions, as well as the putative supplementary motor area in the midline. (B) Semantic decision (control task: tone discrimination). A similar left lateralizing pattern is noted with robust inferior frontal and temporal parietal activation, which is typical for this paradigm. The semantic decision task provides an additional assessment of frontal and temporal language areas and has the added capability of allowing direct assessment of patient performance. (C) Story processing (control task: backwards speech). Clear left lateralizing activation is noted in the temporal lobe. Left lateralizing inferior frontal activation also is noted. These paradigms together indicate typical left lateralization of language in this patient.

animal walk on four legs?"). In the control condition, the patient listens to a series of tones for a specific tonal sequence. The story processing task[44,49,50] typically involves the auditory presentation of simple stories, each composed of sentences with specifically formulated complex syntactic constructions (see Fig. 27.4C). The control tasks are listening to various tonal sequences,[21] speech shaped noise, or identical periods of temporally reversed speech.[50] Other tasks such as linguistic prosody, read response naming, and auditory and reading sentence comprehension also have been used successfully with children.[44,51,52]

## Clinical Examination Interpretation

Interpretation of language fMRI in children can be difficult. Descriptions of language laterality and hemispheric dominance in clinical and research contexts typically have been described on the basis of a region of interest (ROI) "laterality" or "asymmetry" index (LI).[21,25] LI calculations are dependent on the statistical technique and threshold used for calculating activated voxels, ROI, and fMRI task.[53,54] They are more robust when ROIs targeted to typical language areas are used.[55,56] Use of multiple thresholds and fMRI tasks in individual patients to more completely assess language laterality is recommended.[53] Interestingly, visual assessment of lateralization in individual patients actually may be as good as ROI-based LI calculations.[52,57] Recent studies have shown that cerebellar activation laterality is an additional helpful feature when assessing language tasks. Contralateral cerebellar activation is typically seen[58] and can provide additional evidence for language laterality. fMRI examinations are interpreted in clinical patients as left hemispheric dominant (typical activation pattern), right hemispheric dominant, and bilateral or nonlateralizing language representation. Bilateral activation patterns can be problematic in evaluation of individual clinical patients because this fMRI pattern often cannot be conclusively interpreted.[53] Epilepsy,[59,60] perinatal stroke,[61] and prenatally or perinatally acquired lesions[62] can effect language development and lead to altered lateralization of language function (e-Fig. 27.6).

## Validation of Language Functional Magnetic Resonance Imaging

The traditional method for determining language dominance before surgery has been the Wada or intracarotid amobarbital procedure (IAP). Another method of language mapping is direct ECoS either during surgery with the patient awake or with use of subdural grid electrodes.[63] The IAP is expensive, invasive, and more difficult to perform in children.[63,64] It carries with it a small but definite risk of complications,[64-66] and its invasive nature limits repeated assessments.[67] Although it provides lateralization information, the IAP cannot spatially localize language functions in the brain, which is an advantage for fMRI.

Correlation studies between fMRI and IAP for language lateralization consistently have shown an 85% to 90% concordance rate,[20,65,66,68,69] with the use of multiple tasks increasing the degree of concordance.[55,56] Discrepancies are most common in patients who exhibit atypical language lateralization, particularly patients with bilateral, nonlateralized representation.[67,68,70] Discordance between fMRI and the IAP also is more common in patients with neocortical epilepsy (a more common scenario in pediatric patients than in the adult epilepsy population) and left temporal lobe seizure origin.[57] The few studies that have specifically compared language-based fMRI with the IAP in children have demonstrated concordance in 80% to 100% of patients.[67,71] The IAP is still useful when fMRI is not typically lateralizing, or when memory function is a critical concern. Although fMRI may not be able to replace the IAP in all circumstances, routine fMRI can diminish IAP utilization significantly.[72]

fMRI has been used in an attempt to guide resections near eloquent language regions. Because fMRI will demonstrate areas of the brain that are associated with, but not necessarily essential to, a particular task, fMRI will always exhibit a lack of specificity for language mapping in this scenario. Few direct comparisons between language fMRI and ECoS for regional language mapping have been performed, and the results have been variable. The sensitivity of fMRI in identifying critical language areas as established by ECoS varies from 22% to 100%, with specificities of between 61% and 100%.[73] A detailed study in adult patients with a brain tumor found an overall fMRI sensitivity of 80% and a specificity of 78% for critical language areas compared with the results of ECoS.[74] Despite the variable reported correlations, fMRI may be very useful to guide intraoperative ECoS procedures and for counseling parents and children regarding surgery in eloquent areas.[18,75,76]

## Other Indications

The fMRI procedure has been used to investigate a wide variety of clinical conditions in children, including the evaluation of reading and dyslexia, attention deficit–hyperactivity disorder, autism, and hearing loss,[77-79] to name a few. Clinical applications in these conditions are evolving and at present should be regarded as research tools.

Assessment of memory by fMRI is possible and has begun to be assessed in clinical patients. Clinical research studies have been performed that correlate fMRI activation patterns with the IAP[80,81] and postoperative memory after temporal lobe resection in adults,[81] with encouraging results; however, evaluation of the application in pediatric patients is incomplete. Hemispheric language laterality appears to be closely linked with verbal memory lateralization and has been used to predict verbal memory outcome after temporal lobectomy.[82]

The fMRI procedure, often in combination with other functional modalities (e.g., diffusion tensor imaging and magnetoencephalography), may allow for guidance during surgical access and resection using modern neuronavigation systems (functional neuronavigation).[83] Use of fMRI in conjunction with ECoS and frameless stereotaxy has been found to help facilitate tumor resection in children with a wide variety of lesions near eloquent cortical regions (e-Figs. 27.7 and 27.8).[84]

## ADDITIONAL TECHNIQUES

Newer techniques of fMRI acquisition and processing hold promise to expand the utility of fMRI in children. These techniques include advanced connectivity analyses of fMRI data and fMRI performed in the so-called *resting state*.[85] Resting state fMRI (rsfMRI) analyses have begun to be used in evaluating the functional networks in the developing brain[86,87] (e-Fig. 27.9) and may have particular clinical use in identifying functionally important cortex and networks in patients in which task-based fMRI examinations are not feasible (e.g., in neonates, infants, and sedated patients). Although currently primarily a research tool, initial clinical applications have been described in adults and children.[88,89] Evaluation of rsfMRI data does require more sophisticated analysis tools; however, some institutions are applying rsfMRI techniques routinely to presurgical planning with good results.[90]

### KEY POINTS

- Clinical fMRI in children primarily is used to assess eloquent brain regions before surgery relating to lesions or epilepsy.
- Clinical fMRI in children requires special preparation and resources, as well as developmentally appropriate fMRI paradigms.
- Somatosensory and language assessments are the most commonly performed fMRI examinations in clinical patients.
- Standardization of fMRI paradigms and interpretation, as well as better validation and outcome studies, are needed in pediatric patients.
- Newer techniques such as resting state fMRI hold promise to expand clinical fMRI applications to children who currently are unable to perform task-directed fMRI examinations.

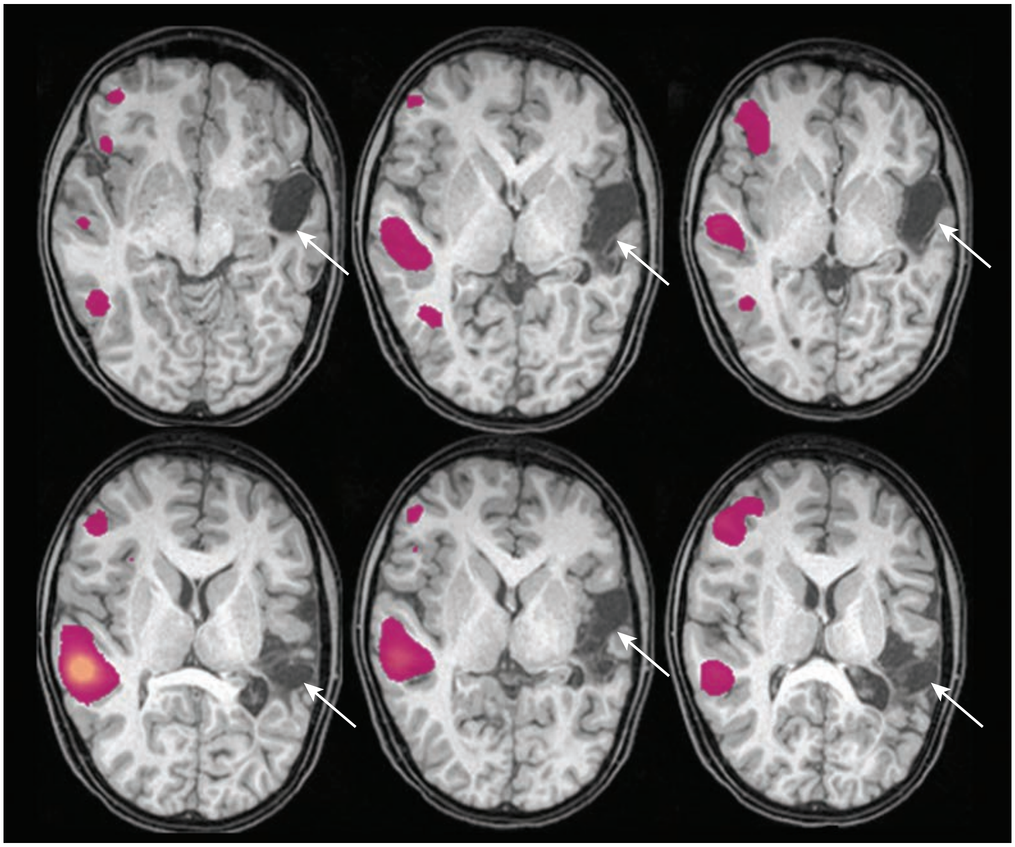
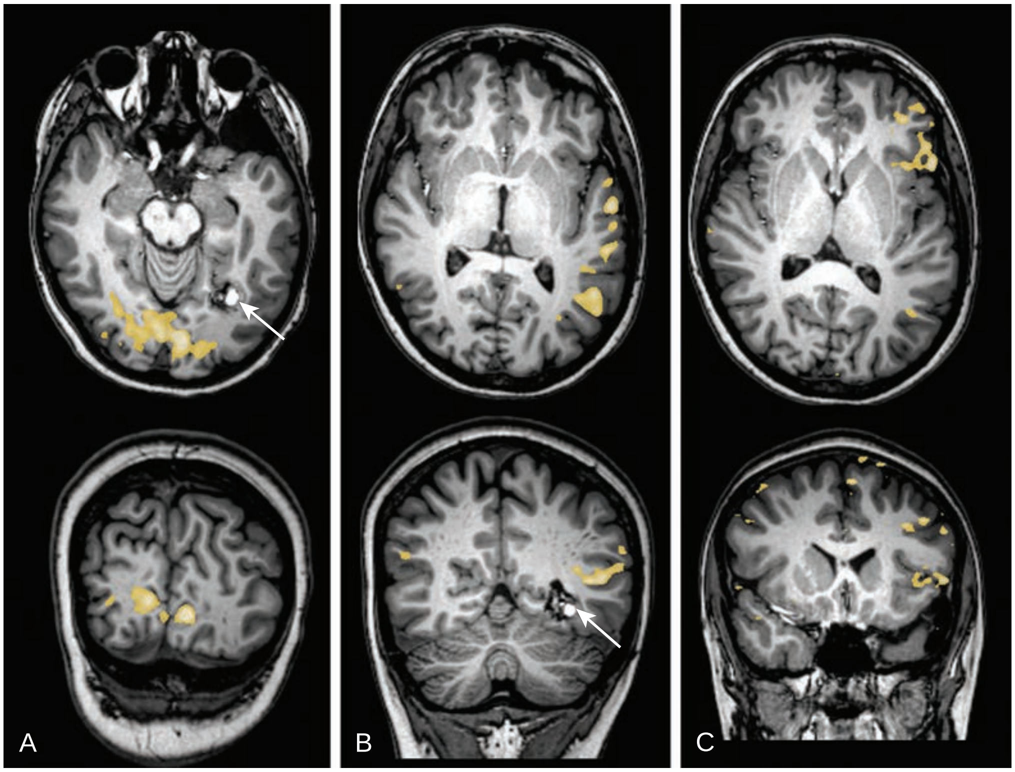
### REFERENCES

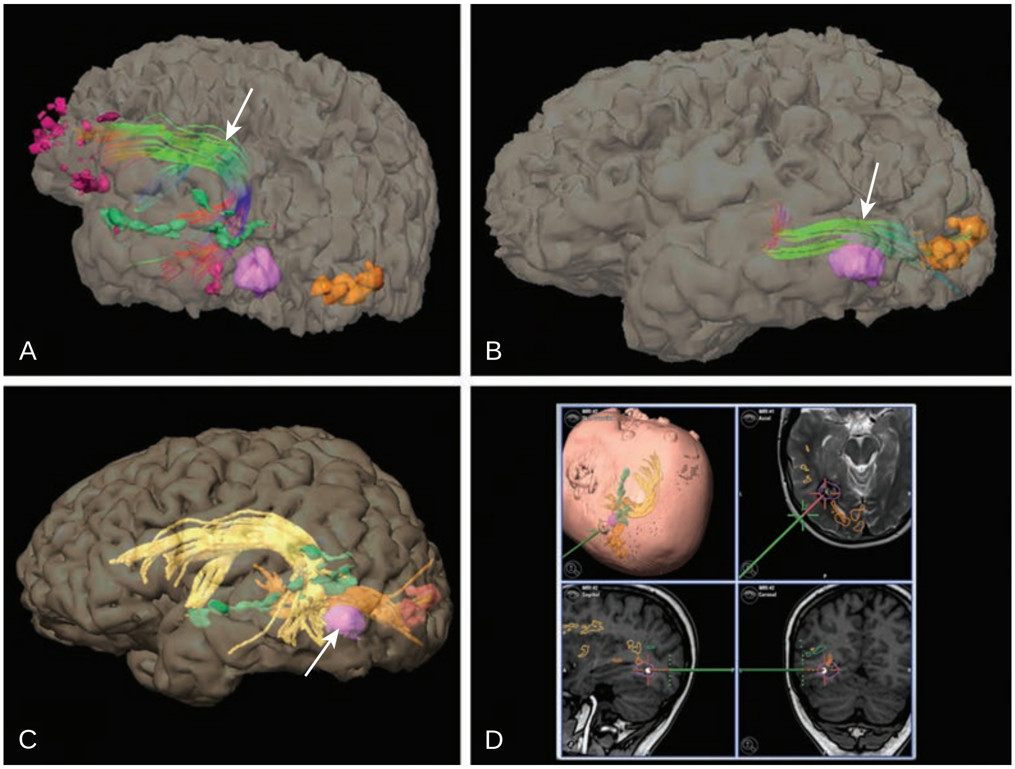
Full references for this chapter can be found on www.expertconsult.com.



**e-Figure 27.6. An 11-year-old boy with intractable epilepsy and a history of perinatal left middle cerebral artery infarct.** Large areas of encephalomalacia are identified in the left hemisphere *(arrows).* Statistical activation maps demonstrate clear right lateralization of activation with verb generation in right hemispheric homologous regions. Right hemispheric dominance for language was confirmed by an intraarterial amobarbital procedure.



**e-Figure 27.7. A 15-year-old boy with seizures and headache.** A cavernous malformation *(arrows)* is identified in the left inferior medial occipital lobe along the temporal occipital junction. The patient was referred for functional magnetic resonance imaging and diffusion tensor imaging–tractography to aid in operative planning. (A) A visual stimulation paradigm demonstrates activation along the calcarine fissure medial to the lesion. (B) A story processing task demonstrates activation along the left temporal lobe very asymmetric to the right, lateral, and slightly superior to the plane of the lesion. (C) A verb generation task demonstrates clear left lateralization of activation in the frontal and temporal parietal regions. Verb generation and story processing tasks were consistent with left hemispheric lateralization of language.



**e-Figure 27.8. Utility of combined functional magnetic resonance imaging (fMRI) and tractography for operative planning** (same patient shown in e-Fig. 27.6). (A) Tractography is performed to outline the arcuate fasciculus orientation *(arrow)* using fMRI activation regions to guide seed points. *Dark purple areas:* fMRI activation regions from verb generation. *Green areas:* fMRI activation areas from a story processing task. *Light purple area:* cavernous malformation (surgical target). *Orange areas:* fMRI activation regions from visual stimulation. The posterior arcuate fasciculus is anterior to the lesion. (B) Tractography is performed to outline the geniculocalcarine tract *(arrow).* The geniculocalcarine tract lies directly above and touches the superior aspect of the lesion. (C) Because of the close proximity of the lesion *(arrow)* to functionally important regions, integration of the tractography and fMRI data with anatomic images was performed. Objects were created from the lesion, temporal lobe language areas as demonstrated by a story processing task, arcuate fasciculus, and geniculocalcarine tract. (D) Images captured during surgery demonstrating the operative approach, which was guided by anatomic and functional imaging. Complete resection was performed with no neurologic deficit. *(Intraoperative images courtesy of Francesco Mangano, DO.)*

## PERFUSION IMAGING

In the cerebrovascular literature, perfusion imaging refers to an all-encompassing term of various methods to measure hemodynamically derived functional parameters in the brain.[1,2] In radiology, the three most common parameters that are assessed and utilized clinically are cerebral blood volume (CBV), cerebral blood flow (CBF), and mean transit time (MTT). CBV refers to the amount (volume) of blood within a given mass of brain tissue at a given time and is measured in mL/100 g. CBF refers to the flow of blood through an area of the brain and is usually measured in mL/100 g of brain tissue per minute. MTT refers to the time it takes for blood to flow between the arterial inflow and venous outflow in the brain, that is, the time that blood spends in the cerebral capillary circulation and is often measured in seconds. The general relationship between these three parameters is depicted by the central volume theorem:

$$\text{CBV} = \text{CBF} \times \text{MTT}$$

A parameter that is being increasing used recently along with MTT is Tmax, or the time to maximum tissue residue function after deconvolution of the tissue contrast agent concentration. Evaluation of these various perfusion parameters can give us an understanding of the physiologic state of the brain and cerebral vasculature in various disorders and help in patient management. Cerebral perfusion can be measured by a variety of methods including magnetic resonance imaging (MRI), computed tomography (CT), and nuclear medicine techniques. These techniques differ in terms of image acquisition duration, spatial resolution, the types of endogenous or exogenous tracers used, and their ability or accuracy in measuring different perfusion parameters.[1] The clinical applications of perfusion imaging include investigation of cerebrovascular disease, brain tumors, and the effect of other diseases on cerebral perfusion.

## Perfusion Magnetic Resonance Imaging

Perfusion MRI can be performed via the injection of dynamic gadolinium-based contrast material or without contrast material injection by tagging intravascular protons using MR labeling schemes (i.e., arterial spin labeling [ASL]).

### Dynamic Susceptibility Contrast Perfusion Magnetic Resonance Imaging

Dynamic susceptibility contrast (DSC) perfusion MRI is based on susceptibility effects using T2-weighted or, more commonly, T2*-weighted images and is the most commonly studied and clinically used perfusion technique in assessment of brain masses and stroke. This method is based on the principle that the signal change that occurs during passage of a high-concentration bolus of gadolinium contrast material in the vessels causes a difference in susceptibility between the vessels that contain contrast material and brain tissue, and this signal change can be converted to a relaxation rate change proportional to the fraction of blood volume within each voxel.[3,4] Data generally are acquired during first-pass perfusion over approximately 1 minute, during which time a high-concentration bolus of gadolinium chelate is rapidly injected intravenously. Time-signal intensity curves drawn during this acquisition will show a rapid decline in signal as the contrast enters the brain, with return of the signal to near baseline after the first pass (Fig. 28.1). These measurements are used to construct a relative CBV map, and the time signal intensity curve can be used to derive other perfusion parameters by various mathematical methods.[1,5,6]

To provide adequate temporal resolution during dynamic contrast administration, most centers currently use gradient echo planar imaging sequences to perform clinical DSC perfusion MRI.[7–9] This technique is very sensitive to structures that cause magnetic field inhomogeneity such as blood, calcium, bone, metals, or air interfaces such as the skull base. The use of DSC imaging entails multiple technical considerations.[10,11] Accuracy of CBV maps can vary substantially depending on the acquisition and postprocessing methods used.[6] It is important to take into consideration the type of acquisition used in applying research results for characterization of lesions, because the results and thresholds may vary.[12] Derivation of the perfusion parameters also depends on the mathematical models used by the processing software, and caution must be exercised in comparing results from different calculation methods.[13,14] Sometimes a small prebolus dose of contrast material is given before the actual DSC acquisition to correct for leakage and more accurate calculation of the perfusion parameters.[6,10]

DSC perfusion applications are used predominantly to assess cerebrovascular disease and in brain tumor evaluation (e-Fig. 28.2). DSC perfusion can assess the ischemic penumbra in persons who have had an acute stroke and aid in their imaging triage and management.[15,16] DSC perfusion has been used in differentiation of brain tumors from other mass-like lesions in the brain, preoperative grading of brain tumors (higher grades generally have higher CBV), differentiation of primary high grade from metastatic tumors, assessment of treatment response, and as an adjunct in differentiation of radiation necrosis from a recurrent tumor.[1,17–23]

### Arterial Spin Labeling Perfusion Magnetic Resonance Imaging

ASL perfusion imaging does not require exogenous contrast injection. It uses magnetically labeled arterial blood water as an endogenous flow tracer.[24] A general scheme of the ASL technique is illustrated in Fig. 28.3. Two sets of images are obtained, one as a baseline image of the brain and the other after labeling (or tagging) blood arterial water protons in the neck using an inversion or saturation radiofrequency pulse. This second set is obtained after a short time delay that allows the labeled blood to flow into the imaging slices. If the baseline and postlabel images are subtracted from each other, the resulting subtracted image is proportional to blood flow that has entered the brain. Quantitative measures of CBF can then be derived from the subtracted images. Numerous schemes exist for ASL tagging and imaging (such pulsed ASL, pseudocontinuous ASL, velocity-selective ASL, and their subtypes).[25] Typically, echoplanar or spiral nonechoplanar techniques are used for image acquisition. ASL imaging takes significantly longer than DSC perfusion MRI because the signal change resulting from the ASL is very small (in the order of 0.5%–3%), and therefore numerous signal averages need to be acquired to gain acceptable signal to noise. Imaging at 3 Tesla significantly increases the signal and quality of ASL images. Given the requirement for image

## Abstract:

Cerebral perfusion imaging encompasses various methods of measuring hemodynamically derived functional parameters in the brain. These various parameters provide important physiologic insights into cerebrovascular health and disease. Other applications of perfusion imaging including neuro-oncologic uses and the assessment of various disease states on cerebral perfusion. There are various techniques including computed tomography, magnetic resonance imaging, or nuclear medicine radioisotopes to assess cerebral perfusion. Arterial spin labeling is a group of magnetic resonance techniques for assessing cerebral blood without the administration of exogenous contrast and has a number of purported and demonstrable benefits in certain pediatric disorders. Magnetoencephalography (MEG) records and analyzes the small magnetic fields produced by the electrical fields of neuronal activity in the brain using highly sensitive magnetic sensor. MEG can be combined with MRI to enable magnetic source imaging for localization of electromagnetic abnormalities. The main clinical utility of MEG is in the detection and localization of abnormal electrical activity and epileptiform discharges in the brain in patients with epilepsy. Meg can be helpful in presurgical assessment and localization of the epileptogenic or ictal onset zones. Additional MEG can be used as a tool for presurgical mapping of motor and sensory cortical areas. We will present the basic principles and applications of these two advanced neuroimaging applications, cerebral perfusion imaging and magnetoencephalography, in pediatric neurological disorders.

**e-Figure 28.2. Perfusion MRI in a 17-year-old patient with an anaplastic astrocytoma a few months after surgical resection and chemoradiation therapy.** An axial fluid-attenuated inversion recovery image (A) and postcontrast T1-weighted image (B) demonstrate a surgical resection cavity with signal abnormality and enhancement around the cavity. Relative blood volume (C) and blood flow (D) maps derived from dynamic susceptibility contrast MR perfusion demonstrate a focus of abnormally increased perfusion posterolateral to the surgical resection cavity consistent with recurrence and progression of the neoplasm.

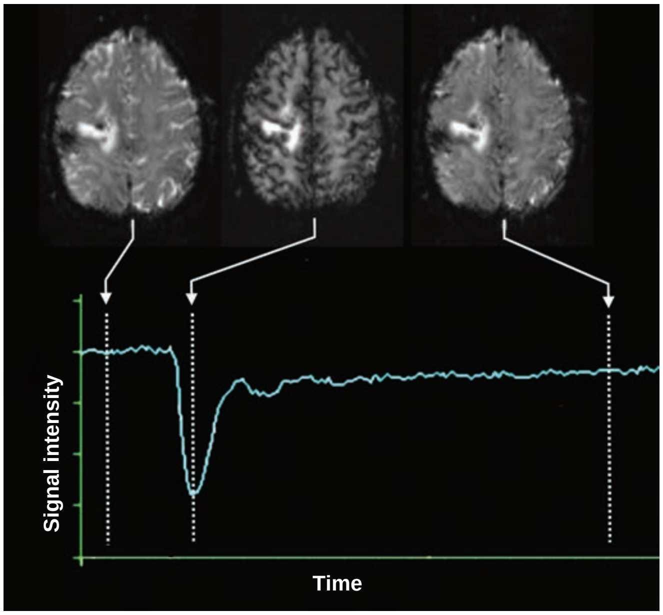

**Figure 28.1. Acquisition of dynamic susceptibility contrast perfusion magnetic resonance imaging.** Typically, a rapid echo planar acquisition is obtained through the head continuously over the course of approximately 1 or 1.5 minutes. A rapid injection of gadolinium-based contrast material is injected, which results in a transient dip in the signal intensity during the course of the first pass of contrast through the brain. After this first pass, the signal returns toward normal, although often not completely. A time-signal intensity curve is plotted before, during, and after the first pass bolus for each voxel, including brain tissue and vascular structures, which in turn is used to derive various perfusion parameters.

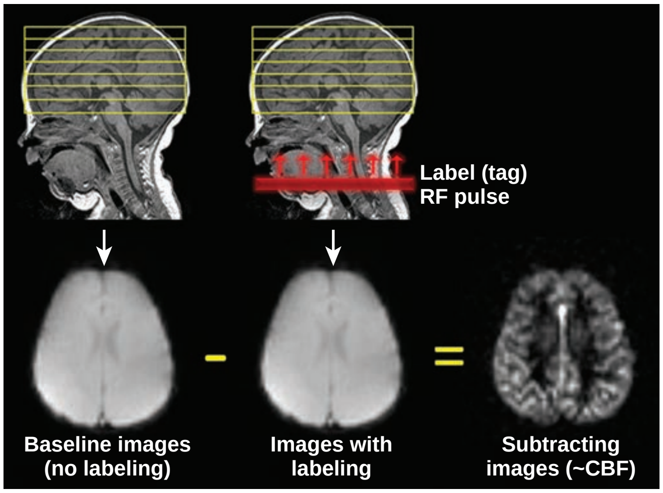

**Figure 28.3. Schematic demonstration of the general principle of arterial spin labeling perfusion MRI.** Images of the head are obtained once without and once with labeling of blood water protons using a radiofrequency (RF) pulse. The labeled (or tagged) blood flows into the brain, and if the images without and with label are subtracted from each other, the difference image results from these labeled blood protons and is proportional to cerebral blood flow (CBF).

subtraction and longer acquisition times, ASL perfusion is very sensitive to motion artifacts.

ASL has a number of potential advantages compared with exogenous contrast–based perfusion methods. ASL does not require rapid injection of a large bolus of contrast, which sometimes can be a problem in young children because of a lack of large bore intravenous access. ASL has the potential to provide quantitative perfusion data and also can be repeated in the same imaging session if the child moves. The disadvantages of ASL perfusion include longer imaging times, sensitivity to patient motion, lack of an easy way to derive CBV and MTT parameters, and specific artifacts as a result of arterial transit delays between the labeling and imaging planes, for example, when blood passes through collateral circulation channels.

Applications of ASL perfusion include cerebrovascular disease, detection of changes during complicated migraine, hypoxic-ischemic injury, depiction of hypoperfusion in mesial temporal sclerosis, and emerging applications in brain tumors.[26–32] In complicated or hemiplegic migraine, ASL can show either hyperperfusion or hypoperfusion depending on the timing of the exam in relation to vasodilation or vasoconstriction[33] (e-Fig. 28.4). After hypoxic ischemic injury or even after cases of arterial ischemic stroke when the vessels are open, a pattern of hyperperfusion may be demonstrated on ASL in the areas of ischemic injury (Fig. 28.5). Changes in perfusion can be detected during acute stroke and chronic cerebrovascular disease, but lack of easy calculation of MTT or Tmax and the presence of arterial transit delay artifacts limits its usefulness. It is perhaps still not reliable and informative enough to be concretely used in triage of acute arterial stroke management. ASL can show arteriovenous shunting in vascular disorders of the brain,[34] but other vascular pathophysiology may also be detected (e-Fig. 28.6). For example, residual high signal in the large brain vessels (with appropriate timing) can be indicative of slow flow due to a stenosis or clot. Similarly, delayed flow via collateral vessels may also sometimes be demonstrated.

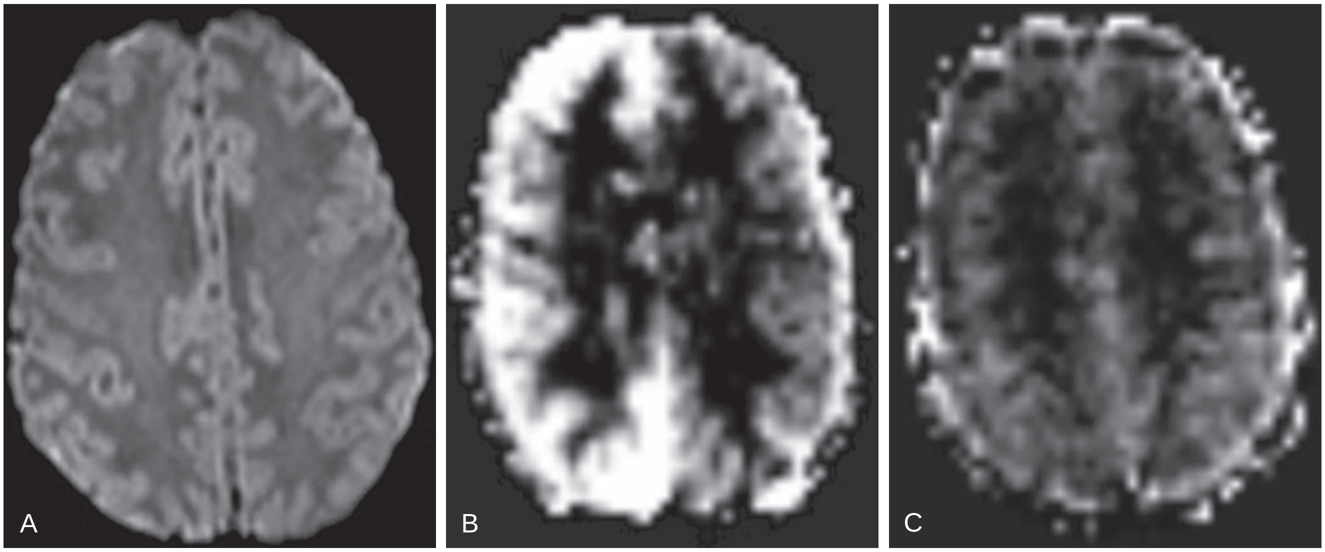
ASL has some utility in imaging evaluation of pediatric brain tumors.[35] In general, higher grade or vascular tumors have higher CBF whereas lower grade or cystic tumors have lower perfusion (Fig. 28.7). Hemangiomas show very high CBF. In one study in children, patients with pilomyxoid astrocytoma could be distinguished from pilocytic astrocytoma.[36] The distinction among grades of adult glioma by DSC perfusion seems more reliable than between various posterior fossa tumor histologies in children.[35] Areas of active or recent seizures can show increased perfusion whereas areas of gliosis and chronic encephalomalacia will show normal to decreased perfusion. Further research is needed to further establish the role of ASL imaging in pediatrics.

## Computed Tomographic Perfusion Imaging

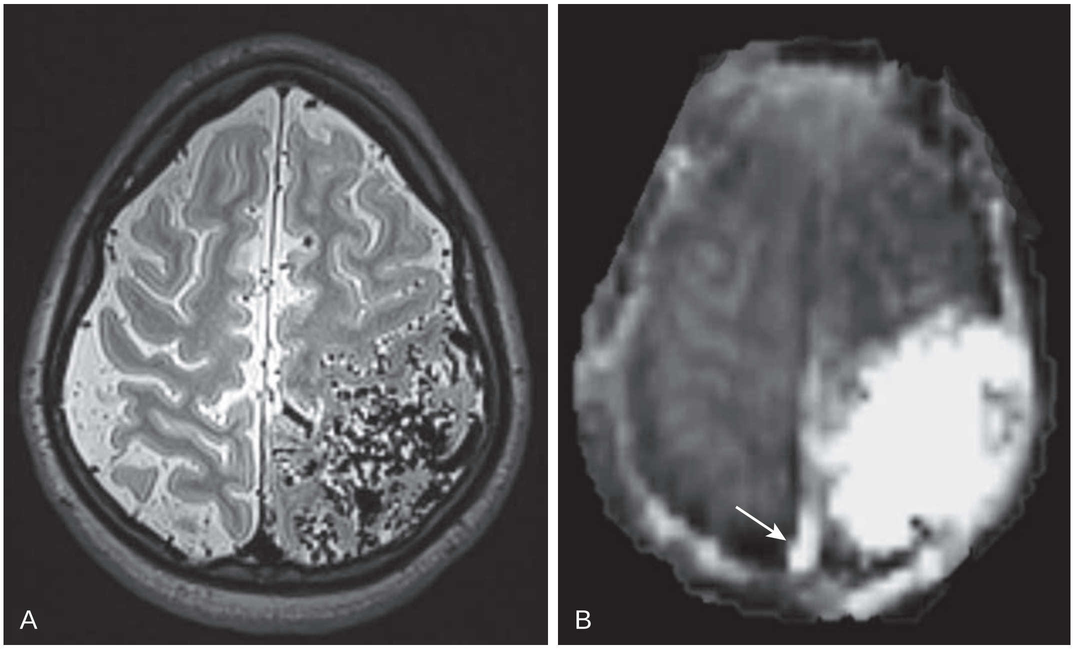
Dynamic CT perfusion imaging bears some similarity to DSC perfusion MRI, in that perfusion parameters are derived from a time-concentration curve obtained during continuous scanning of the first pass of a rapid injection of iodinated contrast material through the brain.[1,37,38] Quantitative maps of CBV, CBF, MTT, and Tmax can be obtained. Dynamic CT perfusion imaging has the advantage of widespread availability and speed, which can be important in the setting of acute stroke or in patients with contraindications to MRI. CT perfusion imaging often is performed in conjunction with CT angiography in the evaluation of cerebrovascular disease. Although continuous scanning of the head for CT perfusion can lead high radiation exposure, CT perfusion can be performed satisfactorily with 80 kVp and a low mA technique, which considerably decreases the radiation dose.[1,39] CT perfusion imaging has been studied extensively in the evaluation of patients with cerebrovascular disease, especially in the setting of acute ischemic stroke.[37,40] It can demonstrate the ischemic penumbra and tissues at risk and can be helpful in patient selection for stroke management (Fig. 28.8).[1,37,41]

## Other Perfusion Imaging Methods

Xenon CT perfusion uses stable nonradioactive Xenon gas inhaled over the course of a few minutes to act as a contrast agent for



**e-Figure 28.4. Arterial spin labeling in a child with hemiplegic migraine.** The patient presented with acute onset left-sided weakness in the face and both the upper and lower extremities, along with headache. MRI was emergently performed to exclude an arterial ischemic stroke. No abnormality was found on diffusion-weighted imaging (A), but ASL perfusion MRI demonstrated increased cerebral blood flow in the right cerebral hemisphere (B). Two days later, the patient's symptoms have completely resolved and a repeat MRI demonstrated normal appearance of the brain on ASL perfusion imaging (C).



**e-Figure 28.6. ASL perfusion imaging in a patient with an arteriovenous malformation (AVM).** There is a large AVM in the left parietal region (A). ASL perfusion imaging shows markedly elevated cerebral blood flow in the lesion. There is also elevated signal in the superior sagittal sinus (B) which shows the drainage pathway of the AVM *(arrow).* ASL can physiologically depict whether there is superficial or deep drainage in most cases of AVM.

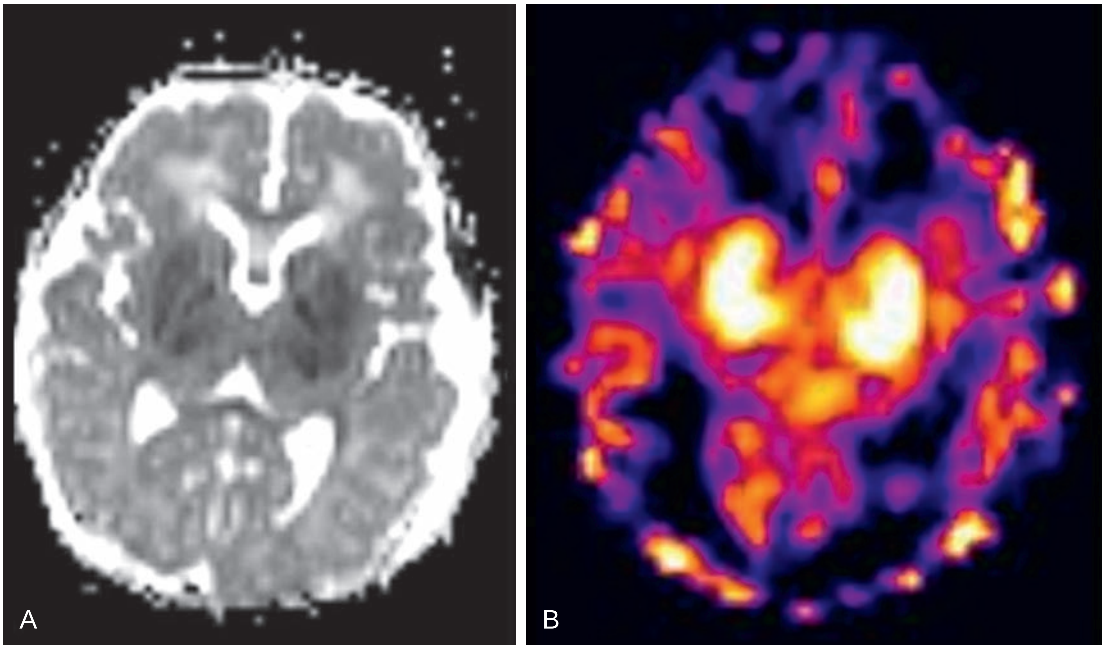


**Figure 28.5. ASL perfusion in an infant with hypoxic ischemic encephalopathy.** Axial apparent diffusion coefficient (ADC) maps show reduced diffusion in the bilateral deep grey nuclei (A) three days after a profound hypoxic event. (B) ASL perfusion map shows markedly elevated cerebral blood flow and hyperperfusion in the areas of reduced diffusion.

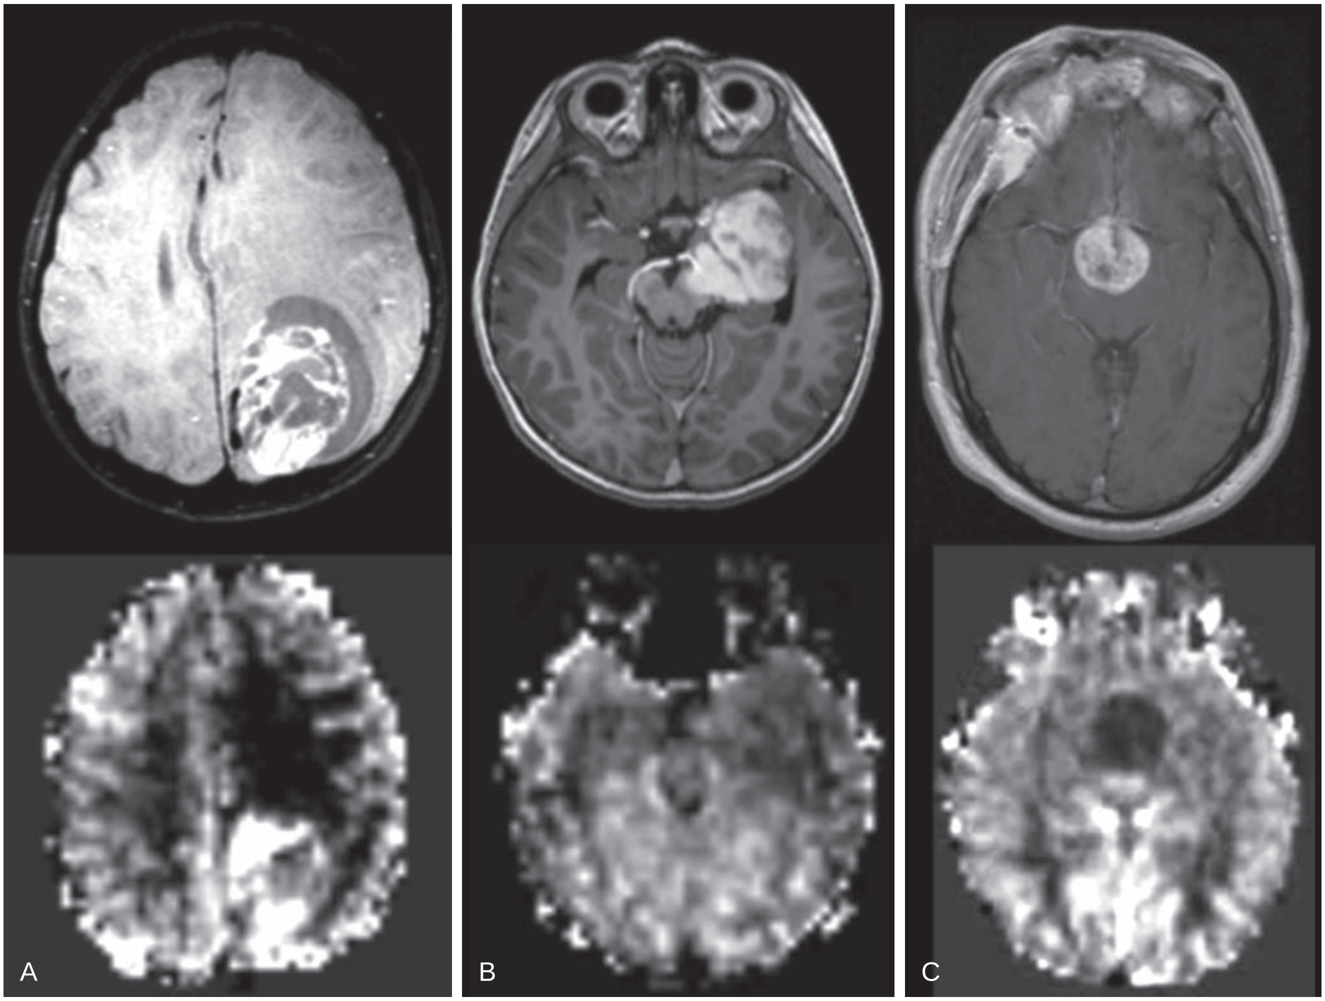

**Figure 28.7. ASL perfusion in three contrast enhancing brain masses.** (A) Elevated perfusion in a patient with a high grade malignant glioma. (B) No elevated perfusion in a patient with a low grade glioma (pilocytic astrocytoma). (C) Low perfusion in a patient with craniopharyngioma.

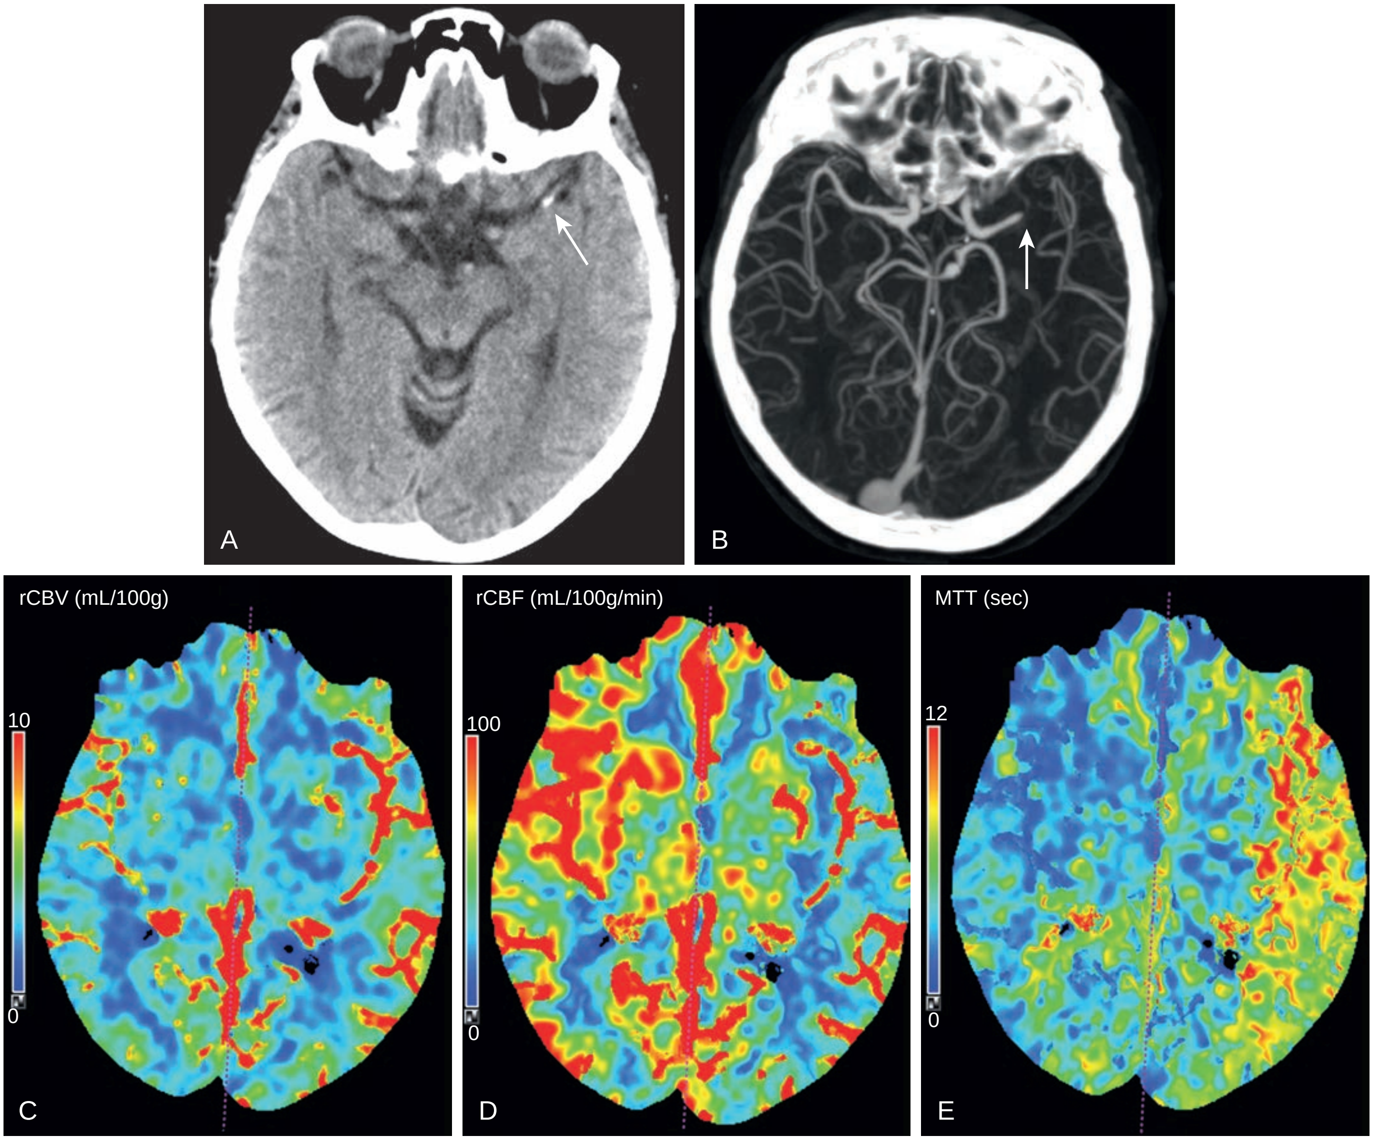

**Figure 28.8. CT perfusion imaging in a patient with acute right-sided weakness and aphasia.** Noncontrast CT examination (A) demonstrated a focus of high density *(arrow)* in the M1 segment of the left middle cerebral artery. No loss of gray white differentiation or edema was seen on CT at this time. CT angiography (B) showed an abrupt cutoff in the left middle cerebral artery *(arrow)*. CT perfusion imaging done immediately after CT angiography showed no large change in relative cerebral blood volume (C), but the relative cerebral blood flow (D) was decreased and mean transit time (E) was elevated in the distribution of the left middle cerebral artery compared with the contralateral side.

perfusion after crossing the blood-brain barrier. Xenon CT perfusion can produce accurate quantitative CBF measurements and even can be used to assess cerebrovascular reserve after a vasodilatory challenge in patients with occlusive or stenotic cerebrovascular disease.[1,42,43] Various nuclear medicine techniques also have been used to quantitatively assess cerebral perfusion. These techniques include positron emission tomography using $H_2{}^{15}O$, $^{15}O_2$, and $C^{15}O_2$ and single photon emission CT using $^{99m}$Tc-HMPAO and $^{133}$Xe. Xenon CT and nuclear medicine perfusion methods are not often performed in pediatric patients because of a lack of widespread availability and clinical expertise with these techniques, and potential concerns about the radiation dose.

## MAGNETOENCEPHALOGRAPHY AND MAGNETIC SOURCE IMAGING

Magnetoencephalography (MEG) is a noninvasive technique that records and analyzes the magnetic fields produced by the electrical currents of neural activity in the brain. MEG signals arise from intracellular currents that flow from dendrites to the cell body.[44] These magnetic signals are extremely weak, on the order of 10 to 1000 femtoTesla ($10^{-15}$ T),[45] requiring special sensors for detection. These magnetic fields induce electrical current in an array of special detector coils coupled to a superconducting quantum interference device.[45] Modern-day MEG machines typically have a few hundred sensor channels that surround the head (e-Fig. 28.9). Given the very weak magnetic fields generated by brain activity and the very high sensitivity of the superconducting quantum interference device sensors, MEG is very prone to interference from external magnetic sources, and thus siting in a highly-shielded room is required to prevent electromagnetic contamination. MEG provides excellent temporal resolution (less than 1 ms), and compared with standard electroencephalography, it provides very good spatial resolution (down to 3–15 mm depending on depth) in the detection of normal and abnormal brain waveforms. The most important current clinical applications of MEG relate to evaluating epileptic disorders and presurgical functional mapping.

In a typical clinical MEG examination, multiple sequential recordings are made via the various channels. The MEG waveform analysis results often are coregistered to a volumetric MRI of the head for source spatial localization of the abnormal waveforms or functional mappings. This combination of MEG with MRI is known as *magnetic source imaging*. For clinical purposes, when one uses the term MEG, it usually refers to magnetic source imaging with MRI coregistration. The registration of MEG and MRI typically is performed by using fiducial markers in predetermined regions.[46] The same fiducial markers can be used for determining patient motion and motion correction, which is important for clinical interpretation. After acquisition of the MEG waveform data, various complex mathematical models and algorithms are used for source localization, along with the ability to provide information from a "virtual depth electrode" in the brain.[45,46]

Various artifacts almost always occur during an MEG examination. Muscle twitching, eye blinking, and cardiac electrical activity can cause changes in MEG waveforms. The presence of dental and orthodontic hardware, vagal nerve stimulators (even when turned off), and metallic piercings will cause artifacts on MEG as well.

## Magnetoencephalography in the Evaluation of Children With Epilepsy

The major goal in the presurgical evaluation of patients with epilepsy is identification of the epileptogenic or ictal onset zones.[47,48] It is hoped that surgical removal of this epileptogenic region will result in a seizure-free state (or at least a significant decrease in seizure frequency) with minimal postsurgical neurologic deficits. Due to lack of methods that measure the epileptogenic zone directly, this area is indirectly identified based on concordant data from a multitude of presurgical noninvasive imaging modalities, electrophysiologic tests, and intracranial recordings. However, the results of these tests are sometimes insufficiently concordant or even inconclusive. The excellent temporal and very good spatial resolution of MEG makes it a very useful tool in the evaluation of patients with epilepsy, especially those who are medically refractory. MEG evaluation typically is performed by passive interictal recording of spontaneous electromagnetic activity and discharges. Patients often are instructed to be sleep deprived overnight to increase interictal activity. In young children, typically 5 years or younger, or in patients with developmental delay or psychiatric issues, general anesthesia may be required to perform the MEG examination. The choice of anesthetic medication is important so as to avoid interference with the detection of epileptiform changes on MEG.[46]

MEG has the potential to be used in the following clinical scenarios in the evaluation of patients with epilepsy:

1. Investigation of inconclusive electroencephalogram (EEG) results (Fig. 28.10)
2. Investigation of discrepancy between EEG and neuroimaging findings
3. When no structural lesion is found on MRI in a patient with epilepsy, MEG results may be used to guide a targeted "second look" at the MRI for possible detection of subtle abnormalities that initially may have been difficult to identify
4. In patients with multiple structural lesions on MRI, determination of whether one of the lesions is primarily responsible for the patient's refractory seizures, indicating surgical feasibility
5. Determination of multiple epileptogenic zones, suggesting an unfavorable outcome or contraindication for surgery

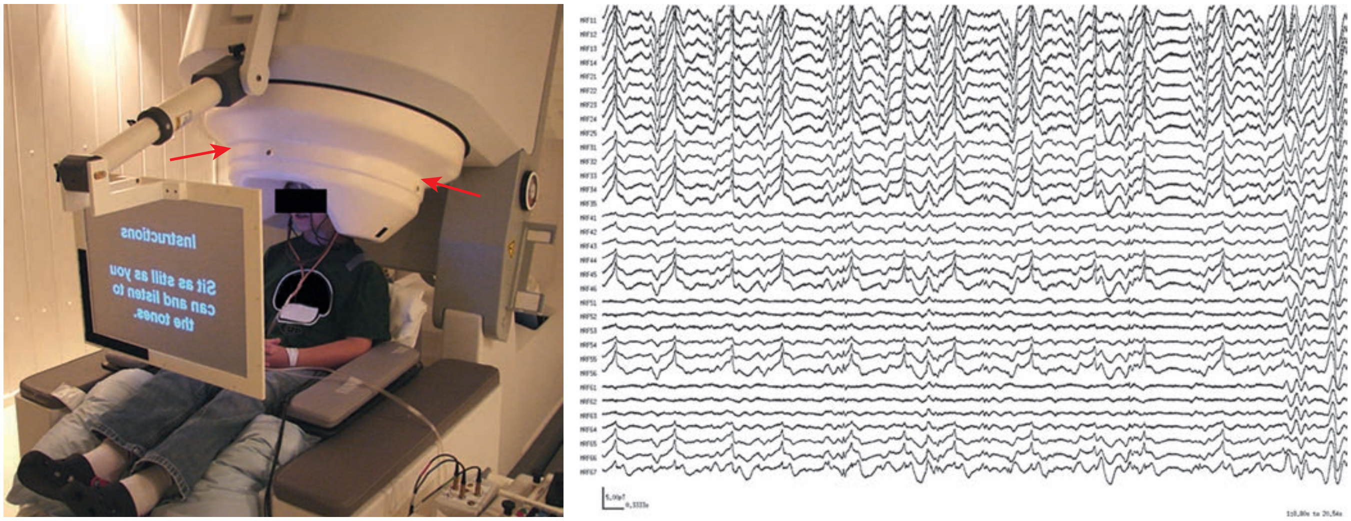
**Figure 28.10. Magnetoencephalography and magnetic source imaging in a patient with inconclusive EEG localization results.** An interictal MEG shows spike and wave and sharp activity localizing to the lateral aspect of the right temporal lobe *(arrow)*. No lesion could be identified on MRI and there was no mesial temporal sclerosis.



**e-Figure 28.9. Magnetoencephalography.** The image on the left demonstrates a typical MEG machine (biomagnetometer) and patient setup for recordings and functional mapping. The patient's head is situated within the helmet-like head element, which houses the multiple arrays of sensors around the head *(arrows)* within an insulated dewar. The image on the right demonstrates a small sample of representative MEG wave recordings from just 33 channels over the course of approximately 20 seconds. Typically, many more channels are recorded and the recordings are done for much longer periods, resulting in a tremendous amount of data to be analyzed for magnetic source imaging.

6. Confirmation of localization based on other methods, allowing surgery to proceed without long-duration invasive intracranial EEG monitoring
7. More accurate spatial localization of the epileptogenic zone to decrease the extent of craniotomy and grid placement for invasive EEG monitoring
8. Evaluation of recurrence of epilepsy after surgery to plan for possible re-resection (e-Fig. 28.11)
9. Delineation of eloquent cortex to aid presurgical decision making

Careful visual scrutiny of the source MEG waves is necessary to help determine the presence or absence of significant epileptiform activity or artifacts. High-frequency oscillations have emerged as new potential biomarkers for the delineation of the epileptogenic zone. Various automated software waveform analyses and statistical tests can be performed to determine the significance of the waveforms detected on MEG. One such measure is determining kurtosis, or "spikiness" of the waves, which can help in identifying areas of significant activity. The addition of MEG to the evaluation of patients with epilepsy has been shown to improve the quality of medical care and surgical outcomes and provides important nonredundant information in a significant proportion of patients.[47–50]

## Brain Functional and Presurgical Mapping Using Magnetoencephalography

Currently, the clinical gold standard for functional mapping of eloquent cortex is intraoperative direct cortical stimulation and mapping. Noninvasive examinations such as functional MRI (fMRI) are often used for preoperative localization and mapping before resection of tumors, vascular malformations, and epileptogenic foci. The blood oxygenation level dependent response used in fMRI localization is a measurement of the hemodynamic response to neuronal activity rather than direct measurement of the neuronal activity (see Chapter 27). Many pathophysiologic processes are known to adversely affect and/or blunt the hemodynamic response measured with fMRI, such as arteriovenous malformations or even some tumors. MEG can be used as another noninvasive method for functional identification of eloquent cortical regions.[51–53] Motor, somatosensory, and language areas typically are examined by MEG in the clinical setting. Auditory and visual centers are also occasionally investigated. Similar to fMRI, MEG recordings are used to evaluate responses to task performance and/or evoked stimulation.

Motor mapping can be performed with self-paced button pressing, for example using left and right index fingers, and recording the MEG response. Typically these motor actions result in event-related desynchronization (ERD) in the beta wave band, approximately 200 to 300 ms after the button press. Depending on the area of interest for motor mapping, occasionally other areas such as the great toes, elbows, or oral musculature also could be used. Somatosensory testing can be performed with use of various stimuli while recording the MEG response as well. Alternatively, and especially in patients who are sedated or anesthetized, somatosensory testing can be performed via painless electric stimulation of the median or tibial nerves. Typically, MEG activity at 20 ms after stimulus is used to map somatosensory function.

Language mapping is another area in which MEG may be useful, either in evaluation of language lateralization or localization. The language tasks used are similar to those used with fMRI; common language tasks in children may include picture naming, word recall, stem completion, and verb generation, among others. The tasks typically are displayed via a screen in front of the patient, with the operator giving audio instructions when they are needed. Similar to motor mapping, ERD associated with neuronal activity can be exploited for assessing language-related centers in the brain, approximately 400 to 500 ms before the patient's response. In our experience, MEG is more successful in language lateralization than language center localization.

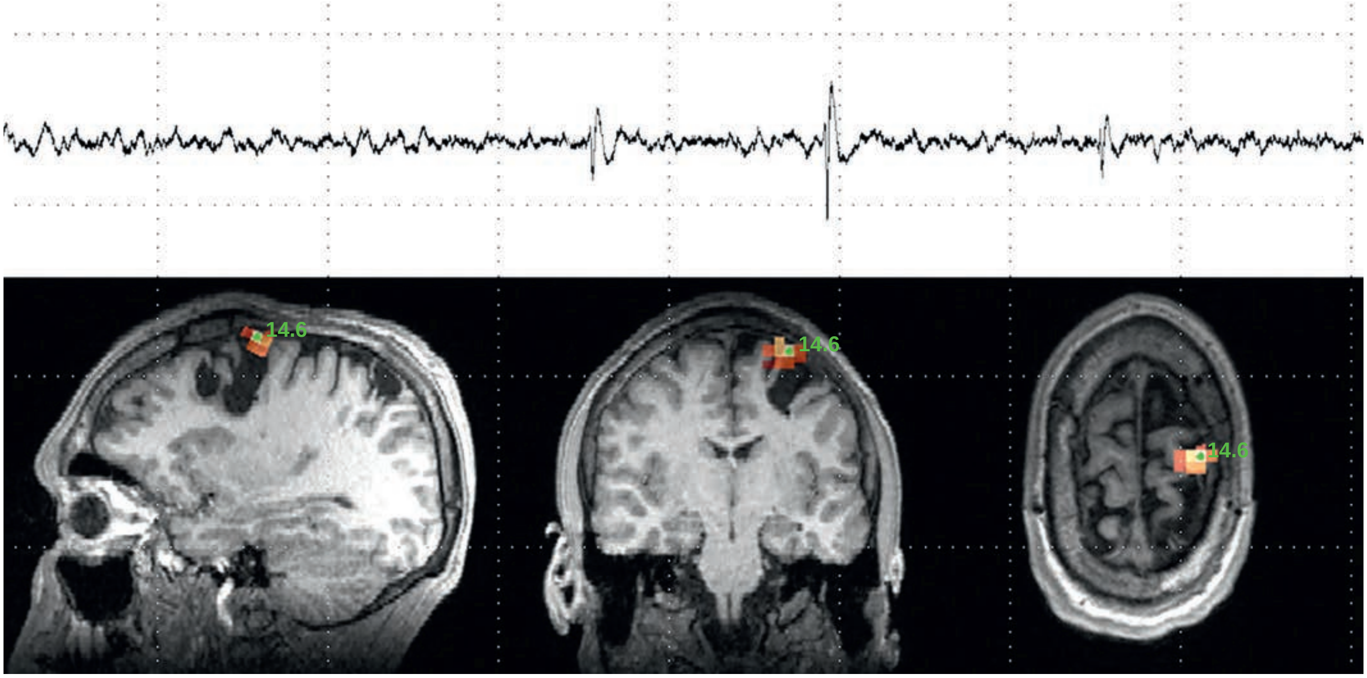
After the functional mapping tasks and stimulations are performed, areas of target activity or statistically significant ERD are overlaid on volumetric MRI to visualize the functional areas mapped by MEG (Fig. 28.12). In small children and in patients who are anesthetized, it generally is not feasible to perform motor and language mapping. Somatosensory mapping only via median or tibial nerve stimulation may be a viable choice. The functional mappings performed by means of MEG are used in determining the feasibility and risks of surgery and occasionally in planning the surgical approach to lesions. Depending on the results and the experience of the center, MEG may be used in conjunction with or in lieu of fMRI.

## Other Current and Future MEG Applications

MEG has many other current and future potential applications in evaluation of brain disorders beyond epilepsy. The strength lies in the combination of electrophysiology and imaging localization capabilities, although there remain challenges in localization and analysis of the complex MEG signals. Many disorders that affect the brain will cause changes in brain electromagnetic oscillations, such as traumatic brain injury, genetic and developmental disorders, autism, disorders of consciousness, and a variety of psychiatric disorders. Many of these disorders do not have overt changes on MR imaging of the brain. However, there may be changes in the electrographic signatures of various parts of the brain that can be detected and evaluated by MEG. For example, autistic children can demonstrate particular changes and delays in the MEG auditory signature.[54] In some patients, these can change over time as the child gets older and there may be correlation with outcome.[55] Somatosensory evoked potentials have been traditionally used to evaluate and predict clinical outcome in at-risk infants. MEG can highlight many key changes in somatosensory processing in typical and atypical development and be used in this cohort.[56] In traumatic brain injury, MEG features such as slow waves and high frequency oscillations may be identified including in patients without overt conventional imaging findings.[57] The potential of MEG is still largely untapped and remains an active area for further investigation.

### KEY POINTS

- Perfusion imaging includes a number of imaging techniques used to measure hemodynamically derived functional parameters in the brain.
- DSC perfusion MRI provides measures of CBV, CBF, and MTT, which are useful in the imaging evaluation of cerebrovascular diseases and brain neoplasms. ASL perfusion MRI is a noninvasive method that uses magnetically labeled arterial blood water as an endogenous tracer to measure CBF.
- Perfusion imaging methods have a large number of applications in evaluation of various aspects of cerebrovascular diseases, neuro-oncology, and effect of other brain disorders on cerebral perfusion.
- MEG is a robust and sensitive tool in the depiction of abnormal epileptiform activity in the brain and can be coregistered with MRI to localize these abnormal discharges in children with epilepsy.
- MEG can be used for presurgical functional mapping of motor, somatosensory, and language areas in the brain. MEG is being increasingly investigated and used in evaluation of a wide spectrum of brain disorders.



**e-Figure 28.11. Magnetoencephalography and magnetic source imaging in a patient with continued seizures even after epilepsy surgery.** The patient had undergone multiple cortical resections after an extensive epilepsy workup and invasive cortical mapping a few years earlier. However, although some improvement in the frequency of seizures occurred, the patient continued to have medically refractory epilepsy. An interictal MEG shows multiple isolated spike and slow wave abnormalities during multiple recordings localized to a focus along the superomedial aspect of the site of surgical resection.

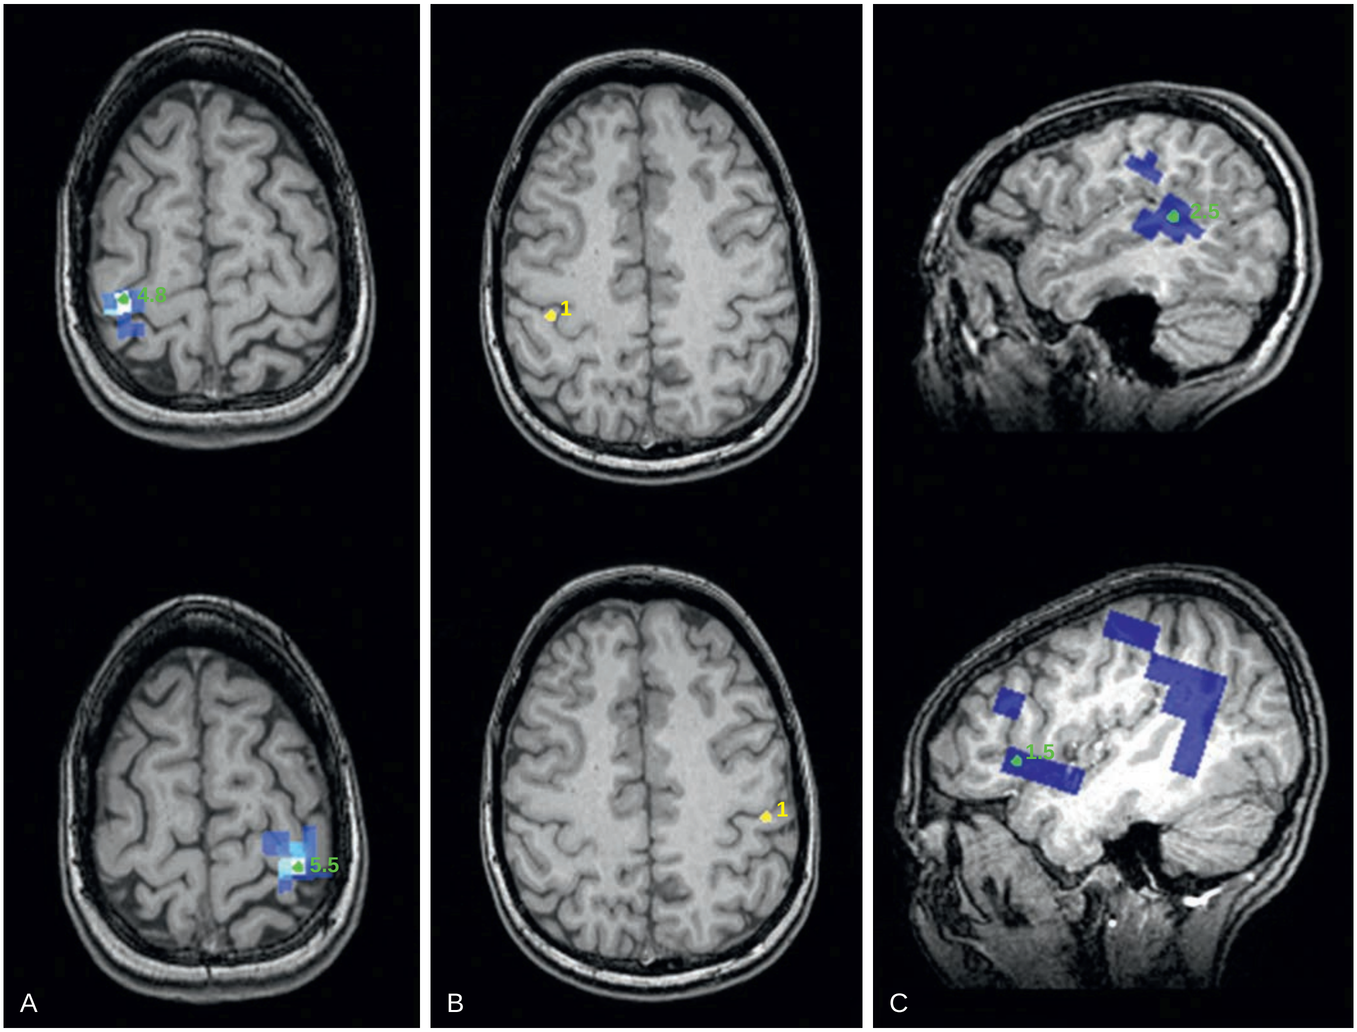


**Figure 28.12. Presurgical functional motor, somatosensory, and language mapping using magnetoencephalography.** Motor mapping (A) of the left and right index fingers by simple finger tapping mapped to the right and left precentral gyri, respectively. Somatosensory mapping (B) using stimulation of the fingers by a puff of air shows mapping to the banks of the contralateral postcentral gyri. Language mapping was performed using various tasks that predominantly localized to the posterior aspect of the left superior temporal gyrus and anterior opercular region of the lateral left frontal lobe (C).

# Prenatal Imaging

Dorothy Bulas

Central nervous system (CNS) anomalies occur in 1.4 to 1.6 per 1,000 live births and 3% to 6% of still births.[1] Whereas some anomalies can be detected as early as the first trimester (such as anencephaly), others may not develop or become apparent until later in gestation.[2]

Ultrasound is the initial imaging modality used for the assessment of fetal CNS anomalies. When ultrasound is carefully performed using established guidelines, it can be very sensitive in evaluating the fetal brain.[3] Axial images are important for the assessment of biparietal diameter and head circumference measurements, ventricular size, and cerebellar configuration. Coronal and sagittal images can confirm the presence of the cavum septum pellucidum and corpus callosum. However, because of limitations from skull shadowing, fetal lie, maternal obesity, and oligohydramnios, evaluation of the fetal brain by ultrasound may be incomplete. When a fetal CNS anomaly is suspected, magnetic resonance imaging (MRI) is an adjunct that can provide additional information.[4–7]

The multiplanar capability of MRI allows for the evaluation of the brain in any plane regardless of fetal lie, oligohydramnios, and overlying bone and gas. Single shot rapid acquisition with relaxation enhancement sequences decrease movement artifact. Slices as thin as 2 mm can be obtained and provide excellent anatomic detail. T1 sequences take longer to obtain and may require thicker slices for sufficient signal, but they are useful for detecting hemorrhage, calcification, and gliosis.

Advanced techniques include diffusion-weighted imaging (DWI), echo planar imaging (EPI), diffusion tensor imaging (DTI), spectroscopy, and functional MRI.[8] The apparent diffusion coefficient normally decreases after 30 weeks' gestational age (GA),[9] but higher apparent diffusion coefficient (ADC) values have been reported in high-risk fetuses.[10] DWI can help detect hemorrhage and acute ischemia (Fig. 29.1). DTI measures the magnitude and direction of diffusion (fractional anisotropy). Although intrinsic anisotropy is low in the fetal brain, imaging improvements will help understand the onset and timing of delayed white matter connectivity.[11,12] Proton MR spectroscopy has advanced the investigation of fetal brain metabolism. Creatine and N-acetylaspartate peaks appear to have a progressive increase, whereas choline decreases in the third trimester.[13] Alterations in these peaks may help identify conditions associated with fetal compromise.

Ongoing enhancement of ultrafast MR sequences and postprocessing methodology has resulted in imaging techniques that can evaluate growth, organization, and remodeling processes that occur during fetal brain development.[14,15] Three-dimensional volumetric studies have demonstrated the value of quantitative assessment of brain growth in healthy versus high-risk fetuses. Fetuses with congenital heart disease have been shown to have impaired third-trimester brain growth compared with control subjects, offering a method to evaluate timing and progression of abnormal brain development.[16] Three-dimensional reconstruction of the fetal brain can provide cortical measures such as surface area and gyrification indices.

Fetal MRI is routinely performed with 1.5 Tesla units, with centers now moving to 3 Tesla. Issues regarding increased specific absorption rate heating and movement artifacts need to be addressed with these higher Tesla units.[17–19]

These advanced neuroimaging techniques improve our ability to assess anomalies and provide methods for monitoring high-risk pregnancies, leading to improved counseling, planning of fetal intervention, and perinatal management. In a large recent multicenter prospective cohort study, fetal MRI was shown to improve the diagnostic accuracy of brain evaluation in 23% of cases age 18 to 24 weeks GA and 29% in cases greater than 24 weeks GA. Diagnostic accuracy was 68% for ultrasound and 93% for MRI. MRI provided additional information in 49% of cases, changed the prognostic information in 20%, and changed clinical management in 30%. This large series helps demonstrate that a fetus with a brain anomaly identified by ultrasound can benefit from a fetal MRI to improve counseling and management planning.[20]

## NORMAL DEVELOPMENT OF THE FETAL BRAIN

Knowledge of normal fetal morphology and development is important when evaluating anomalies. From 18 to 24 weeks' gestation, the brain is smooth, with minimal sulcation. The ventricles and extraaxial subarachnoid space, including the cisterna magna, are prominent until the third trimester[21] (Fig. 29.2).

Neuronal migration patterns can be documented by MRI.[22–25] Before 20 weeks' gestation, three layers are visualized, including the germinal matrix, intermediate/cell sparse zone, and cortex. The germinal matrix has a low signal on T2-weighting and high signal on T1-weighting along the lateral ventricular walls and involutes from posterior to anterior after 28 weeks' gestation. The intermediate zone represents migrating glial cells and eventually becomes the white matter. With a high water content, it appears low on T1-weighting and high on T2-weighting with high ADC due to low cellularity. The cortical ribbon has high T1 and low T2 signal due to high cellularity with low ADC.

From 20 to 28 weeks' gestation, a five-layer pattern is observed. This includes the germinal matrix, subventricular periventricular fiber-rich zone, subventricular cellular/intermediate zone, subplate, and cortical plate. The germinal matrix and cortical plate have low T2 signal and high T1 signal due to high cellularity. The subventricular cellular/intermediate zone is slightly low signal on T2 and high signal on T1, while the subventricular periventricular fiber-rich zone and subplate are of low signal on T1 and high signal on T2.

The fetal cortical mantle follows a predictable course in maturation. Gyration progresses throughout the second and third gestation and can be used to assess GA (Box 29.1). By 32 weeks' gestation, extensive gyration and sulcation is present (Fig. 29.3).[21–26]

## FETAL VENTRICULOMEGALY

The fetal ventricles are prominent in relation to the brain parenchyma until the third trimester. After 25 weeks' gestation, the ventricles lose their colpocephalic configuration. Fetal ventriculomegaly (VM) is defined as an atrial measurement greater than 10 mm with separation of choroid from the medial wall (i.e., floating choroid). VM can be due to obstruction, atrophy, maldevelopment, or, rarely, overproduction of cerebrospinal fluid. Ultrasound and MRI should be used to carefully assess for findings that suggest chromosomal anomalies (e.g., trisomy 13, 18, or 21), malformations (e.g., Chiari 2, Dandy–Walker, agenesis of the corpus callosum [ACC], or holoprosencephaly), or destructive lesions (e.g., infarction or infection).[26–28]

## Abstract:

Central nervous system (CNS) anomalies occur in 1.4 to 1.6 per 1000 live births and 3% to 6% of still births. Whereas some anomalies can be detected as early as the first trimester (such as anencephaly), others may not develop until—or only become apparent—later in gestation.

Ultrasound is the initial imaging modality used for the assessment of fetal CNS anomalies. When ultrasound is carefully performed using established guidelines, it can be very sensitive in evaluating the fetal brain. However, because of limitations from skull shadowing, fetal lie, maternal obesity, and oligohydramnios, evaluation of the fetal brain by ultrasound may be incomplete. The multiplanar capability of MRI allows for the evaluation of the brain regardless of fetal lie, oligohydramnios, and overlying bone and gas. Advanced fetal MR techniques include diffusion-weighted imaging, echo planr imaging, diffusion tensor imaging, spectroscopy and functional MRI. Ongoing enhancement of ultrafast MR sequences and postprocessing methodology has resulted in imaging techniques that can evaluate growth, organization, and remodeling processes that occur during fetal brain development. Three-dimensional volumetric studies have demonstrated the value of quantitative assessment of brain growth in healthy versus high-risk fetuses.

It is hoped that use of these advanced neuroimaging techniques will improve our ability to assess anomalies and provide methods for monitoring high-risk pregnancies, leading to improved counseling, planning of fetal intervention, and perinatal management.

- 22–23, the callosal sulcus
- 24–25, the calcarine fissure
- 24–26, the central sulcus
- 26–28, the precentral and postcentral sulci
- 28, the superior temporal sulcus
- 30 to 32, the anterior superior temporal sulcus

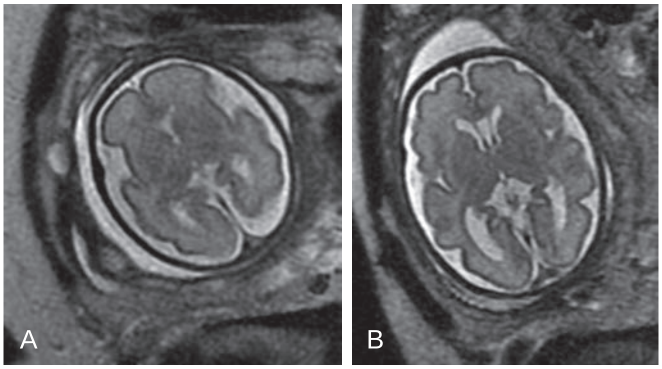

**Figure 29.3. Progression of sulcation.** (A) Axial single-shot fast spin-echo T2-weighted MR image at 28 weeks' gestation shows progression of the sulcation with involution of the germinal matrix. (B) By 32 weeks' gestation, all primary sulcation is present.

The degree of VM has been shown to be associated with the incidence of live birth and survival beyond the neonatal period. Moderate VM (>12–15 mm) is more likely to demonstrate associated anomalies (56%) compared with mild VM (10–12 mm) (6%).[29] Isolated VM has abnormal outcomes in 10% to 25% of cases.[30]

If other anomalies are present, outcome is worse, with only 50% to 80% of fetuses having a normal neurodevelopmental outcome.[31–34] Motor outcomes are more severely affected than cognitive or adaptive outcomes, although prenatal atrial diameter was not consistently associated with postnatal developmental outcome.[35] If VM is severe due to aqueductal stenosis, the overall mortality is 40%; perinatal mortality is 23%, with only 10% of those surviving having normal outcome.[33]

## AGENESIS OF THE CORPUS CALLOSUM

The corpus callosum forms between the eighth and twentieth week from genu to splenium. The rostrum forms last, between 18 to 20 weeks' gestation. Agenesis can be complete (ACC) or partial (hypogenesis). The corpus callosum may be difficult to visualize sonographically, particularly in the early weeks of gestation and/or with hypogenesis.[36] Sonographic and MRI findings include colpocephaly of the occipital horns with parallel orientation of the lateral ventricles, an absent septum pellucidum, and a high-riding third ventricle (Fig. 29.4). Coronal images are particularly helpful in demonstrating the presence or absence of the cavum septum pellucidum and corpus callosum. With ACC, the frontal horns tend to be narrow with straight medial borders secondary to the bundles of Probst, which represent the callosal fibers that have not crossed the midline. The third ventricle may extend superiorly into an interhemispheric cyst. The cerebral convolutions have a radial arrangement on sagittal imaging. An associated lipoma may be present, which will be echogenic on ultrasound and isointense to gray matter on T2-weighted MRI. If associated anomalies are detected, the outcome is typically poor.[27–29,37–39] While isolated ACC may have a good outcome, up to 20% of cases diagnosed

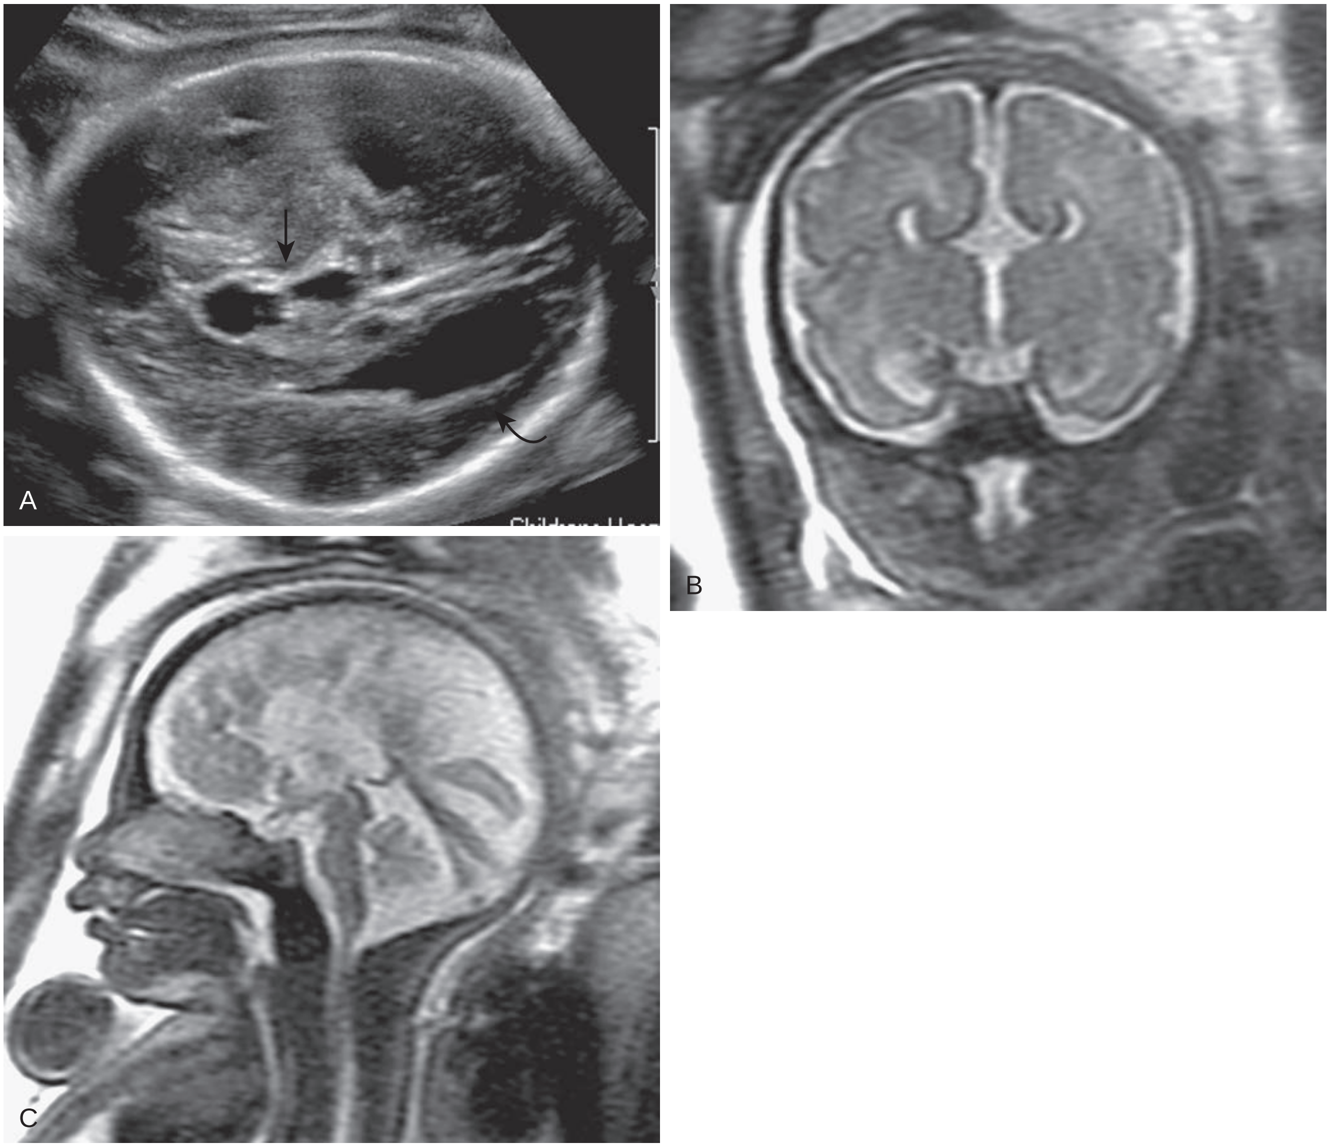

**Figure 29.4. Agenesis of the corpus callosum.** (A) Transverse sonogram of the fetal brain shows dilatation of the occipital horns *(curved arrow)* and a high-riding third ventricle *(arrow)*. (B) Coronal T2-weighted MR image shows that the cavum septum pellucidum is absent, along with a high-riding third ventricle. The medial walls of the anterior horns are indented by the bundles of Probst. (C) Sagittal T2-weighted MR image shows medial sulci radiating perpendicular to the expected course of the corpus callosum. The pericallosal sulcus is absent.

prenatally have additional anomalies noted postnatally. Long-term outcome remains unknown, with several studies suggesting that delays become more apparent in later years and can be associated with autism, attention deficit disorder, and schizophrenia.[40]

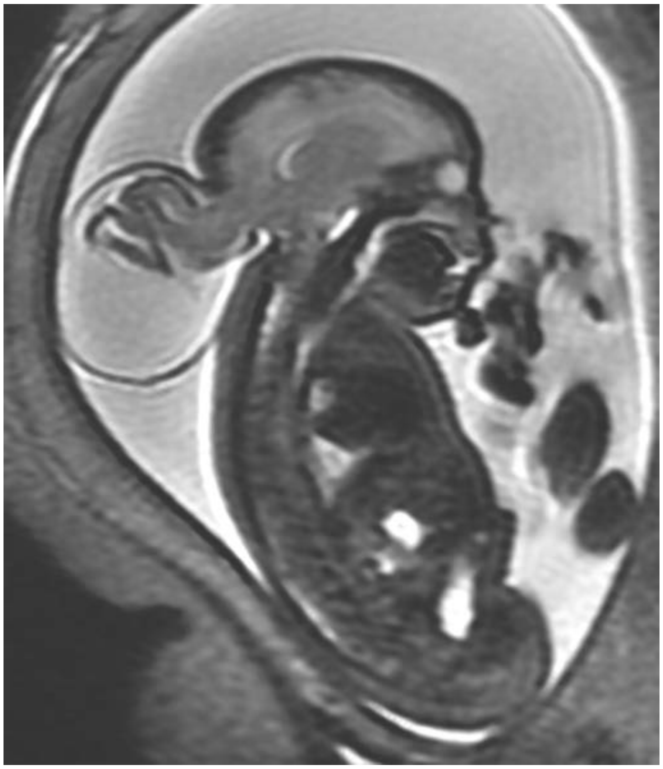
## NEURAL TUBE DEFECTS

Cranial neural tube defects can be assessed by ultrasound and include anencephaly, iniencephaly (cervical dysraphism and fixed fetal head extension), Chiari 2 malformation (low occipital/high cervical encephalocele), and cranial encephaloceles (e-Figs. 29.5 and 29.6). Ultrasound can identify many of these anomalies, but MRI is useful to further evaluate the amount of herniated brain and associated cranial anomalies.

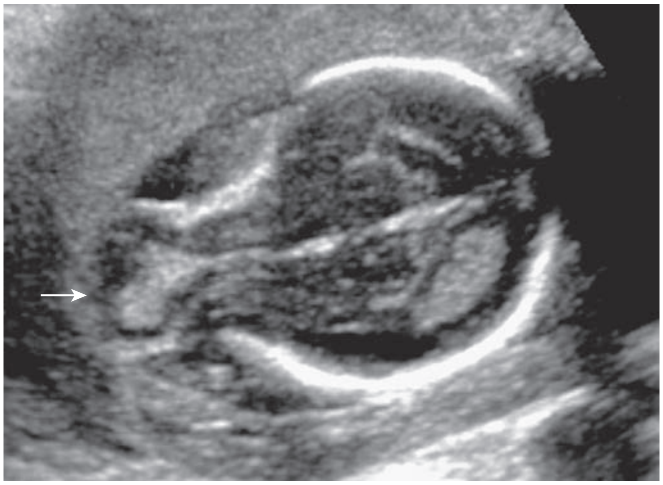
Meningomyeloceles associated with Chiari 2 malformation are the most common neural tube defect. Cranial findings identifiable sonographically include a small or absent cisterna magna, cerebellar herniation (banana sign), frontal concavity (lemon sign), and VM.[41,42] MRI can further delineate the amount of brainstem and cerebellar herniation, beaking of the tectum, heterotopias, small subarachnoid space, and callosal dysgenesis. If fetal surgery is performed, hindbrain herniation may reverse, decreasing the need for shunting postnatally.[43,44]

## HOLOPROSENCEPHALY

Failure of prosencephalic cleavage results in holoprosencephaly; septo-optic dysplasia is the mildest form, and alobar holoprosencephaly is the most severe form.[45] These anomalies are associated with several genetic syndromes including Meckel–Gruber, Smith–Lemli–Opitz, trisomy 13 and 18, and teratogen exposure. Midline and facial structures often are abnormal as well and can include proboscis, trigonocephaly, cyclopia, hypotelorism, and facial clefts (Fig. 29.7). Ultrasound can identify the most severe



**e-Figure 29.5. Occipital encephalocele.** Sagittal T2-weighted MR image at 33 weeks' gestation demonstrates a large posterior skull defect with brain tissue herniating into a skin-covered sac. Note the obliterated subarachnoid space.



**e-Figure 29.6. Frontal encephalocele.** Axial sonogram of the fetal brain at 16 weeks' gestation shows a frontal skull defect with brain contents herniated anteriorly *(arrow)*.

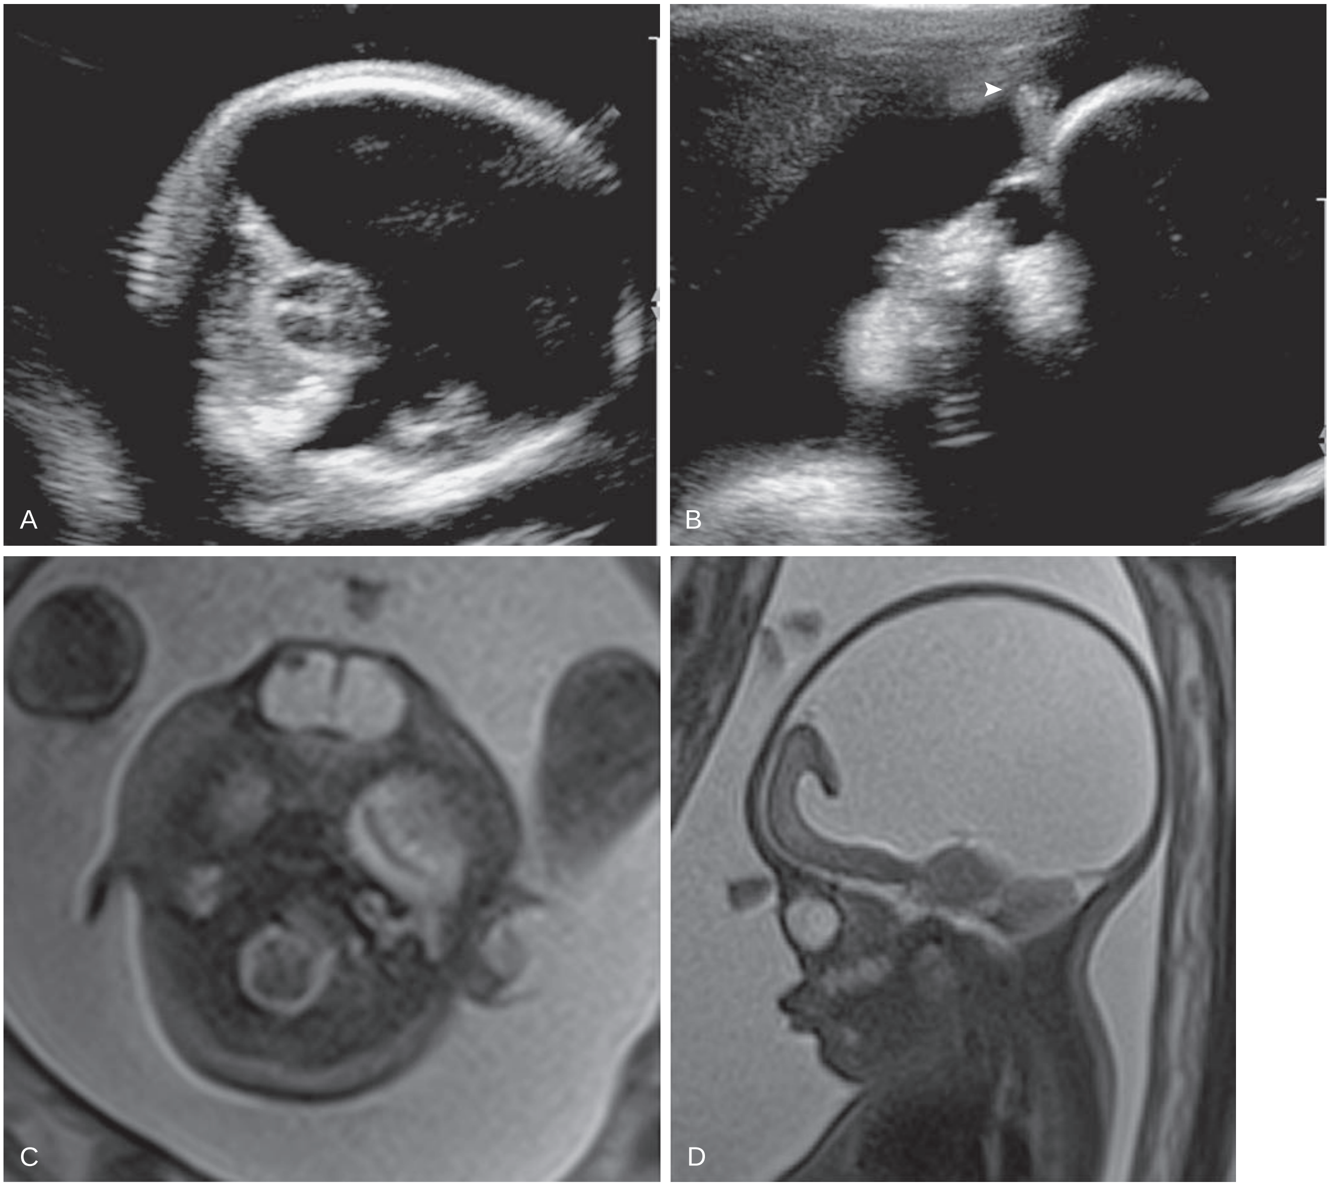


**Figure 29.7. Cyclopia.** (A) Axial sonogram of the fetal brain demonstrates alobar holoprosencephaly with a monoventricle, absent falx, and fused thalami. (B) Sagittal image of the fetal face shows a single midline orbit, absent nose, and supraorbital proboscis *(arrowhead)*. (C) Axial T2-weighted MR at 30 weeks' gestation demonstrates a single midline orbit with partially fused globes. (D) Sagittal T2-weighted image of the fetal brain and face demonstrates a proboscis superior to the orbit. There is a large posterior dorsal cyst.

alobar form, but subtle cases of lobar holoprosencephaly may be difficult to diagnose, even with MRI.

Alobar holoprosencephaly is complete failure of division of the promesencephalic vesicle. A monoventricle is identified with "kissing choroid" by ultrasound. The thalami and basal ganglia are fused. The falx, corpus callosum, and interhemispheric fissure are absent (Fig. 29.8). With semilobar and lobar forms, a posterior interhemispheric fissure is present, with absence of the genu of the corpus callosum. Lobar holoprosencephaly may have a normally formed thalamus and callosal splenium. The anterior frontal lobes are fused and the frontal lobes typically are hypoplastic. The septum pellucidum and anterior falx are absent. Syntelencephaly is a variant in which the anterior parietal lobe or posterior frontal lobes are contiguous across the midline.[46,47]

Septo-optic dysplasia may be identified by the presence of ventricular dilation, an absent septum pellucidum, and flat roof of the frontal horns. Schizencephaly, heterotopias, and callosal dysgenesis often are associated with this sporadic anomaly and are better seen by MRI.[27]

## POSTERIOR FOSSA MALFORMATIONS

Malformations of the cerebellum and brainstem can be categorized by posterior fossa size: small, normal, or large. The cisterna magna is measured by ultrasound from the midline posterior aspect of the vermis to the inner occiput and normally measures between 3 to 10 mm. Although ultrasound can identify many posterior fossa anomalies, MRI is particularly useful in evaluating the vermis, brainstem, and location of the tentorium.[48–50]

When a small posterior fossa is noted, a Chiari malformation should be considered, with a close search for an associated meningomyelocele. The tentorium is low, and the cisterna magna

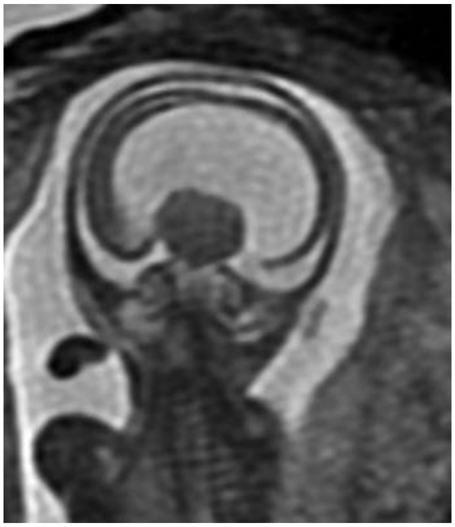

**Figure 29.8.** Alobar holoprosencephaly at 17 weeks' gestation. Coronal T2-weighted MR image shows a single mantle of neural tissue with a monoventricle and fused thalami.

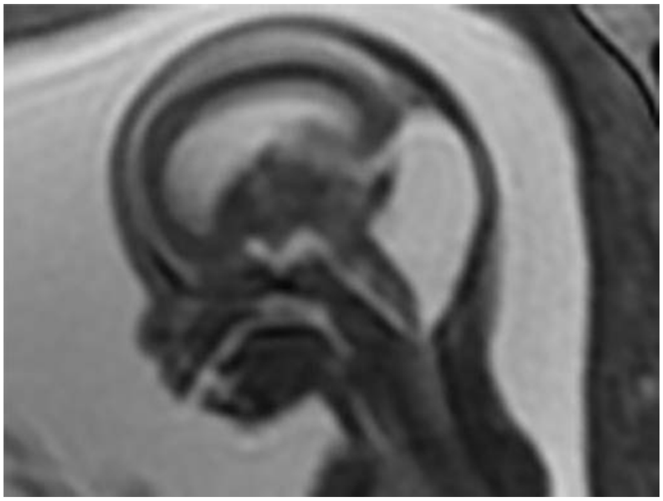

**Figure 29.11. Dandy–Walker malformation.** Sagittal single-shot fast spin-echo T2-weighted MR image at 18 weeks' gestation demonstrates an enlarged posterior fossa, elevated torcula, hypoplastic rotated vermis, and retrocerebellar fluid collection connected to the fourth ventricle.

and fourth ventricle are small. The differential diagnosis includes cerebellar hypoplasia.

When the posterior fossa is normal in size, abnormalities include cerebellar/pontocerebellar hypoplasia and vermian dysgenesis (partial or total absence of the vermis). Rarely, rhombencephalosynapsis (agenesis of the vermis with fusion of cerebellum) can be identified prenatally (e-Fig. 29.9). The fetal vermis is not completely developed until 18 weeks' gestation, and the fetal cerebellum continues to form in the third trimester, with cellular migration occurring through the first year of life. Thus mild cerebellar hypoplasia may be difficult to diagnose prenatally.[51–54] Volume measurements may aid in the diagnosis. Although pontocerebellar hypoplasia has a poor prognosis, the outcome for vermian dysgenesis is not as clear.

When the posterior fossa is enlarged, the differential diagnosis includes mega cisterna magna, Blake's pouch cyst, Dandy–Walker malformation, or arachnoid cyst. Mega cisterna magna is a wide cistern (anteroposterior greater than 10 mm) with a normal vermis and cerebellum (e-Fig. 29.10). The tentorium is located in a normal position. Mega cisterna magna can be a normal finding, although it has been associated with aneuploidy. If no additional anomalies are found and chromosomes are normal, the outcome should be good.[55]

Blake's pouch cyst is a posterior protuberance of the inferior medullary velum into the cistern. This fluid collection is posterior inferior to the vermis and communicates with the fourth ventricle. The vermis typically is intact, with mass effect and elevation of the tentorium. The cyst does not communicate with the subarachnoid space.[56]

Dandy–Walker malformation is a retrocerebellar cyst that communicates with the fourth ventricle. The posterior fossa is enlarged, with an elevated tentorium. The vermis is incomplete, elevated, and rotated (Fig. 29.11). Hydrocephalus usually is present. Prognosis depends on the degree of vermian hypoplasia, brainstem hypoplasia, and associated anomalies such as ACC, heterotopias, and encephaloceles.

Arachnoid cysts can develop in the posterior fossa, causing mass effect on the vermis, which otherwise is normally formed (e-Fig. 29.12). These cysts do not communicate with the fourth ventricle. The tentorium may be elevated. Symptoms can occur if hydrocephalus develops or the brainstem is compressed.

## CORTICAL DEVELOPMENT

Disorders of neuronal cell migration can be difficult to recognize in the fetal brain both by ultrasound and by MRI.[57,58] The cortex is poorly visualized by ultrasound, and whereas MRI demonstrates the cortical mantle relatively well, the cortex is not well developed in the second trimester. Thus a relatively smooth brain at 20 weeks that is normal can be indistinguishable from smooth pachygyria.

Abnormalities of cellular differentiation include unilateral megalencephaly and tuberous sclerosis (TS).[59] Subependymal hamartomas are present in up to 80% of patients with TS. Subependymal and subcortical tubers may be noted as intermediate-signal lesions on T2-weighted images and high-signal lesions on T1-weighted images in the third trimester (e-Fig. 29.13).

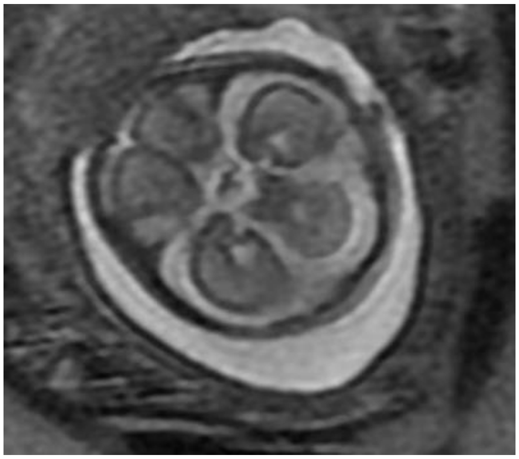
Neuronal heterotopias result when neurons fail to reach their destination at the cortical plate. Clusters can remain in the subependymal region or subcortical layer or form bands in the subcortical white matter. Subependymal heterotopias may be unilateral or bilateral, projecting as small lumps into the ventricles. The differential diagnosis includes hamartomas of TS and subependymal hemorrhage. Subcortical heterotopias are clumps of neurons and glial cells in the white matter that often are associated with ACC or neuroepithelial cysts. Associated microcephaly may not develop until the late third trimester or postnatally.

Agyria/pachygyria results from arrest of migration of neuroblasts with abnormal cortical lamination and failure of sulcation. Classic lissencephaly has few sulci, whereas pachygyria is less severe. In fetuses with cobblestone lissencephaly, cellular overmigration is present with hydrocephalus. Prenatally, ventricles typically are enlarged. Fetal MRI may show abnormal cortical sulcation in the third trimester (Fig. 29.14).[60]

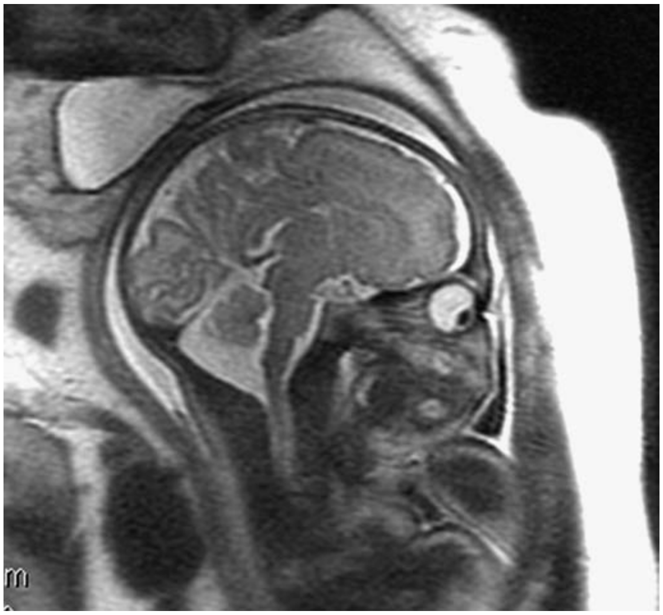
Polymicrogyria is excessive folding of cerebral cortical cell layers with fusion of the gyral surface. It is common after cytomegalovirus infection in the second trimester and is difficult to diagnose before the third trimester. Multiple small, irregular sulci may be noted with mild VM.

## SUMMARY

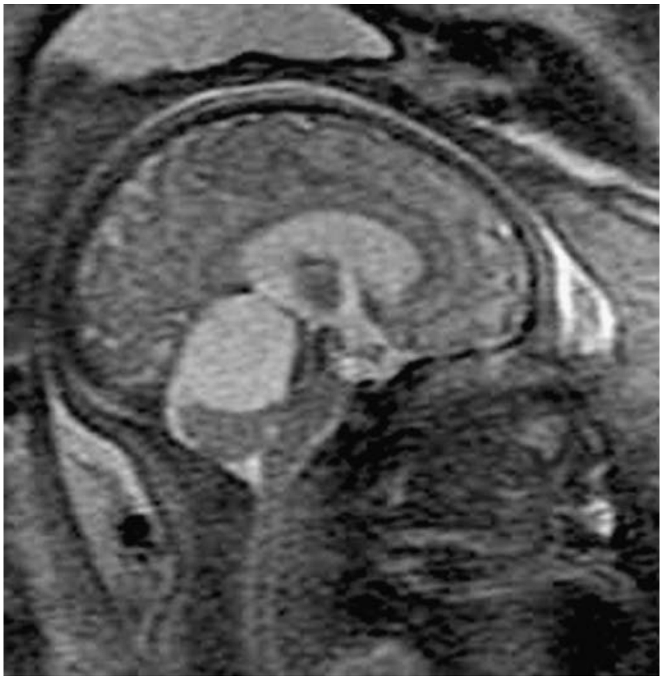
Interpreting fetal MR images can be challenging because structures are small and change with fetal maturation. Great care must be



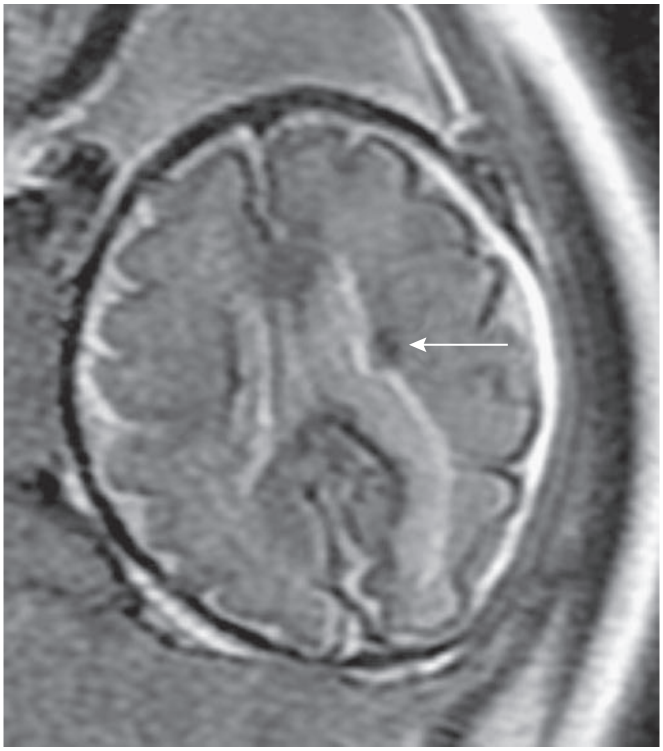
**e-Figure 29.9. Rhombencephalosynapsis.** Axial T2-weighted MR image of the posterior fossa at 23 weeks' gestation demonstrates cerebellar hemispheric folia continuous across the midline with absence of the anterior vermis.



**e-Figure 29.10. Mega cisterna magna.** Sagittal single-shot fast spin-echo T2-weighted magnetic resonance image shows a prominent cisterna magna. The vermis is intact. The cerebellar volume and brainstem are normal for gestational age.



**e-Figure 29.12. Arachnoid cyst.** Sagittal single-shot fast spin-echo T2-weighted MR image of a 37-week fetus shows an enlarged posterior fossa with a cystic structure deviating the vermis inferiorly. The cyst does not connect to the fourth ventricle. A sonogram at 21 weeks' gestation was normal.



**e-Figure 29.13. Subependymal hamartoma.** Axial single-shot fast spin-echo T2-weighted MR image shows a low-signal subependymal mass *(arrow),* which had high signal on T1-weighted imaging. The fetus had rhabdomyomas involving the heart as well. After delivery, tuberous sclerosis was confirmed.

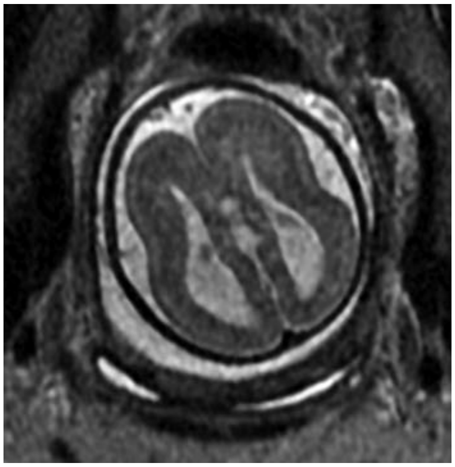


**Figure 29.14. Lissencephaly.** Axial single-shot fast spin-echo T2-weighted MR image of a 36-week gestation fetus demonstrates an abnormal smooth surface with lack of gyri and sulci. The cortical and subcortical layers are disorganized. Colpocephaly is present with dilated atria. The infant was diagnosed with Miller–Dieker syndrome after delivery.

taken when performing and interpreting these studies. Prognosis of abnormalities can be varied, making counseling difficult, even when anomalies are well delineated. Long-term follow-up studies are necessary to provide accurate data. Ultrasound remains the screening modality of choice in the assessment of the fetal brain. However, when a CNS anomaly is identified, MRI has become an important adjunct in further assessment.

## KEY POINTS

- Neuronal migration and gyration follows a predictable course throughout the second and third trimester.
- Fetal VM outcome is variable. Associated anomalies and aneuploidy bode for a worse prognosis.
- The fetal vermis does not develop until 18 weeks' gestation and the cerebellum continues to form in the third trimester. Thus vermian and cerebellar hypoplasia may be difficult to diagnosis accurately in the second trimester.
- Cortical dysplasias may not be visualized in the second trimester.

# Neonatal Brain Injury

Andre Dietz Furtado, Jessica L. Wisnowski, and Ashok Panigrahy

A significant number of deaths and permanent neurologic disabilities occur during the first month of life, the neonatal period. During the first month of life, term infants and particularly preterm neonates are vulnerable to a wide range of adverse events that may cause brain injury. Imaging is used not only to diagnose and understand neonatal brain injury but also to predict the neurodevelopmental outcome.[1]

Because of its portability, cranial ultrasound is usually the first imaging modality to be performed and can be used serially to monitor the evolution of certain injuries. Ultrasound is usually sufficient for evaluation of germinal matrix hemorrhage (GMH) and intraventricular hemorrhage (IVH), serial assessment of ventricular size in hydrocephalus, cystic white matter changes, and severe brain malformations. Ultrasound is less sensitive than computed tomography (CT) or magnetic resonance imaging (MRI) in the detection of small calcifications and is less sensitive than MRI in the detection of hypoxic-ischemic injury and subtle brain malformations. MRI also is excellent for the evaluation of punctate white matter lesions, which are seen in the setting of premature white matter.

Because of the associated ionizing radiation, the use of CT is mainly restricted to instances in which there is a suspicion of intracranial calcifications, lesions that contain fat, acute intracranial hemorrhage, and to evaluate the bones. MRI is the most sophisticated modality to evaluate the neonatal brain, and with advanced imaging techniques such as diffusion-weighted imaging (DWI), functional magnetic resonance imaging (fMRI), and magnetic resonance spectroscopy (MRS), it has the advantage of providing information regarding physiology, function, and metabolism. Arterial spin labeling techniques provide assessment of brain perfusion in the neonate without the use of intravenous contrast material. Intravenous contrast is not routinely used because of the physiologic renal immaturity in the first few days to weeks after birth.

## IMAGING TECHNIQUES

High-resolution images with good tissue contrast are essential for an adequate evaluation of the neonatal brain. Ultrasound provides high-resolution images of the neonatal brain, but it has limitations regarding visualization of deeper structures and the cerebellum. Because increased tissue contrast in CT usually is achieved at the expense of increased radiation dose, CT usually is performed with use of low radiation dose protocols and is reserved for a limited number of situations.

MRI is the imaging modality with the highest sensitivity for differentiating abnormalities from normal brain. Conventional MRI, including T1-weighted, T2-weighted, DWI, and gradient-echo sequences or susceptibility-weighted images, provide the most useful diagnostic information. Sequences should be modified to optimize signal to noise for the neonatal brain. Structurally, the brains of preterm infants and neonates have much higher water content and much lower lipid content compared with brains of older children. With myelination, these compositions invert. Myelination begins along specific tracts in the third trimester and continues well into the postnatal years. Longer echo times are useful for younger patients because of the differences of extracellular lengthening of the T2-relaxation time with decreasing age. Similarly, the T1 relaxation is longer for infants and young children and varies with the magnetic field strength. Longer inversion times of T1-weighted scans provide additional contrast between myelinated and unmyelinated white matter in infants. Finally, the higher water content and lower anisotropy in infants necessitate a lower b-values (600–700 s/mm$^2$) to optimize signal to noise in DWI.

Dedicated neonatal MR head coils improve image contrast and resolution at the smaller field of view optimal for neonatal imaging.[2,3] These dedicated coils improve gray-white matter differentiation and provide better visualization of the brainstem and posterior fossa. If a dedicated neonatal head coil is not available, coils for small body parts (i.e., knee coil) should be used to improve image quality.

### Patient Preparation, Safety, and Hazards

Ultrasound can be performed at the bedside and does not use contrast material or ionizing radiation. The only precaution with ultrasound is prevention of infection, which can be achieved with use of sterile gel and a probe cover. CT scanning time is short but usually requires transportation of the neonate to the scanner. Portable CT scanners may be useful in selected patients. Contrast material is rarely needed and should be avoided in neonates because of their physiologic renal immaturity, which is present in the first few days to weeks after birth.

Because of the magnetic resonance (MR) environment and length of most MRI examinations, MR safety is a particular concern for neonates. Before the MR examination, any patient, including neonates, should be screened for possible cardiac devices, implants, non–MR-compatible leads, or surgically implanted wires. The compatibility of any device must always be verified with the manufacturer. Continuous monitoring and support for respiratory and cardiovascular functions can be achieved with MR-compatible equipment. Thermoregulation, which can be a particular concern for preterm neonates, can be supported through use of MR-compatible incubators and monitored through use of an MR-compatible temperature probe. Special attention should be given for loops in conductive cables, which may cause burns and possibly fires.

Increasingly, neonates undergoing MRI are scanned during natural sleep (“feed and bundle” procedures). Although acoustic noise and table vibration from the MR scanner may awaken an older infant (i.e., >3 months of age, a developmental stage at which infants normally begin to awaken to startling noises), young infants (<3 months) often tolerate even long MR protocols when imaging is performed during natural sleep. At our institution, we routinely use MR-compatible noise-canceling headphones designed for neonates. When imaging during natural sleep is not possible, neonates and older infants are scanned while sedated. Sedation should be performed only by properly trained and credentialed clinicians.

## BIRTH TRAUMA

Birth trauma is more common in vaginal delivery, particularly if forceps or vacuum extraction is used. The most common traumatic birth lesions are extracranial hematomas, skull fractures, osteodiastasis, and subdural hematomas.

## Abstract:

A significant number of deaths and permanent neurologic disabilities occur during the first month of life, the neonatal period. During the first month of life, term infants and particularly preterm neonates are vulnerable to a wide range of adverse events that may cause brain injury, namely birth trauma, hypoxic-ischemic encephalopathy, infarction, hemorrhage, hydrocephalus, white matter injury, and metabolic disorders. Because of its portability, ultrasound is usually the first imaging modality to be performed and can be used serially to monitor the evolution of certain injuries. Ultrasound is usually sufficient for evaluation of germinal matrix hemorrhage and intraventricular hemorrhage, Computed tomography (CT) or magnetic resonance imaging are more sensitive in the detection of small calcifications and is less sensitive than MRI in the detection of hypoxic-ischemic injury and subtle brain malformations. Because of the ionizing radiation, the use of CT is mainly restricted to instances in which there is a suspicion of intracranial calcifications, lesions that contain fat, acute intracranial hemorrhage, and to evaluate the bones. MRI is the most sophisticated modality to evaluate the neonatal brain, providing information regarding physiology, function, and metabolism.

## Extracranial Hematomas

The major types of extracranial hematomas are cephalohematoma, caput succedaneum, and subgaleal hematoma (also see Chapter 23). In subgaleal hematomas, the hemorrhage accumulates between the epicranial aponeurosis of the scalp and the periosteum (e-Fig. 30.1). The hematoma may enlarge rapidly and lead to potentially life-threatening hypovolemia. Anemia, coagulopathy, metabolic acidosis, renal impairment, and skull fracture have been reported as predictors of poor outcome. Early recognition and management are essential. Upon imaging, extracranial hematomas appear as a hemorrhagic collection overlying the calvarium and crossing the sutures. They may extend underneath the attachments of the occipitofrontalis muscle to the orbital margins anteriorly, the temporal fascia laterally, and the nuchal ridge posteriorly (e-Fig. 30.2).

Caput succedaneum is common after vaginal delivery, particularly when vacuum extraction is used. Typically, resolution occurs within a few days without complications. Caput succedaneum represents edema, which may be accompanied by hemorrhage, within the subcutaneous tissues, which are not limited by the cranial sutures (see e-Fig. 30.2).

Cephalohematomas are rarely associated with complications but may be associated with skull fracture and epidural hematomas. Blood degradation within a hematoma may cause jaundice. Cephalohematomas are subperiosteal hemorrhages confined by cranial sutures. Typically, hematomas increase in size after birth, and a small proportion of them calcify and may cause skull deformity (calcified cephalohematoma).

## Subdural Hematomas

The most common intracranial hemorrhage in term neonates is subdural hematoma, and most common is asymptomatic in parafalcine location or over the tentorium. The incidence of these small subdural hematomas in neonates has been reported as high as 46% in the first 72 hours after birth.[5] Most subdural hematomas are venous in origin related to tearing of the dura, inferior sagittal sinus, and cortical veins. The typical appearance of subdural hematomas is of an extraaxial collection that may cross under sutures, but respect the dural reflection, such as the falx and tentorium (see e-Fig. 30.2). Arterial subdural hematomas caused by arterial bleeding are rare but should be suspected in large hyperacute subdural hematomas. Most lethal cases are related to large infratentorial hemorrhages with compression of the brainstem. Associated small subarachnoid hemorrhages related to tearing of cortical veins are not infrequent. Large subdural hematomas may cause parenchymal infarction as a result of impaired arterial supply and venous drainage, leading to hemorrhagic venous infarction. Large subdural hematomas may interfere with cerebrospinal fluid (CSF) reabsorption and cause hydrocephalus. Subdural hematomas that are not evacuated undergo absorption or evolve into subdural hygromas, which can persist for several months.

Finally, late subdural hematomas after the first week of life may be a presentation of a nonaccidental trauma, in addition to late hemorrhagic disease of the newborn (vitamin K deficiency).

## Spontaneous Superficial Parenchymal and Leptomeningeal Hemorrhage

Spontaneous superficial parenchymal and leptomeningeal (subpial) hemorrhage may also occur in otherwise healthy asymptomatic neonates. They are most common in the temporal lobes, adjacent to a suture. The hemorrhage may extend into the adjacent sulci but is confined by the pia matter (e-Fig. 30.3). Mild surrounding decreased diffusion is typically present.[6]

# HYPOXIC-ISCHEMIC ENCEPHALOPATHY

Brain damage in the term neonate is highly variable and depends on the severity and duration of insult. Moreover, the imaging findings vary dramatically in relation to the timing of imaging studies. Imaging before 72 hours may underestimate the severity because of delayed cell death. Therapeutic hypothermia, which typically is applied for 72 hours beginning within 6 hours of life, may further delay this process.

## Central Pattern of Hypoxic-Ischemic Encephalopathy

The central pattern of hypoxic-ischemic encephalopathy (HIE) usually occurs with profound asphyxia, when there is an abrupt interruption of the blood supply, depriving the neonatal brain of oxygen and glucose. Highly metabolic structures such as the thalami, basal ganglia, and brainstem are more vulnerable to hypoxia and ischemia, more specifically the ventral lateral thalami, posterolateral lentiform nuclei, posterior midbrain, hippocampi, lateral geniculate nuclei, and perirolandic cerebral cortex (Fig. 30.4).[7] Quadriparesis,

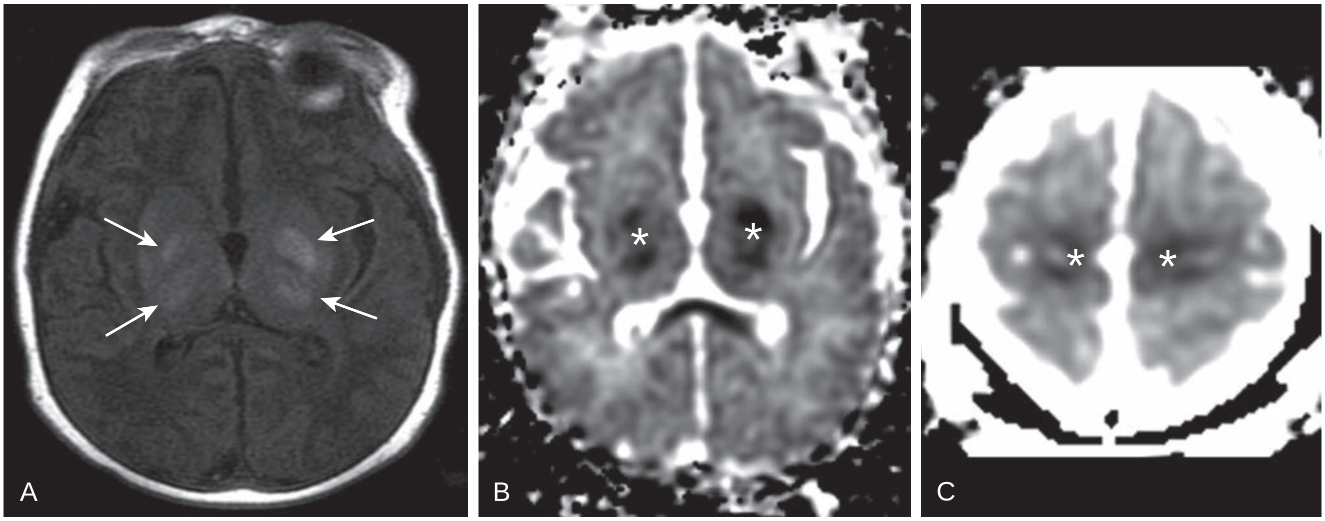

**Figure 30.4. Central hypoxic-ischemic injury.** (A) Axial T1-weighted MR image shows increased T1 signal in the globi pallidi and ventrolateral thalami bilaterally *(arrows)*. (B and C) Reduced apparent diffusion coefficient is seen in the globi pallidi and thalami and in the perirolandic regions bilaterally *(asterisks)*.

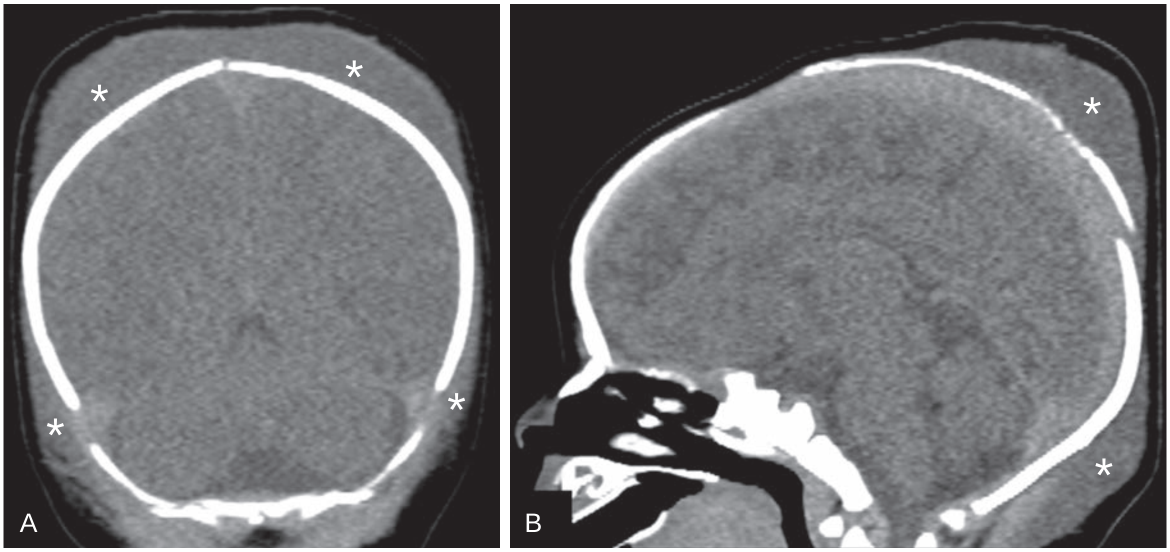
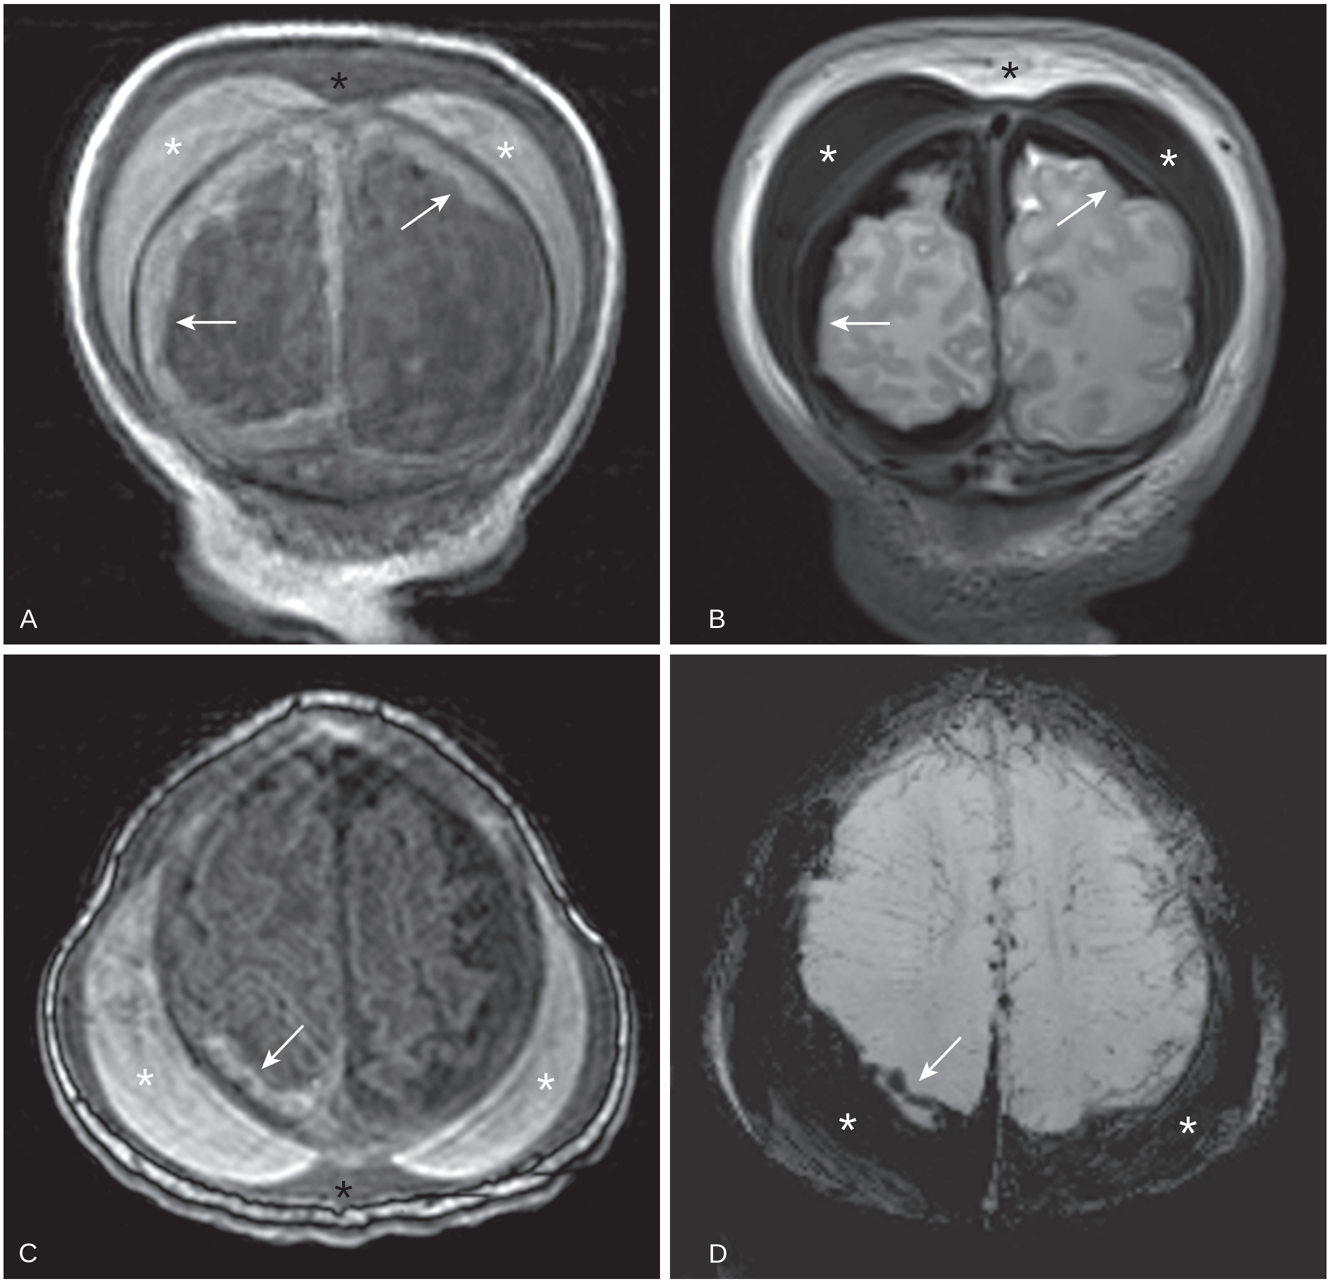
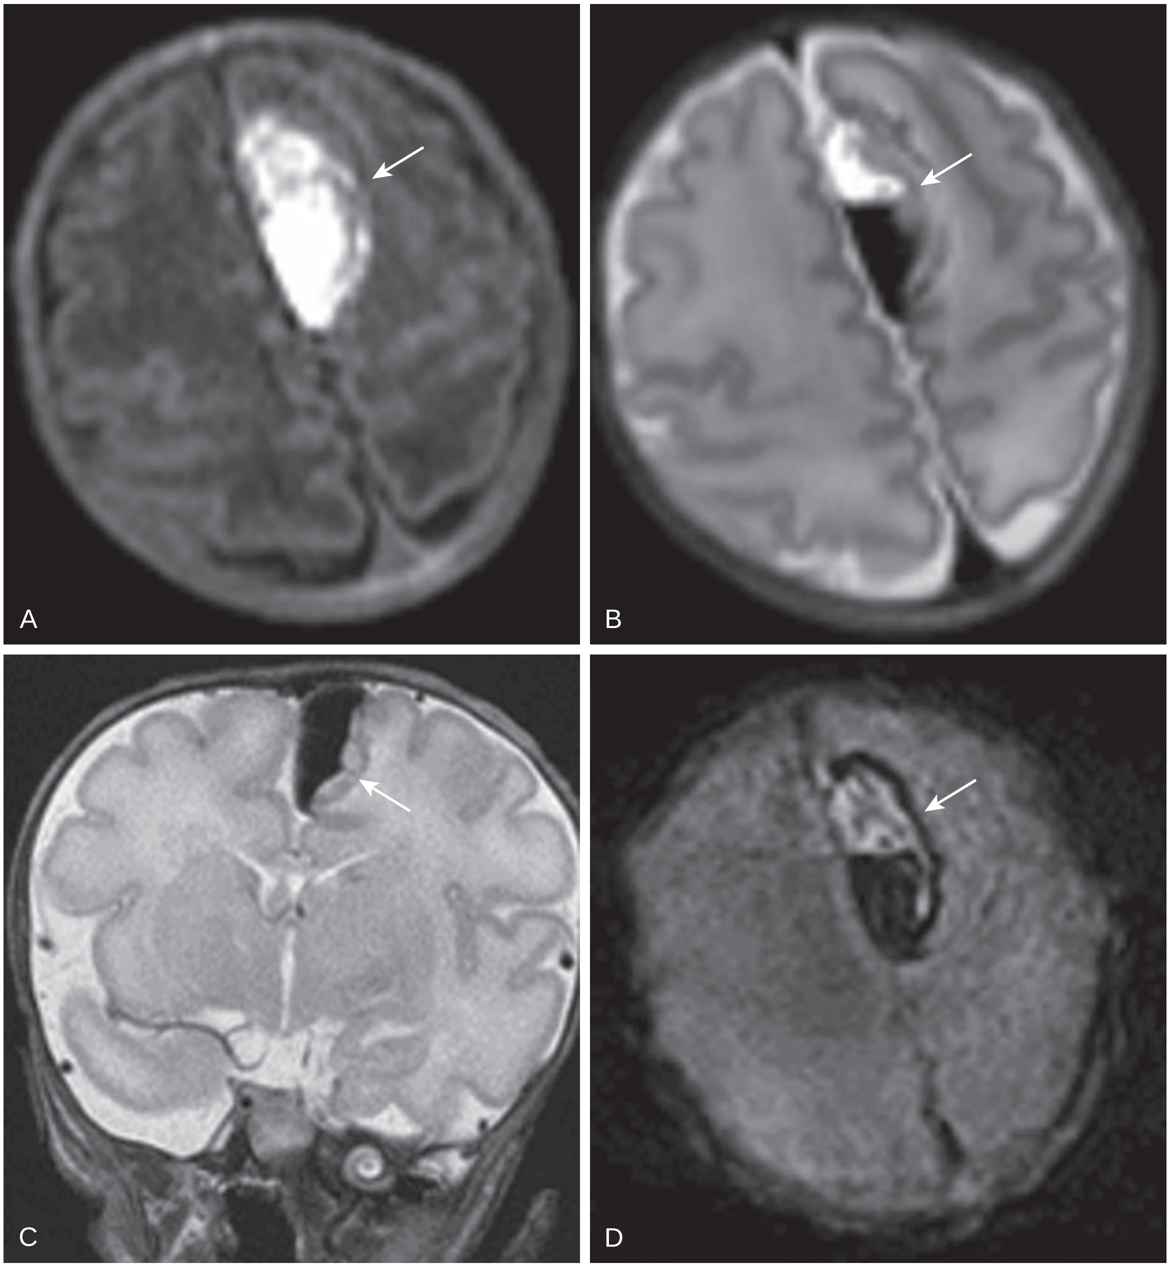


**e-Figure 30.1. Subgaleal hematoma in a newborn.** (A) Coronal and (B) sagittal CT images show large subgaleal hematoma crossing the cranial sutures and extending into the suboccipital region *(asterisks)*.



**e-Figure 30.2. Caput succedaneum, cephalohematoma, and subdural hematoma in a newborn.** Caput succedaneum crossing over the sagittal suture *(black asterisk)*, cephalohematoma respecting the sagittal and bilateral coronal sutures *(white asterisk)*, subdural hematoma along the posterior hemispheres, falx, and tentorium *(arrows)*. (A and C) T1-weighted MR images. (B) T2-weighted MR image. (D) Susceptibility-weighted MR image.



**e-Figure 30.3. Spontaneous superficial parenchymal and leptomeningeal (subpial) hemorrhage.** (A) T1-weighted MR image; (B and C) T2-weighted MR images; (D) susceptibility-weighted MR image *(arrows)*.

choreoathetosis, seizures, mental retardation, and cerebral palsy have been associated with profound asphyxia.[8] Ultrasound and CT have low sensitivity to detect early ischemic changes in the deep structures of the brain. The most common pattern on ultrasound is transient or persistent hyperechogenicity, which may progress to cavitation in the basal ganglia and thalami, particularly in the globus pallidus and ventral lateral nuclei of the thalamus. With more severe insults involving the cortex and subcortical white matter, ultrasound and CT may depict indirect evidence of edema, such as effacement of the sulci, loss of gray-white matter differentiation, and compressed lateral ventricles.

MRI is the imaging modality of choice for neonatal encephalopathy. MRS performed 24 hours after the insult is considered sensitive for hypoxic-ischemic brain injury. Elevated lactate and diminished N-acetyl-aspartate (NAA) are the most common MRS findings in neonates with neurologic and developmental abnormalities (e-Fig. 30.5). Lactate rises after the hypoxic-ischemic event, peaking at 3 to 5 days, whereas NAA starts to decline around the third day. Although a minimally elevated lactate level (lactate/choline ratio <0.15) may be detected in the normal neonatal brain at term, an increased lactate level relative to the total creatine peak in the basal ganglia provides an early indication of brain injury. It has been suggested that resuscitation may rapidly clear lactate and that a secondary increase in lactate may occur after 12 to 24 hours. This may cause false-negative MRS with normal spectra but abnormal outcomes. The metabolites tend to normalize after about day 5, although in some cases abnormal metabolite ratios persist. Persistently elevated lactate levels in the basal ganglia provide prognostic information about the severity of the brain injury and the subsequent adverse neurodevelopmental outcome.

DWI is a sensitive technique for assessment of acute brain injury and shows deep gray matter and perirolandic gray matter lesions before they are seen with conventional MRI. If DWI is performed in the first few hours after the injury, it may underestimate the extent of the injury or even show normal results. Paralleling the clinical presentation of HIE, in which neonates may actually transiently improve before demonstrating a more permanent decline in neurologic functioning because of delayed cell death via apoptotic mechanisms, some patients demonstrate mild brain damage for the first few days and then proceed to demonstrate extensive brain involvement around 5 days after the injury. Apparent diffusion coefficient (ADC) values always evolve over time; they decrease initially after the injury, with the nadir around 3 to 5 days, and increase (via facilitated diffusion) later in the chronic phase. As ADC values increase, a point of transient "pseudonormalization" exists in which injured tissue can be misdiagnosed as "normal." Conventional MRI findings are usually unremarkable during the first few days but then begin to demonstrate first an increased T1-weighted signal and a decreased T2-weighted signal in the subacute period followed by an increased T2-weighted signal in the more chronic period. Evidence suggests that hypothermia therapy delays the onset of MR changes (in metabolic, diffusion, and conventional imaging) associated with injury and, in particular, delays the onset of pseudonormalization in the ADC signal.[9]

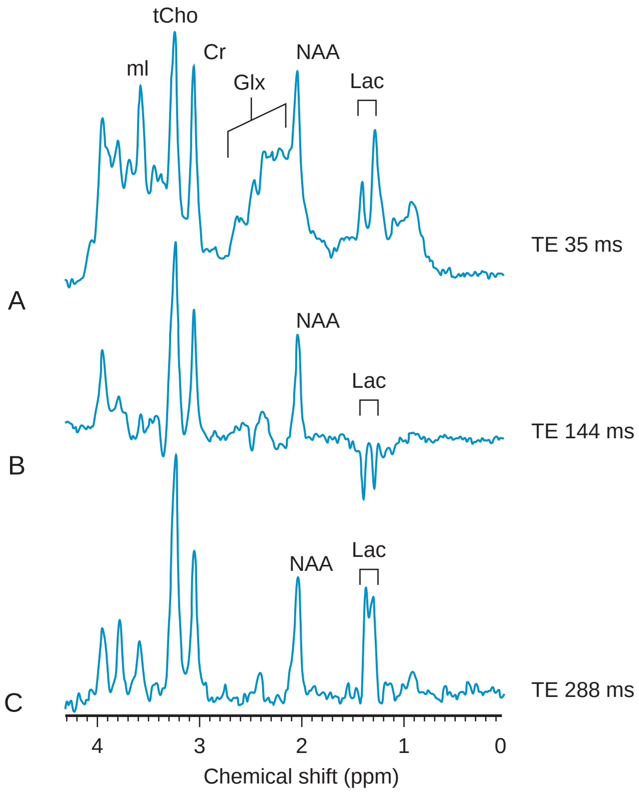
## Peripheral Pattern of Hypoxic-Ischemic Encephalopathy

The peripheral pattern of HIE usually results from a period of decreased blood supply to the brain (rather than a near total and abrupt interruption) and is thought to develop as a result of a compensatory shunting of blood to vital brain structures, such as the brainstem, thalami, basal ganglia, hippocampi, and cerebellum, at the expense of less metabolically active structures, namely the cerebral cortex and white matter (Fig. 30.6). Therefore the brainstem, cerebellum, and deep gray matter structures generally are spared from injury in mild to moderate hypoxic-ischemic insults. More prolonged insults result in injury to the intervascular border (watershed) zones, which are relatively hypoperfused as a result of this shunting. Neurologic examination varies depending on the severity of the insult, from asymptomatic in mild cases to proximal extremity weakness or spasticity and cerebral palsy in persons who sustain severe insults.[8] Increasing severity of watershed-distribution injury is associated with impaired neurocognitive functioning, including language, visuoperceptual, and executive functioning impairments.

Ultrasound lacks sensitivity in assessing partial prolonged hypoxia-ischemia because it provides poor visualization of the triple watershed zone. CT also is not sensitive to the early changes but may show effacement of the gray-white junction, hypoattenuation with mass effect from acute edema, or hypoattenuation with volume loss in the watershed zone. Similar to central HIE, in the acute phase, MRI can detect lactate and restricted diffusion with corresponding low ADC values in the affected brain regions, which predominantly involve the cortex and underlying white matter along the parasagittal frontal-parietal cortex. With time, increased T2/fluid-attenuated inversion recovery signal and mass effect related to edema may develop. Chronically, gliosis and volume loss mainly involving the deep portion of the gyri result in mushroom-shaped gyri (known as ulegyria), which sometimes is associated with an epileptogenic focus. Atrophic changes and gliosis predominately involve the subcortical white matter in the border zone between the anterior and the middle cerebral arteries, in the parasagittal watershed zone, and in the parietal lobes at the border zone of the three major cerebral arteries, that is, the triple watershed zone.

## NEONATAL ARTERIAL INFARCTION

Infarctions involving the vascular territory of a major artery, most commonly the middle cerebral artery, are more common in term than in preterm neonates. Symptoms are subtle and nonspecific, and many neonatal arterial infarcts may be unrecognized until motor or cognitive symptoms develop later in infancy or childhood. In the neonatal period, the most common presenting symptom is a focal motor seizure involving the contralateral limbs, which may secondarily generalize. Infarcts of the anterior and posterior cerebral arteries are underdetected because they may be asymptomatic and difficult to visualize on ultrasound. Several causes have been described, including sepsis, bacterial meningitis, inherited or acquired coagulopathies, and cardiac abnormalities, but often no specific cause is identified. Initial imaging shows a loss of gray-white matter differentiation, which in severe instances may be detected on ultrasound but is most readily visualized on MRI as increased signal on DWI with low ADC values (Fig. 30.7). Later (after 24–48 hours) the edema becomes apparent as increased echogenicity on ultrasound, hypoattenuation on CT, increased signal on T2-weighted MRI, and decreased signal on T1-weighted MRI. Although the high water content of the unmyelinated neonatal brain poses significant challenges for the detection of edema on CT or conventional MRI sequences, loss of gray-white matter differentiation frequently is present. This lack of contrast between the normal brain and the infarction is particularly relevant at 5 to 10 days after infarction when the ADC may be pseudonormalized. With time, ADC values increase (via facilitated diffusion); after a few weeks, volume loss and encephalomalacia become apparent. Hemorrhagic transformation of an ischemic stroke is rare in neonates, but increased signal on T1-weighted imaging along the cortex related to laminar necrosis is not uncommon. Interestingly, acutely after a perinatal ischemic infarct, hyperperfusion as demonstrated on arterial spin label sequences frequently is observed in the regions corresponding to areas of low ADC on diffusion-weighted MRI.



**e-Figure 30.5. Magnetic resonance (MR) spectroscopy in hypoxic-ischemic encephalopathy.** Increased lactate on MR spectroscopy performed with TE of 35 ms (A), 288 ms (C) and inverted with TE of 144 ms (B). *Cr,* Creatine; *Glx,* glutamate/glutamine; *lac,* lactate; *ml,* myo-inositol; *NAA,* N-acetyl asparatate; *tCho,* total choline.

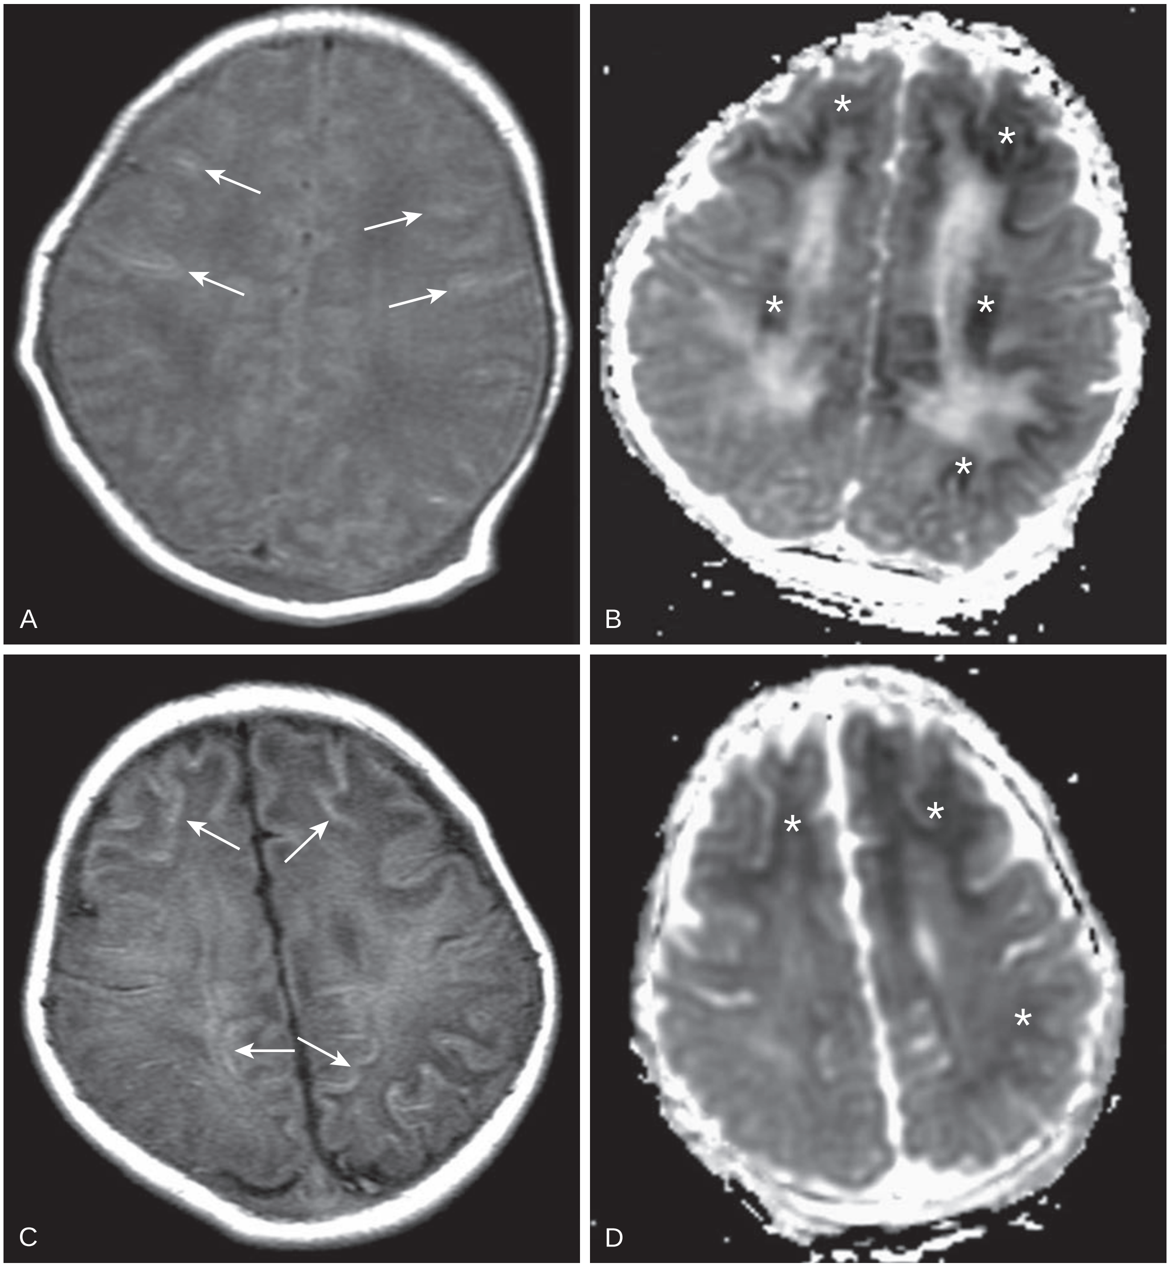


**Figure 30.6. Peripheral pattern of hypoxic-ischemic injury.** (A and B) At day 2 after the ischemic insult, increased signal on axial T1-weighted MR images *(arrows)* and reduced apparent diffusion coefficient (ADC) *(asterisks)* mainly involving the juxtacortical white matter *(arrows)*. (C and D) At 7 days after the insult, axial T1-weighted images demonstrate progression on the areas of increased signal *(arrows)* and less conspicuously reduced ADC *(asterisks)*.

## INTRAVENTRICULAR AND LARGE PARENCHYMAL HEMORRHAGE

Intraparenchymal hemorrhage occurs infrequently in full-term neonates. Most parenchymal bleeding in the term infant involves the thalamus, is associated with IVH, and develops in infants at risk for venous thrombosis. The most documented cause of intraparenchymal hemorrhage is cerebrovenous sinus thrombosis, followed by coagulopathy, infection, hypoglycemia, vascular malformation, tumor, and genetic disorders. A hemorrhagic and thrombotic screening is the first step in any neonate with intracranial hemorrhage. Additionally, confirmation of vitamin K administration and examination of alloimmune antibodies in the mother's blood should be obtained. Although hemorrhage may occur anywhere in the term neonatal brain, the thalamus and the choroid plexus are the most common locations. Rarely, hemorrhages occur in areas of residual germinal matrix (GM). Blood degradation products without surrounding edema or hydrocephalus with chronic blood products in the first days of life are suggestive of intrauterine hemorrhage, which are most commonly caused by maternal factors such as anticoagulants, vasogenic agents (including illicit drugs), diabetes, and trauma. Less commonly, fetal conditions such as

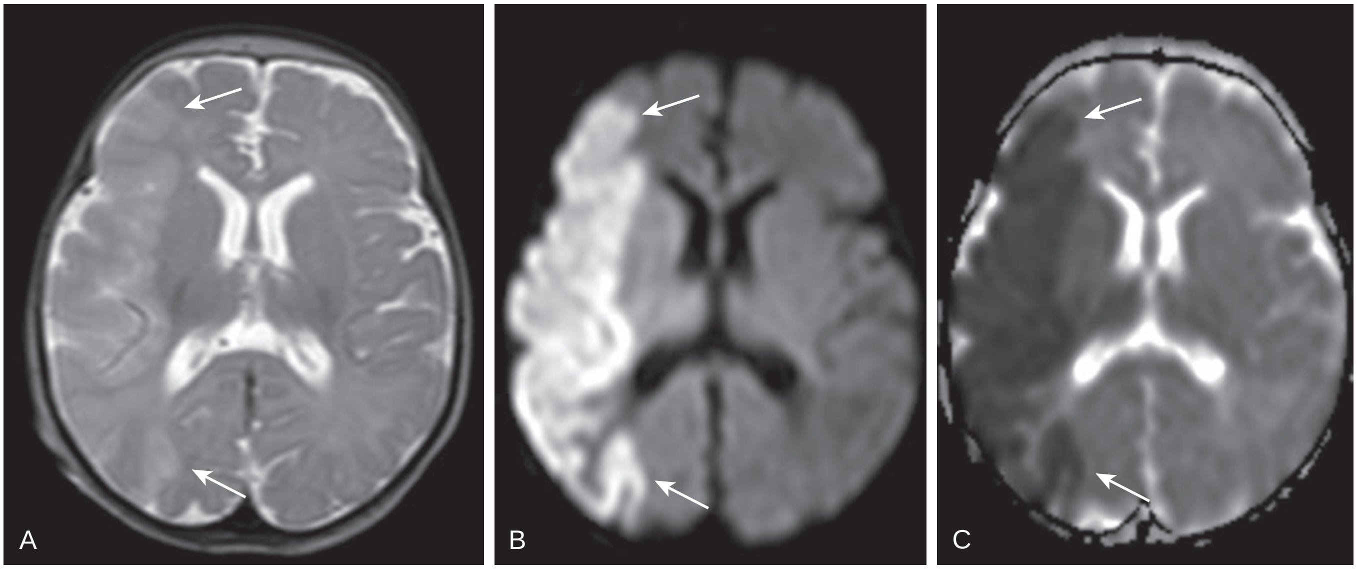

**Figure 30.7. Ischemic infarct.** (A) Axial T2-weighted MR image shows developing edema with loss of the gray-white matter differentiation involving the territory of the right middle cerebral artery *(arrows)*. (B) Corresponding restricted diffusion *(arrows)* and (C) low apparent diffusion coefficient values *(arrows)*.

arteriovenous malformation (AVM and vein of Galen malformation), congenital brain tumor, and genetic disorders may lead to prenatal hemorrhage.

## NEONATAL CEREBROVENOUS SINUS THROMBOSIS

Neonatal cerebrovenous sinus thrombosis (CVST) is a rare but devastating condition. It may be a result of trauma, increased hematocrit, sepsis, dehydration, cardiac failure, and thrombotic disorders such as factor V Leiden. The impaired venous drainage commonly results in cytotoxic edema, vasogenic edema, and parenchymal hemorrhage, and in more severe cases acute or chronic hydrocephalus. Although venous infarction can occur anywhere in the brain, the most characteristic locations are the thalami, resulting from thrombosis of the straight sinus and vein of Galen, and the bilateral parasagittal cortex and subcortical white matter, resulting from thrombosis of the superior sagittal sinus. Diffuse cerebral swelling may be a result of extensive CVST.

The diagnosis of CVST may be achieved by demonstrating the thrombus or the lack of normal venous flow in the venous sinuses. Doppler ultrasound may detect superior sagittal sinus thrombosis in neonates, but it has limited sensitivity in evaluating the remainder of the venous system (Fig. 30.8). Serial Doppler ultrasound is an easily performed and inexpensive alternative for monitoring sinovenous thrombosis. CT without contrast may demonstrate a hyperattenuating sinus with a large thrombus but has limited value for small thrombi. False-positive results can occur with unenhanced CT because of relative hyperattenuation of normal neonatal blood due to the high hematocrit and the adjacent hypoattenuating nonmyelinated brain tissue. Moreover, hyperattenuating subdural hematomas that are present in up to a third of the neonates can be misinterpreted as a thrombus. The demonstration of filling defects using CT venography is confirmatory of CVST. Beam hardening artifact from dense bone adjacent to the dural sinus and normal arachnoid granulations may mimic a filling defect. The normal dural sinus and veins have flow voids on unenhanced MRI. Phase-contrast MR venography and two-dimensional time-of-flight MR venography are specific for flow and are valuable in demonstrating obstruction. High signal on unenhanced MRI or lack of flow-related signal on two-dimensional time-of-flight MR venography can be related to thrombus or slow flow. Thin-slice images oriented perpendicular to the flow in the sinus with an abnormal signal is usually sufficient to correct for this “artifact.” MR venography and contrast-enhanced MRI are complementary to unenhanced MRI to show the filling defect and to differentiate venous thrombosis from adjacent subdural hematoma. The best unenhanced conventional MR sequences for detection of sinus venous thrombosis are spin echo T1 and proton density images (see Fig. 30.8). Although full anticoagulation is controversial in the neonatal period, CVST is a medical emergency, and a definite diagnosis should be confirmed as soon as possible. When the aforementioned diagnostic modalities are inconclusive, digital subtraction angiography is the gold standard.

## VASCULAR MALFORMATIONS

Most vascular malformations are silent during the neonatal period but may be diagnosed prenatally or incidentally. A full description of all the major vascular malformations is beyond the scope of this chapter. Instead, we will focus on those that more commonly manifest in the neonatal period: cerebral (pial) vascular malformations, aneurismal malformation of the vein of Galen, and malformation of the dural sinuses.

### Arteriovenous Malformations

AVMs are abnormal thin-walled vessels that connect arteries to veins without intervening capillaries. Most cases of AVM manifest later in childhood or in early adulthood. Neonates with an AVM tend to present with systemic cardiac manifestations or seizures related to parenchymal hypoperfusion. Macrocephaly and hydrocephalus related to abnormally increased venous pressure and spontaneous hemorrhage are less common manifestations of AVMs in the neonatal period.

In symptomatic patients, early diagnosis and emergency endovascular embolization is important because progression to atrophy and leukomalacia may occur rapidly. Unenhanced CT is useful to detect acute hemorrhaging, but it lacks the sensitivity necessary to detect the underlying vascular malformation. CT angiography (CTA) involves radiation exposure but provides exquisite anatomic detail of a nidus (if present), feeding arteries, draining veins, and the presence of possible aneurysms. MR

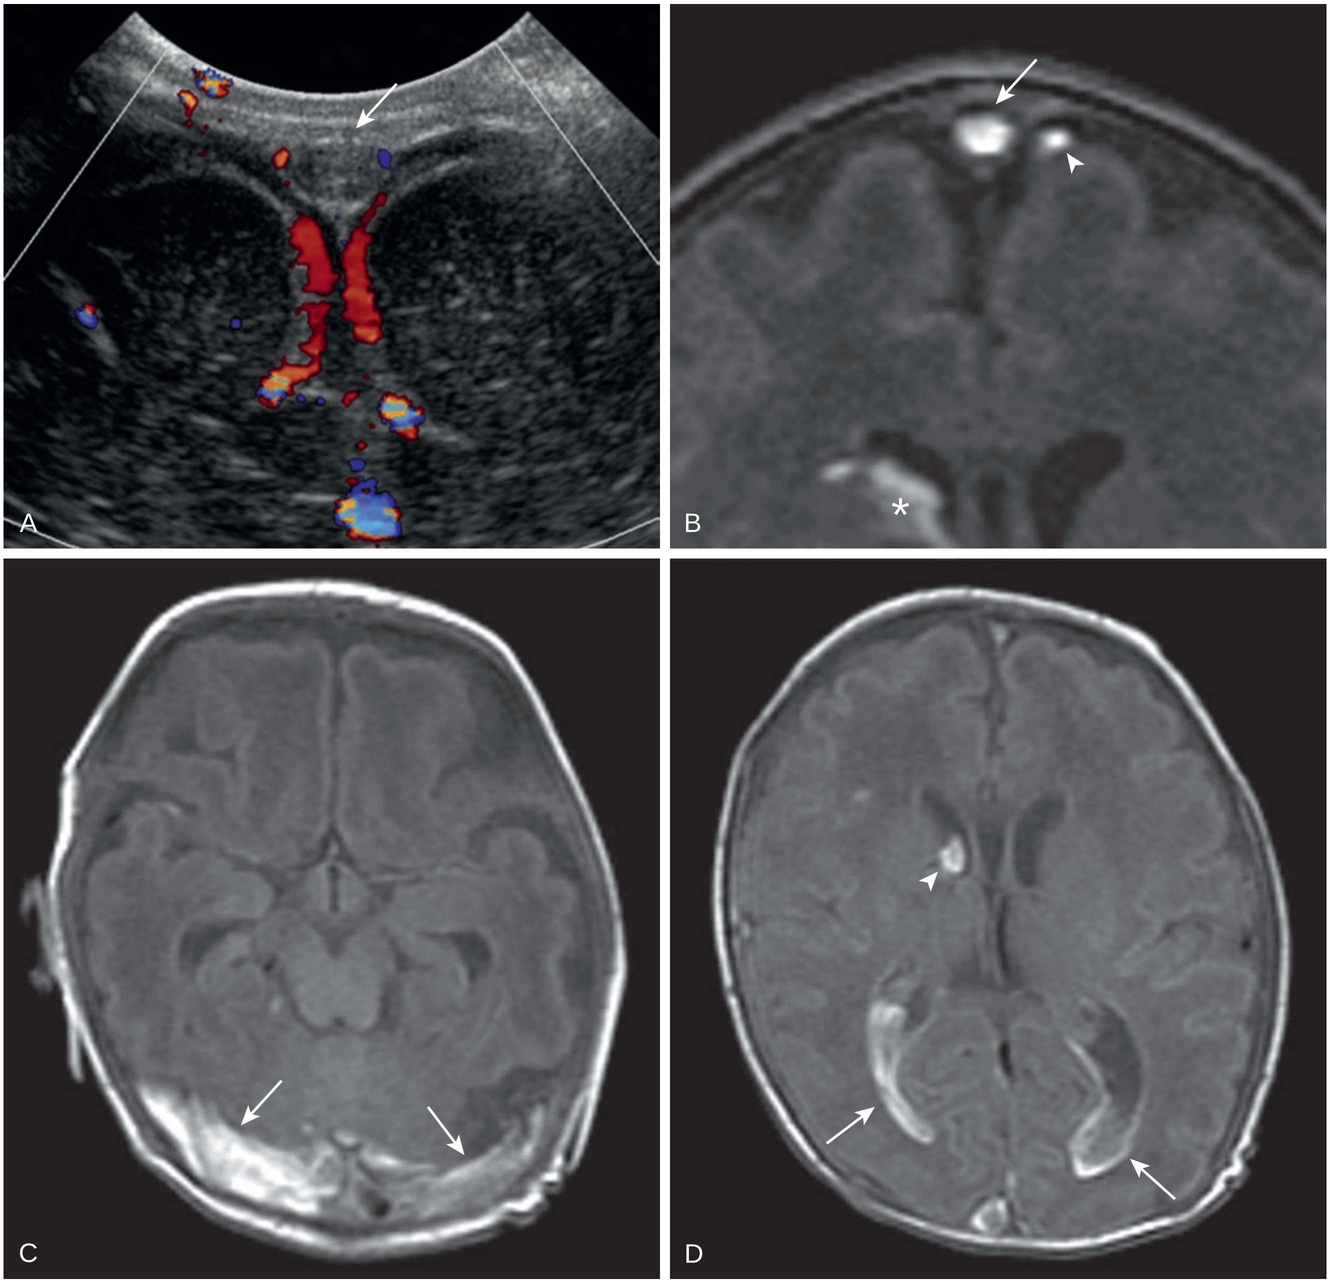

**Figure 30.8. Venous sinus thrombosis.** (A) Coronal color Doppler sonogram shows an enlarged superior sagittal sinus without Doppler flow *(arrow)*. (B) Axial T1-weighted MR image shows increase signal within the sagittal sinus *(arrow)*, and thrombosis of a cortical vein *(arrowhead)* and right germinal matrix hemorrhage *(asterisk)*. (C) Axial T1-weighted MR image shows increase signal within the bilateral transverse sinus *(arrows)*. (D) Axial T1-weighted MR image shows right germinal matrix hemorrhage *(arrowhead)* and intraventricular hemorrhage layering in the occipital horns *(arrows)*.

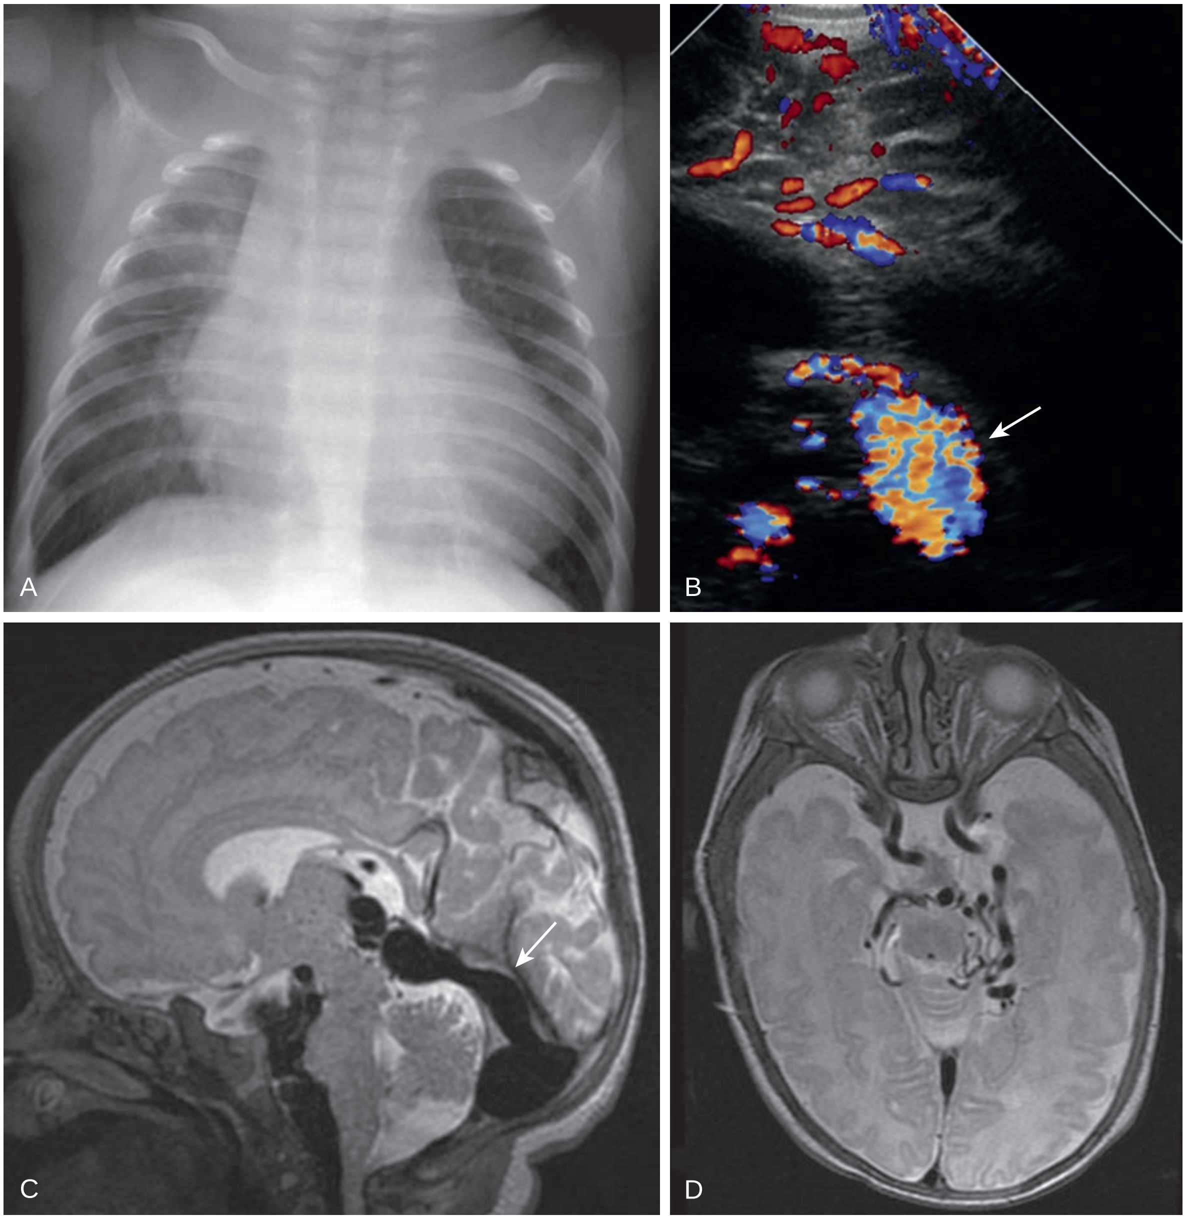
angiography (MRA) is excellent for the detection of hemorrhage and to delineate the AVM, although smaller vascular malformations may go undetected. The flow void seen in the tangled vessel of the nidus has been described as a “bag of black worms.” High-resolution T1-weighted sequences are important to define the location of the nidus. Three-dimensional (3D) time-of-flight MRA has slightly less special resolution than does CTA, but it does not expose the neonate to radiation. Time-resolved MRA has less special resolution than 3D time-of-flight (TOF) MRA and CTA, but it may provide sufficient information to differentiate feeding arteries and draining veins.

## Vein of Galen Malformation

Malformations involving the vein of Galen are true congenital arteriovenous connections between thalamic perforating, choroidal, and anterior cerebral arteries with the embryonic median prosencephalic vein. Associated cardiovascular anomalies may be present, such as aortic coarctation and secundum atrial septal defect.[10] The most common clinical presentation is high-output cardiac failure (e-Fig. 30.9). The prognosis is mainly related to the number of abnormal arteriovenous connections and the amount of associated parenchymal injury from arterial steal and hypoperfusion. The



**e-Fig. 30.9. Vein of Galen malformation.** (A) Chest radiograph shows enlargement of the cardiac silhouette and high-output pulmonary vascular congestion. (B) Oblique sagittal color Doppler sonogram and (C) sagittal T2-weighted MR image shows a dilated median prosencephalic vein *(arrow)*. (D) Axial T2-weighted MR image shows enlarged posterior choroidal arteries.

most common is the choroidal type with innumerous connections, which usually is fatal. The mural type with one to four connections has a better prognosis and is less likely to present in the neonatal period. This type usually presents during infancy as developmental delay, hydrocephalus, and seizures, or in older children as hemorrhage. Endovascular therapy is the treatment of choice. Prenatal and postnatal spontaneous thrombosis has been reported.

### Malformation of the Dural Sinuses

Saccular malformations of the dural sinus are rare; when they occur, they are associated with thrombosis, likely related to slow flow. The neonatal venous system has poor capacity to establish collateral circulation, and the drainage to the cavernous sinus is not yet developed. The propagation of the venous thrombosis within a dural sinus malformation may cause venous infarcts. The treatment of choice is preventive anticoagulation.

### Encephalopathy of Prematurity

For more than a century, it has been recognized that the developing white matter is exceptionally vulnerable to injury during the second half of fetal gestation (i.e., the period during which preterm infants are born, and in most cases, survive beyond infancy). Several terms have been used (e.g., white matter injury of prematurity, periventricular leukomalacia, venous infarcts, ischemic coagulation necrosis). It is increasingly recognized that injury to the preterm neonate can involve many regions in the central nervous system (CNS), from gray matter (thalamus, cortex, and basal ganglia) to white matter to the brainstem and cerebellum. As a result, we use a more comprehensive term, “encephalopathy of prematurity” (see Suggested Readings).

## GERMINAL MATRIX AND INTRAVENTRICULAR HEMORRHAGE

The GM is a transient area of proliferation and migration of the neuronal and glial precursor cells located within the walls of the ventricles (ventricular/subventricular zones). The GM is highly vascular; it has thin-walled vessels with limited capability to compensate for hemodynamic and oxygen tension changes, which makes it susceptible to hemorrhage after hypoperfusion followed by reperfusion. GMH may extend into the lateral ventricles (IVH), and in severe instances, it may result in hydrocephalus. The choroid plexus also may hemorrhage, usually in association with GMH. During the end of the second trimester, the GM starts to involute. One of the last areas to involute is the ganglionic eminence located deep to the ependyma in the caudothalamic notch, a groove between the head of the caudate nucleus and the thalamus. After 34 weeks of gestational age, the GM matures, and hemorrhage becomes very unlikely to occur. Most infants with a small area of GMH are asymptomatic or demonstrate subtle signs that are easily overlooked. An unexplained drop in the hematocrit may occur with larger areas of bleeding.

Hemorrhagic brain injury of prematurity has been classified into four groups. Grade I is hemorrhage confined to the GM; grade II is GMH extending into the ventricles without evidence of ventricular dilatation; grade III is IVH with evidence of ventriculomegaly; and grade IV is IVH with an associated parenchymal infarction, as a result of congestion of the venous outflow (Table 30.1). Grades I and II of GMH/IVH have a low morbidity and mortality, whereas grades III and IV have higher mortality rates and a substantial risk of poor neurodevelopmental outcome among survivors (Fig. 30.10). Posthemorrhagic ventricular dilation can be managed with a temporizing neurosurgical procedure, including a ventricular reservoir, a subgaleal shunt, or a ventriculoperitoneal shunt.

**TABLE 30.1** Classification of Germinal Matrix Hemorrhage/Intraventricular Hemorrhage

| Grade | Definition |
|---|---|
| 1 | Hemorrhage confined to germinal matrix |
| 2 | Intraventricular without ventriculomegaly |
| 3 | Intraventricular with ventriculomegaly |
| 4 | Parenchymal hemorrhage related to venous infarction (not directly related to grades 1–3) |

The cerebellum also has a GM, located in the granular layer. Hemorrhage into the immature cerebellum is an underrecognized complication of premature birth. Large cerebellar hemorrhage often occurs concomitantly with supratentorial hemorrhage and is associated with high mortality and cerebral palsy. Cerebellar hemorrhage involving the medial part of the cerebellum (vermis) is particularly associated with cerebral palsy. Isolate petechial hemorrhages are of uncertain clinical significance. Multiple hemorrhages, especially if of different types and in different locations, may be a manifestation of an underlying clotting disorder.

### White Matter Injury in Preterm Neonates

The pattern of injury in preterm neonates has changed during the past several decades in parallel with advances in neonatal intensive care. Historically, cystic periventricular leukomalacia, characterized by multiple areas of cavitary necroses in the periventricular and deep white matter with surrounding astrogliosis, was a frequent observation, particularly among neonates who underwent autopsy. In the modern era, subtle changes in the white matter are more often observed on neuroimaging (microscopic necroses 1–2 mm or less visualized on MRI as punctate lesions with high T1-signal intensity in the periventricular and deep white matter).[7,11] A transient mild elevation of the concentration of lactate may be detected in preterm neonates and neonates who are small for gestational age using MRS and is often considered a “normal” finding unless it persists for more than a week or is associated with other findings (Fig. 30.11).

Several other pathologic and nonpathologic processes may be confused with encephalopathy of prematurity. Viral encephalitis and venous thrombosis may also present with periventricular and/or subcortical lesions, which may demonstrate reduced diffusivity. Metabolic disorders such as organic acidemia and neuromuscular disorders such as Fukuyama muscular dystrophy are other causes of increased T2 signal in the white matter. Signal abnormality involving the gray matter may be seen in organic acidemias, particularly propionic acidemia, cortical dysplasia, and also in newborns with Fukuyama muscular dystrophy. The normal developmental congenital periventricular cysts of the frontal horns should not be misdiagnosed as cystic white matter changes. The location of these anatomic variants is very characteristic and therefore is useful in distinguishing the variants from injury. Periventricular connatal cysts, septations, and coarctations of the frontal horns are normal variants located at or below the level of the ventricular angles, often following the normal contour of the ventricular wall.

As previously noted, ultrasound is most often the first neuroimaging modality used in the evaluation of a preterm neonate. Normal periventricular white matter is relatively echogenic in preterm neonates. To be considered “normal” in a diagnostic setting, the echogenicity in the white matter must be bilaterally homogenous and symmetric. Asymmetry, heterogeneity, and focal areas of increased echogenicity relative to the choroid plexus are all considered to be a concern for abnormality. Serial ultrasound often is performed before white matter injury is more definitively diagnosed. Abnormally increased periventricular echogenicity representing edema or hemorrhage most commonly occurs in the

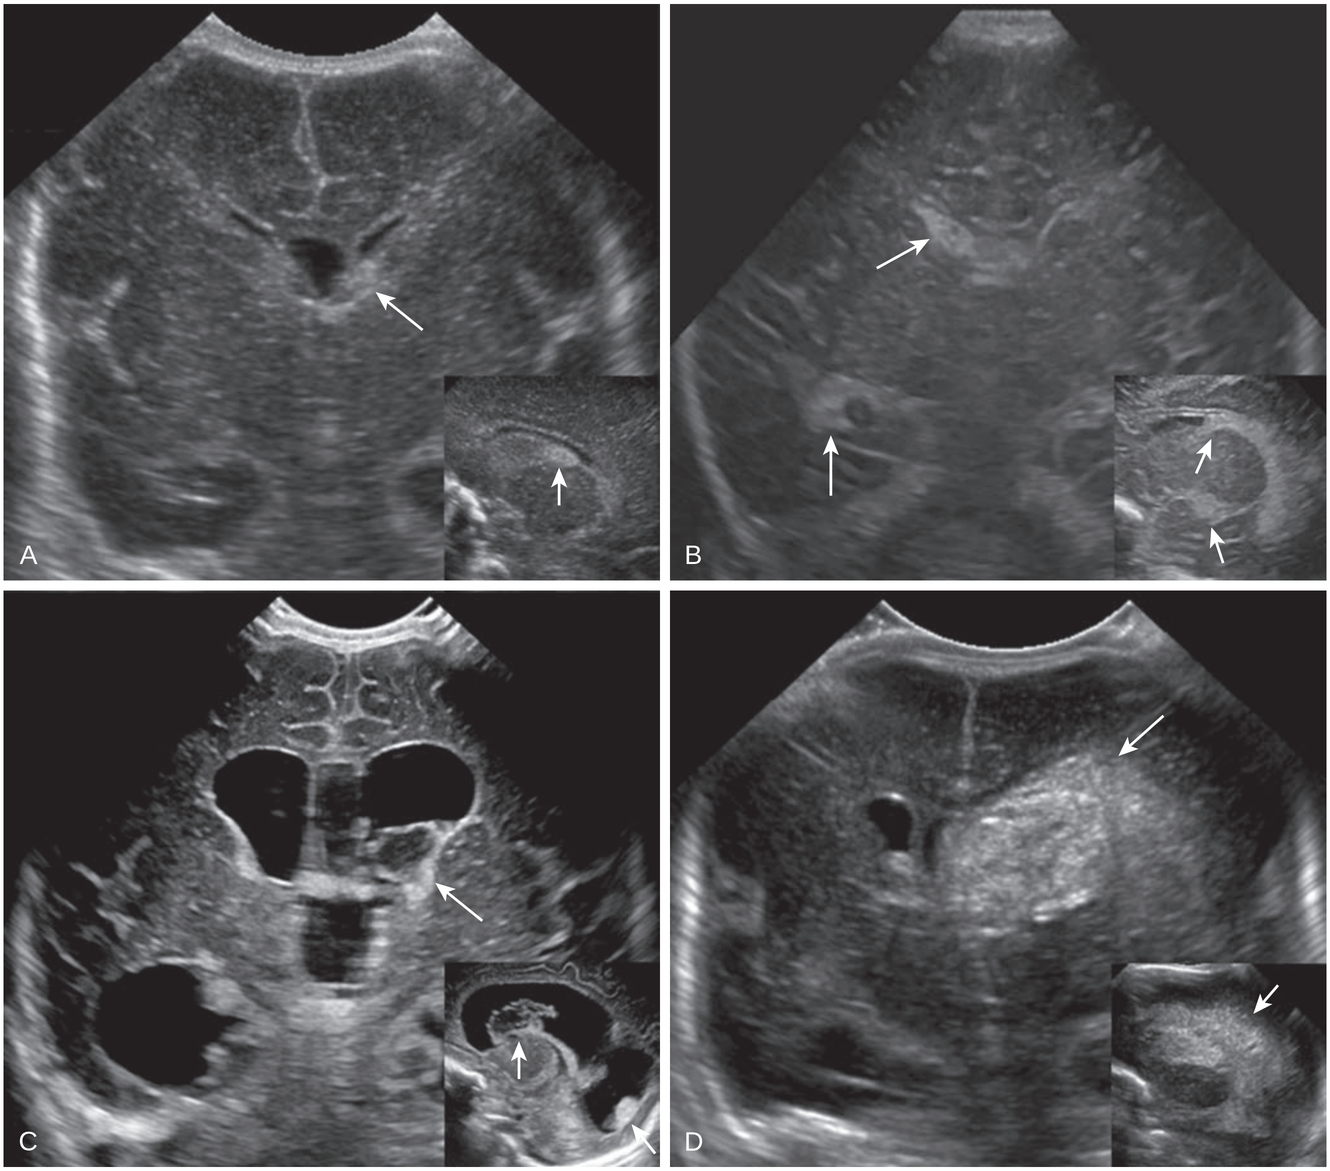


**Figure 30.10. Germinal matrix hemorrhages on ultrasound.** Coronal images with sagittal image insets. (A) Grade 1: hemorrhage confined to the left germinal matrix *(arrows)*. (B) Grade 2: right germinal matrix hemorrhage extending into the lateral ventricle *(arrows)*. (C) Grade 3: left germinal matrix hemorrhage extending into the lateral ventricle with ventriculomegaly *(arrows)*. (D) Large intraparenchymal hemorrhage *(arrows)*.

first week of life, and when present, the cystic changes develop at approximately 3 to 4 weeks of age. Ultrasound shows unilateral or bilateral linear hyperechoic hemorrhagic material in the region of the caudothalamic notch, choroid plexus, ventricles, and periventricular white matter. Ultrasound findings of extensive periventricular cystic lesions and white matter damage portends a poor prognosis, but normal ultrasound findings do not necessarily imply a normal neurodevelopmental outcome.

## CONGENITAL AND NEONATAL INFECTION

Neonatal brain infections are an important cause of severe long-term neurologic morbidity. Viral, bacterial, and parasitic infections may be transmitted to the fetus or newborn in utero (congenital), intrapartum, or postnatally. As a general rule, bacterial and fungal infections are most commonly transmitted intrapartum or postnatally, whereas toxoplasmosis, syphilis, rubella, and cytomegalovirus (CMV) are most commonly transmitted in utero. The transmission of herpes simplex virus infection and human immunodeficiency virus (HIV) may occur in utero, intrapartum, or postnatally.

### Bacterial Infections

The most common bacterial neonatal brain infections are caused by group B streptococcus, *Escherichia coli*, *Streptococcus pneumoniae*, *Haemophilus influenzae* type B, and *Listeria monocytogenes*. Imaging should be performed in neonates with bacterial meningitis if a rapid response to treatment does not occur or if a focal neurologic deficit develops. Complications of meningitis include empyema, ventriculitis, hydrocephalus, infarction, sinovenous thrombosis, cerebritis, or abscess. In uncomplicated meningitis, imaging is usually normal. Leptomeningeal enhancement may be seen as a result of vascular engorgement.

Ventricular enlargement resulting from impaired CSF absorption by fibrinous inflammatory exudate is the most common imaging finding in persons with meningitis and does not necessarily indicate

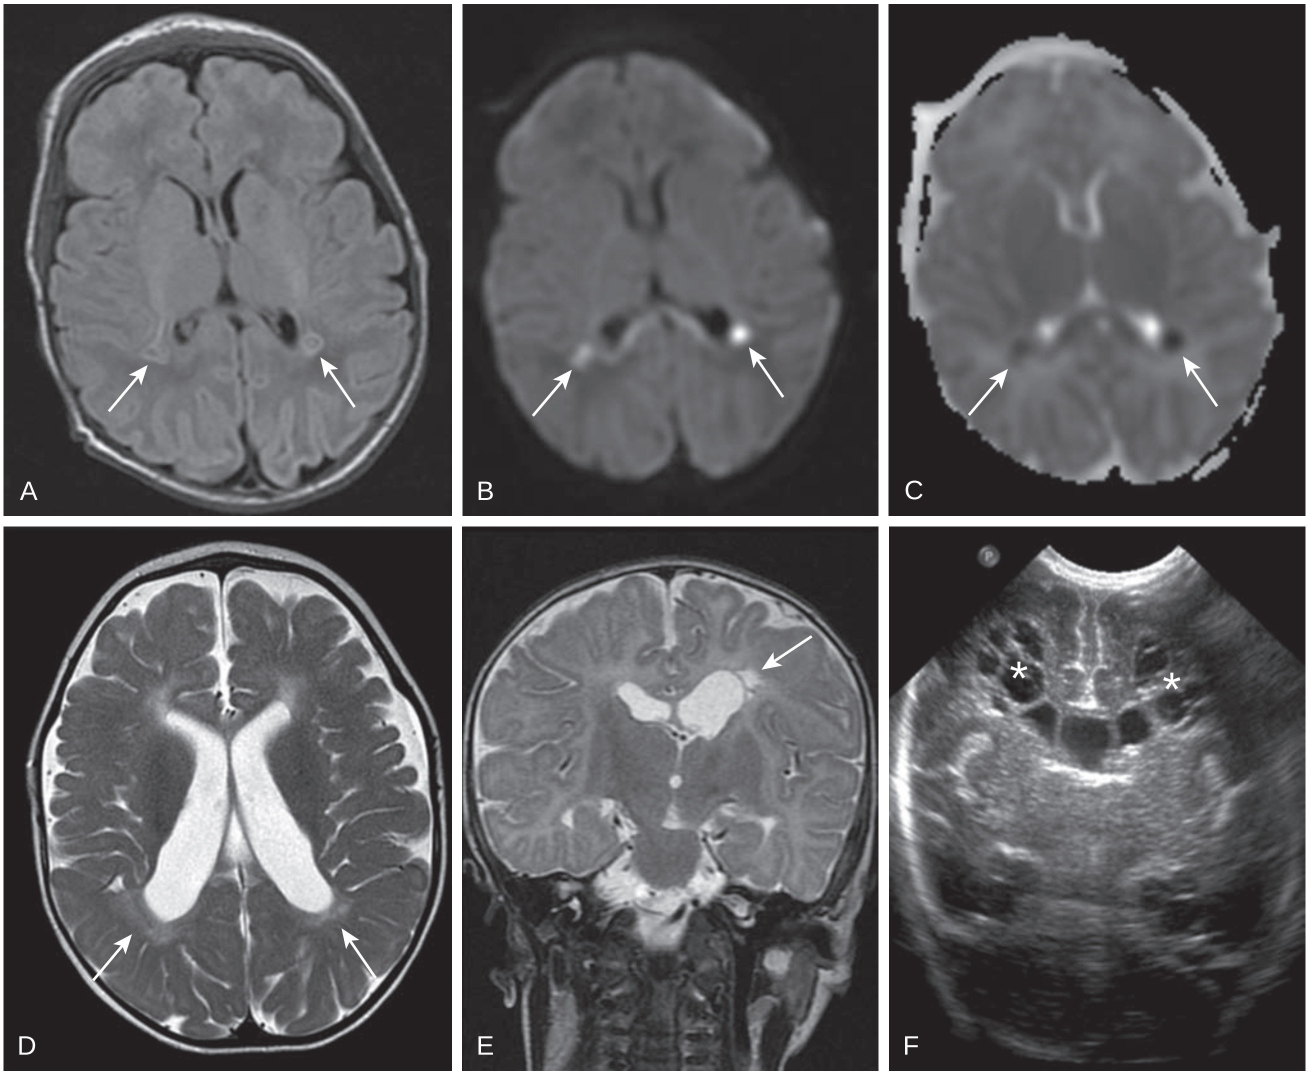

**Figure 30.11. White matter injury of prematurity.** (A) Acutely, focal areas of necrosis with increased signal are seen on this axial T1-weighted MR image *(arrows)*. (B and C) Restricted diffusion and low apparent diffusion coefficient *(arrows)*. (D) Axial T2-weighted MR image in a different patient at 2 years of age shows increased T2 signal and volume loss involving the periventricular white matter bilaterally *(arrows)*. (E) Coronal T2-weighted MR image shows unilateral white matter injury with small cysts *(arrow)*. (F) Coronal sonogram shows bilateral cystic white matter lesions *(asterisk)*.

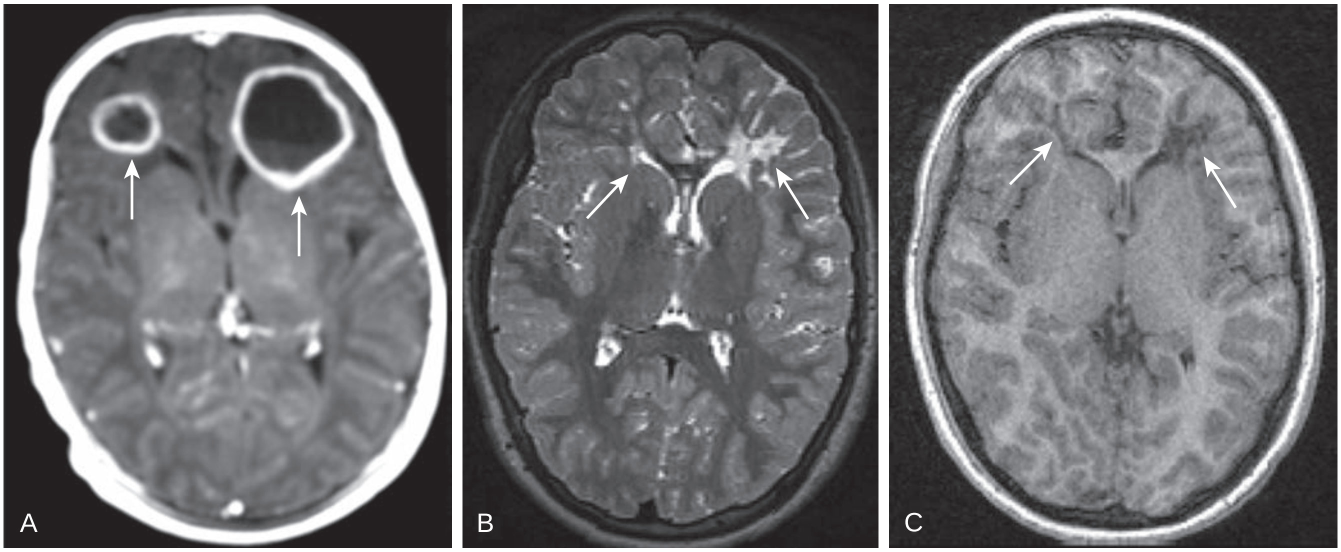
ventriculitis. Ventriculitis usually presents with ependymal enhancement and sometimes with a pus-fluid level. Ventriculitis often is associated with hydrocephalus and sometimes with intraventricular abscess. Sterile subdural effusions are not uncommon in neonates with meningitis; however, in approximately 2% of cases empyemas develop. Subdural collection with a signal intensity different from that of CSF, peripheral enhancement sometimes with septa, and signal abnormality involving the brain parenchyma are suggestive of empyema. Cerebritis is not uncommon in autopsies of neonates with meningitis despite normal findings of in vivo imaging. When imaging findings are present, cerebritis appears as an area of vasogenic edema with or without patchy areas of enhancement and/or cortical enhancement that may resolve with treatment. If the infection progresses, the enhancing areas become more confluent, and later an abscess forms with restricted water diffusivity and an enhancing capsule. Neonatal *Citrobacter koseri (diversus)* meningitis is rare but often is complicated by formation of abscesses, with a predilection for the frontal lobes. Neonatal pneumocephalus also has been reported as a complication of *C. koseri* meningitis. *Citrobacter* meningitis usually has a poor neurologic outcome (e-Fig. 30.12).

## Fungal Infection *(Candida)*

*Candida* is a neonatal commensal fungus. Infection is caused by organisms that are already present in the intestine and other locations. The key risk factors are catheters and use of wide-spectrum antibiotics; premature infants are particularly susceptible. It causes meningitis, multiple enhancing hemorrhagic microabscesses, macroabscesses, and extensive brain necrosis. Multiple macroabscesses within the subcortical and periventricular regions and basal ganglia are the most common imaging findings in the neonate; however, imaging findings may be normal.

## Herpes Simplex Virus Type 2 Infections

Women who have their first outbreak of herpes simplex virus type 2 genital herpes during pregnancy are at high risk of miscarriage



**e-Figure 30.12.** ***Citrobacter.*** (A) Axial contrast-enhanced T1-weighted MR image shows bilateral frontal abscesses *(arrows)*. After resolution of acute infection, there is volume loss and gliosis/encephalomalacia *(arrows)* on T2-weighted (B) and T1-weighted (C) MR images.

or delivering a baby with a low birth weight. The infection can be passed to the neonate in utero or, most commonly, during birth. The most serious risk to the infant is herpes simplex virus type 2 encephalitis. Signs and symptoms in the newborn are nonspecific, with irritability, a high-pitched cry, fever, and poor feeding. Diagnosis is made via a viral culture or polymerase chain reaction (PCR) of the CSF. If the infection occurs early in pregnancy, it may cause hydranencephaly, basal ganglia calcifications, and microphthalmia (the classic TORCH pattern). Late pregnancy or intrapartum transmission involves the bilateral gray-white matter diffusely, which rapidly develops into whole brain necrosis. Multiple cortical hemorrhagic foci and sometimes leptomeningeal enhancement often are present. With time, cystic white matter changes develop (Fig. 30.13).[12]

## Enterovirus and Parechovirus Infection

Enterovirus and parechovirus belong to the family *Picornaviridae*. Enteroviruses are well known for causing neonatal hepatitis, myocarditis, and meningoencephalitis, which can lead to death or severe long-term morbidity. Parechoviruses recently have been reported as causing severe neonatal infection, including involvement of the CNS. The diagnosis is made by PCR; however, PCR for enterovirus does not detect parechovirus. Meningoencephalitis in the neonatal period causes extensive white matter abnormalities, which appear as hyperechogenicity on ultrasound, hypoattenuation on CT, increased signal on T2-weighted MRI images, and decreased signal on T1-weighted MRI images, with or without restricted water diffusivity (e-Fig. 30.14). This pattern of injury easily may

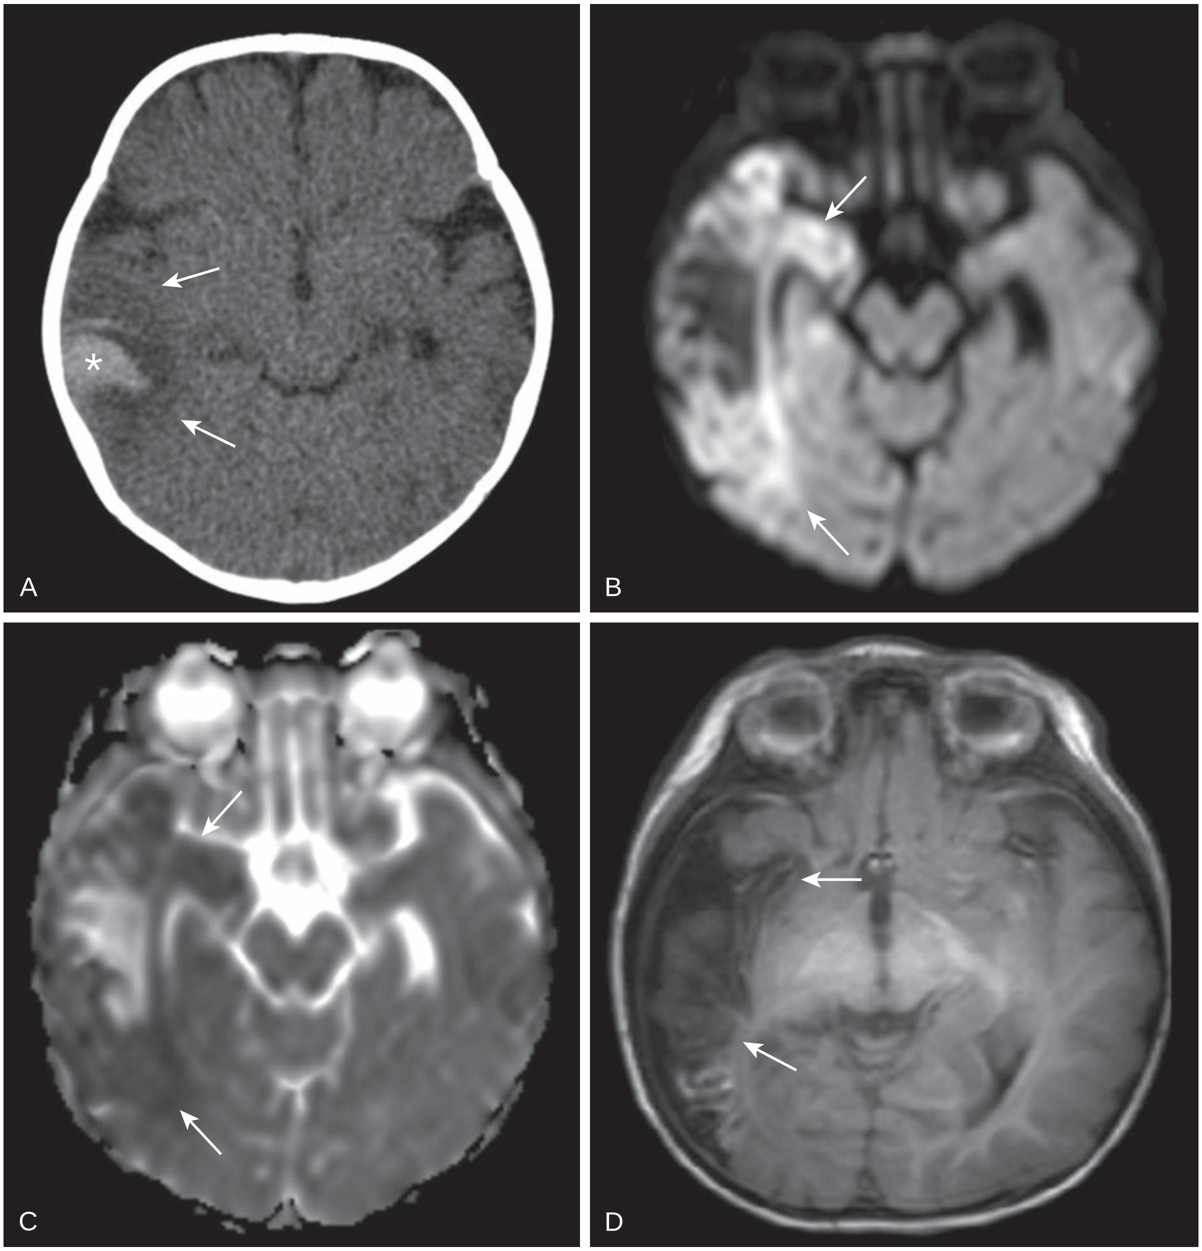


**Figure 30.13. Herpes encephalitis.** (A) Axial noncontrast CT showing parenchymal edema in the right temporal lobe *(arrows)*. Peripheral area of increased attenuation represents confluent petechial hemorrhages *(asterisk)*. (B and C) Axial diffusion-weighted MRI demonstrating restricted diffusion on DWI and low ADC values. (D) Axial T1-weighted MR image, 30 days after the first CT, shows encephalomalacia.

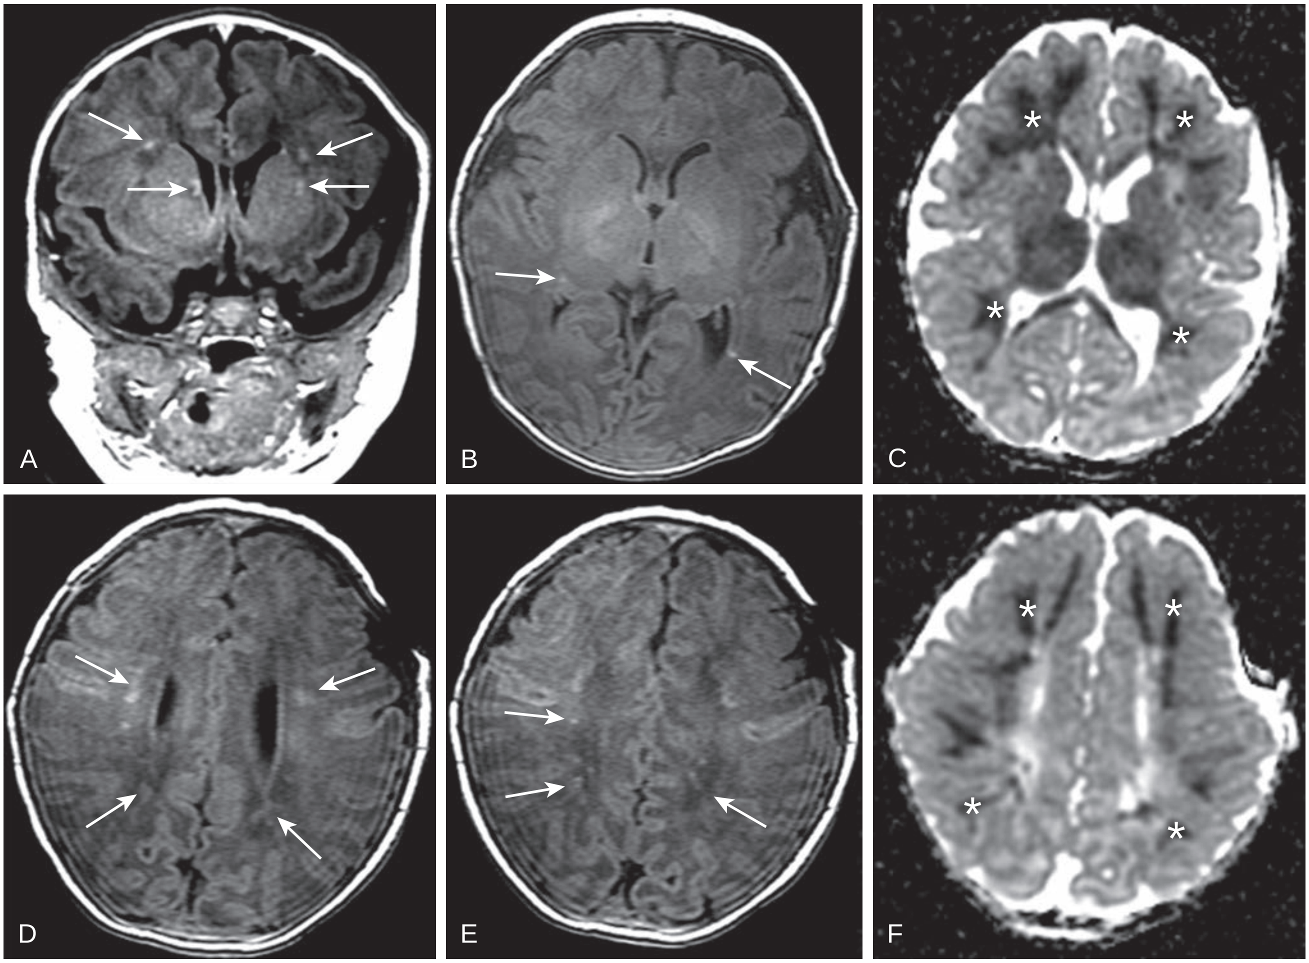

**e-Figure 30.14. Parechovirus.** (A, B, D, and E) T1-weighted MR images demonstrate multiple necrotic foci in the matter and basal ganglia bilaterally *(arrows)*. (C and F) Diffusion-weighted images show reduced ADC involving the white matter, basal ganglia, and thalami bilaterally *(asterisk)*.

be misinterpreted as white matter injury of prematurity or as being caused by hypoxic-ischemic injury, particularly the partial prolonged type.[13]

## Congenital Cytomegalovirus Infection

CMV is the most common congenital viral infection in the United States. Between 30% and 50% of women of childbearing age in the United States have never been infected with CMV, and about 1% to 4% have a primary CMV infection during a pregnancy. The transmission rate to the fetus is about 33%. More than 5000 children each year experience permanent problems caused by CMV infection in the United States. Maternal antibodies, which protect the fetus from rubella and toxoplasmosis, do not prevent fetal transmission of CMV, but they do lessen the severity of the disease. Chorioretinitis occurs in 15% to 20% of cases. Diagnosis of CMV infection in the newborn is usually made via a urine culture. No cure exists for CMV infection. Treatment is primarily supportive.

The brain is the most commonly affected organ. CMV interferes with normal fetal brain development and is associated long term with mental retardation, blindness, deafness, or epilepsy. Depending on the timing of infection during fetal development, neonates with congenital CMV may have microcephaly, predominately periventricular calcifications, ventriculomegaly, lissencephaly, polymicrogyria, cerebellar hypoplasia, dysplastic white matter, and porencephaly (Fig. 30.15).[14] Other findings include intrauterine growth restriction, hepatosplenomegaly, cardiomyopathy, echogenic bowel, and hydrops. CT can detect and characterize diminutive periventricular and subependymal calcifications. CMV is also the leading infectious cause of sensorineural hearing loss; CT may demonstrate a Mondini malformation with an absent interscalar septum, a large vestibule, and an enlarged vestibular aqueduct.

## Congenital Toxoplasmosis Infection

It is estimated that 400 to 4000 cases of congenital toxoplasmosis occur each year in the United States. In the first trimester, maternal infection is less likely to result in congenital infection (2%–10%), but when it occurs, it is more likely to be severe or to result in abortion. Severe congenital toxoplasmosis meningoencephalitis is associated with intrauterine growth restriction, hydrocephalus, microcephaly, calcifications, porencephaly, or hydranencephaly. Maternal infection after 20 weeks of gestation has a much higher rate of transmission to the fetus (20%–30%). The sequelae are generally less severe but still include blindness, epilepsy, and mental retardation.

Although the neurologic outcome is good in the absence of brain abnormalities, congenital toxoplasmosis may be unrecognized until late in infancy when infants present with seizures or other neurologic symptoms. Nonshadowing cerebral and hepatic calcifications are the most typical ultrasound findings. Intracranial calcifications may be periventricular or random in distribution. Other less specific imaging findings are subependymal cysts, echogenic lenticulostriate and thalamostriate arteries (candlestick sign), and cystic white matter changes. CT is sensitive for the detection and characterization of cerebral calcifications and may demonstrate hydrocephalus and microcephaly. The ocular calcifications seen on CT may mimic retinoblastoma. Because of its high sensitivity and absence of ionizing radiation, MRI may be used serially throughout pregnancy to evaluate for the development of brain abnormalities. Acutely, the fetal brain abnormality consists of white matter signal abnormality such as loss of the intermediate zone layer in young fetuses. In fetuses with advanced gestational age, cystic lesions with a mural nodule are characteristic; however, MRI is not sensitive for small calcifications. After birth, calcifications, variable degrees of white matter dysplasia and gliosis, and cortical malformations all may be detected on MRI.

## Congenital HIV Infection

HIV transmission to the fetus or neonate occurs in utero, intrapartum, or postpartum via breast milk. Without treatment, about 30% of pregnant women with HIV pass the infection to their fetus. Intrapartum treatment with protease inhibitors, elective caesarean section, and avoiding breast-feeding decreases the transmission to the fetus to less than 2%. HIV penetrates the blood-brain barrier via macrophages very early in the course of disease and incites a subacute encephalitis with perivascular mononuclear inflammatory cell infiltration. Neuroimaging findings usually are normal in neonates with HIV. The onset of neurologic decline generally occurs between 2 months to 5 years. Atrophy, delayed myelination, corticospinal tract degeneration, cervical lymphadenopathy, benign lymphoepithelial cysts in the parotid glands, aneurysms, opportunistic infections, progressive multifocal leukoencephalopathy, and CNS lymphoma are all associated late findings of congenital HIV infection.

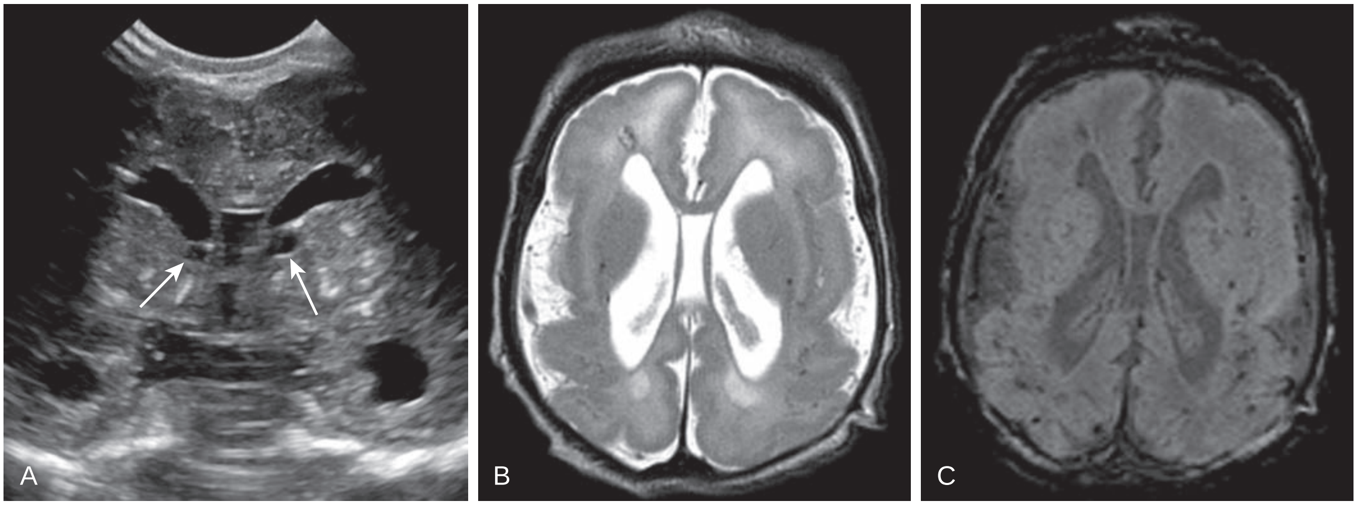

**Figure 30.15. Cytomegalovirus.** (A) Coronal sonogram demonstrates white matter volume loss, multiple calcifications in the brain parenchyma, nonshadowing echogenic foci, and germinolytic cysts *(arrows)*. (B) Axial T2-weighted MR image depicts extensive cortical malformation bilaterally. (C) Axial susceptibility-weighted MR image shows multiple dark foci bilaterally due to susceptibility effect from the calcifications in the brain parenchyma.

## Congenital Rubella Infection (German Measles)

Congenital rubella infection is extremely rare as a result of vaccination and screening of pregnant women. The most common manifestation is rash, fever, and symptoms of an upper respiratory tract infection. Rubella infection during early pregnancy can pass through the placenta to the fetus and cause serious birth defects, including heart abnormalities, mental retardation, blindness, and deafness. Imaging usually shows nonspecific findings such as microcephaly, ventriculomegaly, abnormal myelination, and calcifications, particularly of the basal ganglia.

## Congenital Syphilis Infection

Syphilis is a sexually transmitted bacterial infection that can be transferred from mother to fetus through the placenta. It is estimated that in up to 50% of cases of congenital syphilis, the neonate is born prematurely, is stillborn, or dies shortly after birth. Nevertheless, congenital syphilis rarely manifests with neurologic symptoms in the neonatal period. Only a few patients present with meningitis, choroiditis, hydrocephalus, or seizures. Severe ischemic-hemorrhagic lesions involving predominantly unilateral periventricular white matter, which are thought to be a result of endarteritis, have been reported in neonates. Other findings of congenital syphilis are generalized lymphadenopathy, hepatosplenomegaly, jaundice, and rash. The findings of CNS syphilis, such as leptomeningeal enhancement (particularly involving the basal meninges) and intraparenchymal mass (gumma), as well as frontal bossing, saddle nose deformity, mulberry molars, peglike upper frontal incisor, and saber shin, typically are observed later in infancy or childhood.

## Congenital Varicella Infection

The incidence of congenital varicella syndrome after maternal varicella infection during the first two trimesters is less than 1%. As with CMV and toxoplasmosis, intrahepatic and intracranial calcifications are very common. Intrauterine encephalitis, cortical atrophy, and porencephaly have been reported in cases of congenital varicella infection before 20 weeks of gestational age. Other possible fetal abnormalities are polyhydramnios, limb hypoplasia, and contractures, as well as paradoxical diaphragmatic motion as a result of unilateral paralysis. Neonates may demonstrate dysfunction of the autonomic nervous system (neurogenic bladder), hydroureter, esophageal dilation, aspiration pneumonia, and cutaneous lesions in a dermatomal distribution.[15]

## Congenital Lymphocytic Choriomeningitis Virus

Lymphocytic choriomeningitis virus (LCMV) primarily infects rodents, but it also can infect humans through inhalation of aerosolized particles of rodent urine, feces, or saliva; through ingestion of contaminated food; or through direct contact of open wounds to virus-infected blood. Human-to-human transmission may occur via the placenta or through solid-organ transplantation. The disease is usually mild in healthy individuals, but it may cause serious consequences to immunosuppressed persons and pregnant women. Miscarriage, birth defects, and long-term neurologic problems may result from congenital LCMV. LCMV causes chorioretinitis, ependymitis with ependymal calcifications, polymicrogyria, and microcephaly or hydrocephalus. These findings are similar to those of congenital toxoplasmosis and CMV; however, hepatosplenomegaly usually is not present in persons with LCMV.

## Zika Virus

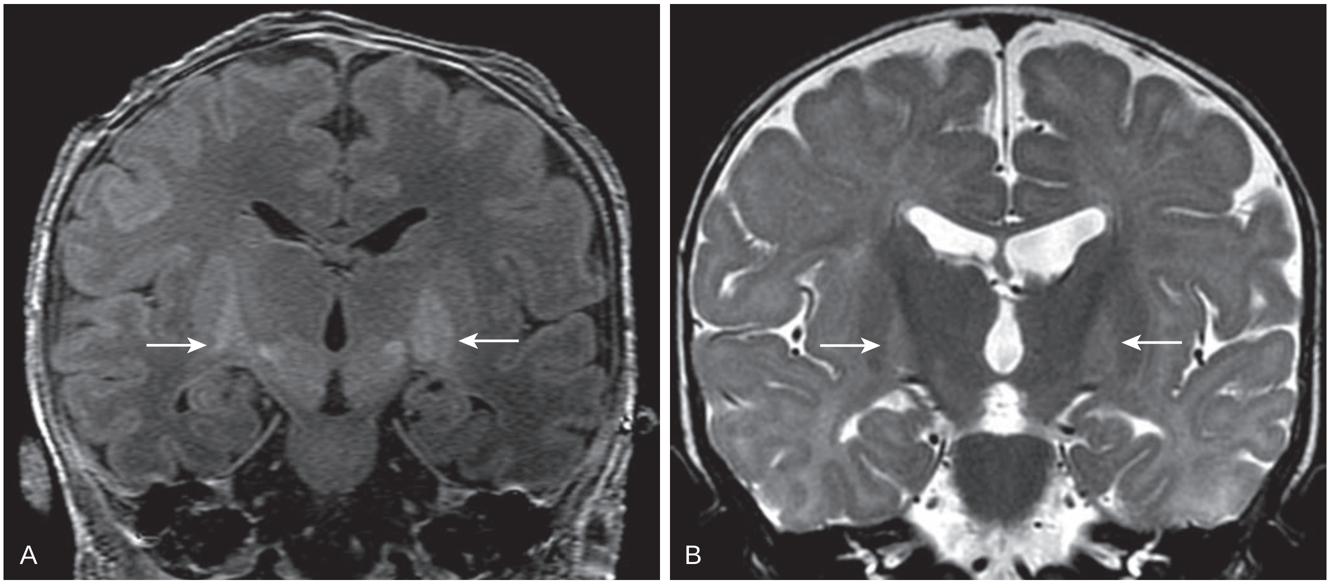
Zika virus is a single-stranded RNA virus of the Flaviviridae family. The transmission from human to human occurs primarily through the bite of infected mosquitos of the genus *Aedes*; however, it has been reported that Zika virus can be sexually transmitted and could be passed from the mother to the fetus. Growing evidence suggests that vertical transmission of Zika during pregnancy is associated with severe brain damage and resultant microcephaly. Although proving Zika virus is linked to microcephaly is challenging at least in part due to lack of resources in epidemic areas, there has been an increase in the incidence in infants born with microcephaly in Brazil coinciding with an epidemic of Zika infection and, of those, approximately one-third have been confirmed to have Zika infection during pregnancy. Cases have since been reported in other Latin American countries and the southern United States. The most common neuroimaging findings reported in cases of presumed Zika infection during pregnancy are generalized brain parenchyma volume loss, ventriculomegaly, malformation of cortical development, and calcifications in the basal ganglia, periventricular white matter, and in the junction between the cortex and the juxtacortical white matter (Fig. 30.16).[16]

# ACQUIRED METABOLIC DISORDERS

## Kernicterus (Bilirubin Encephalopathy)

Kernicterus is caused by markedly elevated or sustained unconjugated hyperbilirubinemia. Kernicterus usually develops in the first week of life; however, it may occur as late as the third week. Severe hemolytic conditions, especially Rh hemolytic disease with hydrops fetalis, are the most common causes. Other risk factors include prematurity, polycythemia, resolving hematomas, sulphonamide administration, glucose-6-phosphate dehydrogenase deficiency, and Crigler-Najjar and Gilbert syndromes. Although risk factors are usually present, kernicterus has been reported in otherwise healthy babies. Acutely, kernicterus manifests as lethargy, decreased feeding, hypotonia or hypertonia, a high-pitched cry, spasmodic torticollis, opisthotonus, the setting sun sign, fever, seizures, and even death. In severe cases, kernicterus results in a tetrad of movement disorder, auditory dysfunction, oculomotor impairments, and dental enamel hypoplasia of the deciduous teeth. Persons with mild cases are still at risk for isolated hearing loss or some degree of neurologic, cognitive, learning, and movement disorders.

Pathologically, kernicterus causes damage to the globi pallidi, subthalamic nuclei, hippocampi (CA2 and CA3 regions), pars reticulata of the substantia nigra, and dentate nuclei. Ultrasound and CT are not sensitive in detecting early abnormalities in persons with kernicterus. On MRI, the classic description of a transient increased signal seen on T1-weighted images seems to be inconsistent particularly in infants with mild or moderate hyperbilirubinemia. Moreover, conventional T1 spin echo images appear to be more reliable than 3D T1 spoiled gradient echo images, because the latter are associated with a high signal in normal subthalamic nuclei, which may cause false-positive results. Increased signal on T2-weighted images of affected areas that develops later is a more reliable finding (e-Fig. 30.17), when hyperechogenicity may appear on ultrasound and hypoattenuation may appear on CT.[17] Acutely, these areas may demonstrated restricted diffusion[18]; however, when restricted diffusion is present, other conditions such as hypoxia-ischemia should also be considered. Hypoxic-ischemic injury typically involves the putamen more than the globus pallidus, and kernicterus typically involves the globus pallidus and subthalamic nuclei more than the putamen. A metabolite signature of acute kernicterus has been proposed on MRS using an echo time of 35 ms with elevated ratios of taurine, glutamate, glutamine, and myoinositol, and a decreased ratio of choline relative to creatine with no significant elevation of lactate.



**e-Figure 30.17. Kernicterus.** (A) Coronal T1-weighted MR image shows increased signal in the bilateral globus pallidus at 1 week of age *(arrows)*. (B) Coronal T2-weighted MR image 1 month later shows increased T2 signal *(arrows)*.

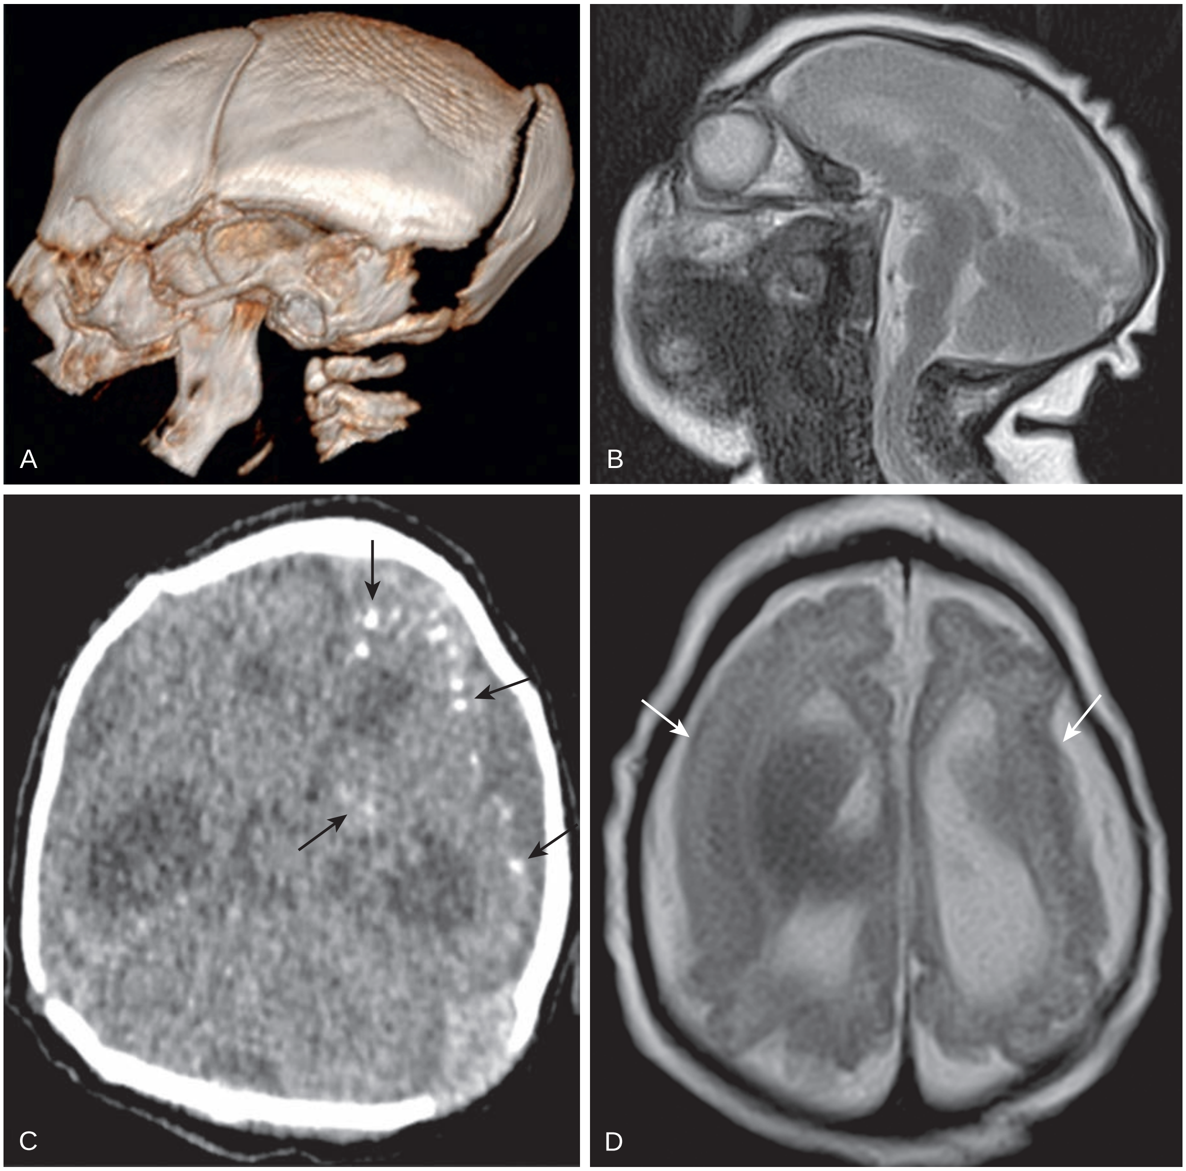


**Figure 30.16. Zika-linked microcephaly.** (A) 3D reconstructed CT shows severe microcephaly. (B) Sagittal T2-weighted MR image shows severe volume loss involving the cerebral hemispheres. (C) Axial unenhanced CT shows juxtacortical and basal ganglia calcifications *(black arrows)*. (D) Axial T2-weighted MR image shows brain parenchyma volume loss with ex-vacuo dilation of the lateral ventricles and extensive bilateral cortical malformation *(white arrows)*. *(Case courtesy Dr. Celso Hygino.)*

### Hypoglycemia

Neonatal encephalopathy resulting from hypoglycemia typically occurs when glucose concentrations are less than 30 mg/dL in the term infant and less than 20 mg/dL in the preterm infant. The clinical presentation of neonatal hypoglycemia may be subtle, including stupor, jitteriness, seizures, respiratory abnormalities, and hypotonia. MRI is the imaging modality of choice, showing abnormalities in the posterior parietal and occipital cortex and adjacent white matter. Acutely, there is restricted diffusion on DWI as well as edema on T1- and T2-weighted imaging (Fig. 30.18). MRS with an echo time of 30 ms exhibits an increased lactate-lipid peak and a decreased NAA peak in the involved areas. In the chronic phase, the involved areas evolve into encephalomalacia and atrophy. If the hypoglycemia is severe and prolonged, progression to diffuse brain damage occurs with involvement of the hippocampus, corpus striatum, and cerebellum.[19]

## INBORN ERRORS OF METABOLISM

Inborn errors of metabolism present with signs and symptoms related to the involvement of one or more of the organ systems, including the CNS. Inborn errors of metabolism are classified into organic acidemia, disorders of amino acid oxidation, disorders of fatty acid oxidation, primary lactic acidosis, mitochondria function, lysosomal storage disorders, and peroxisome disorders (also see Chapter 33). Whereas some inborn errors of metabolism manifest immediately at birth (e.g., primary lactic acidosis, type 2 glutaric aciduria, long-chain acyl coenzyme A dehydrogenase, hydroxymethylglutaryl-CoA lyase, ornithine transcarbamylase, and carbamyl phosphatase synthetase deficiencies), in others, it takes a few days for signs and symptoms to develop (e.g., isovaleric acidemia, methylmalonic acidemia, propionic acidemia, nonketotic hyperglycinemia, citrullinemia, argininosuccinic aciduria, and maple syrup urine disease).

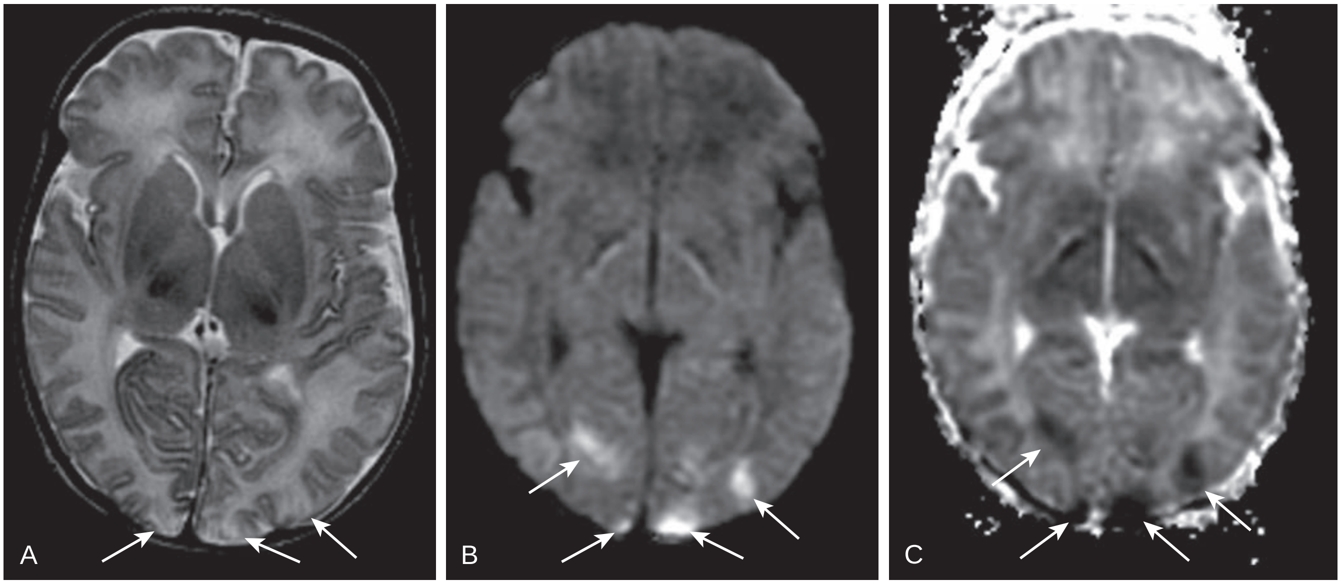

**Figure 30.18. Hypoglycemia.** (A) Axial T2-weighted MR image shows edema with increased signal in the occipital lobes *(arrows)*. (B and C) Axial diffusion weighted images show decreased diffusion and low ADC values *(arrows)*.

The inborn errors of metabolism that affect the nervous system exclusively (namely l-2-hydroxyglutaric aciduria, glutaric aciduria type 1, 4-hydroxybutyric aciduria, alpha-ketoglutaric aciduria, mevalonic aciduria, and N-acetylaspartic aciduria [Canavan disease]) present later in life and are not encountered in neonates. MRS can provide valuable information regarding specific metabolites in certain neonatal metabolic disorders: increased branched-chain amino acids (e.g., l-leucine, l-isoleucine, and valine) in persons with maple syrup urine disease, increased glycine in persons with nonketotic hyperglycinemia, and absence of creatine in persons with guanidinoacetate methyltransferase deficiency (also see Chapter 25).

## Organic Acid Disorders

Methylmalonic acidemia and proprionic aciduria are examples of organic acid disorders. These disorders cause ketoacidosis, often leading to severe acidosis, vomiting, tachycardia, lethargy, seizures, coma, and death. In these disorders, edema is present in both myelinated and unmyelinated structures. The edema involving the myelinated white matter is related to vacuolating or spongiform myelinopathy, which acutely demonstrates restricted water diffusivity because the water is trapped within vacuoles. Findings on conventional imaging include edema with increased T2 signal and decreased T1 signal involving the white matter. In more severe cases, the deep gray structures may be involved, with a predilection for the globi pallidi in persons with methylmalonic acidemia and for the putamina and caudate nuclei in persons with proprionic aciduria. MRS detects a reduction in myoinositol and NAA and an elevation of glutamine. Elevation of lactate as a result of hyperammonia, ketoacidosis, and/or mitochondrial dysfunction also may be present during an acute metabolic crisis.

## Amino Acid Disorders

Maple syrup urine disease results from an interruption of the metabolism of the essential amino acids leucine, isoleucine, and/or valine. The most severe form manifests in the first week of life with seizures, vomiting, dystonia, fluctuating ophthalmoplegia, and coma. The imaging findings are almost pathognomonic. Conventional MR shows edema in the deep cerebellar white matter, brainstem tegmentum, posterior limb of the internal capsule, perirolandic white matter, and precentral and postcentral gyrus. Restricted water diffusivity is seen acutely in the areas of vacuolating edema in the myelinated white matter. MRS shows a peak at 0.9 parts per million (ppm) related to the accumulation of abnormal branched-chain amino acids and branched-chain alpha-ketoacids. The imaging findings by diffusion imaging and MRS may resolve with treatment.[20]

## Urea Cycle Disorders

Urea cycle enzyme defects include ornithine carbamyl transferase deficiency, carbamyl phosphate synthetase deficiency, argininosuccinic aciduria, citrullinemia, and hyperargininemia, resulting in hyperammonemia and elevation of glutamate. Cases with severe impairment of elimination of nitrogen waste products manifest as irritability, lethargy, poor feeding, hypothermia, and seizures during the neonatal period.

Imaging in the acute phase shows markedly diffuse vasogenic edema, predominantly in the unmyelinated white matter, with early involvement of the subcortical U fibers and relative preservation of the myelinated white matter. The underlying pathophysiology of the urea cycle defects is related to vasogenic edema, in contrast to vacuolating myelinopathy in persons with maple syrup urine disease. As a result, the mean diffusivity maps in the urea cycle defect will show increased signal intensity in the unmyelinated white matter. In some cases, the lentiform nuclei (particularly the globi pallidi), the posterior insular cortex, and the perirolandic cortex also may be involved with increased T1 signal. This presentation causes some overlap between the conventional imaging findings of urea cycle disorders and hypoxic-ischemic injury. However, involvement of the globi pallidi and putamina in urea cycle disorders is predominant as opposed to thalami in cases of hypoxia-ischemia. MRS in patients with urea cycle defects typically demonstrates increased levels of glutamate and glutamine and decreased levels of myoinositol, NAA, choline, and creatine.

## Nonketotic Hyperglycinemia

Nonketotic hyperglycinemia is caused by a defect of the glycine cleavage system, which is present in the liver, kidney, and brain, leading to the accumulation of glycine in blood, urine, and CSF. The diagnosis is established by calculating the CSF/plasma glycine concentration ratio. A value of greater than 0.08 is diagnostic. Confirmation of the diagnosis requires measurement of the activity of the glycine cleavage system in liver tissue. The neonatal (classic) form of nonketotic hyperglycinemia is far more common than the infantile, late-onset, or transient phenotypes. The neonatal form presents in the first days of life with encephalopathy, hypotonia, lethargy, seizures, and characteristic hiccups, which can progress rapidly to intractable seizures, coma, and respiratory failure. The outcome is invariably poor.

On MRI, abnormal myelination and a hypoplastic or dysgenic corpus callosum are seen, which progresses to diffuse cerebral atrophy. Increased T2 signal and restricted water diffusivity involving the myelinated portion of the posterior limb of the internal capsules, pyramidal tracts, middle cerebellar pedicles, and dentate nuclei have been reported. The underdevelopment of the corpus callosum is difficult to assess in the neonate because of its small size and lack of myelin, but it becomes evident later. Atrophy and delayed myelination also are common findings in other metabolic disorders, particularly in organic acidurias. MRS exhibits a large glycine peak at 3.55 ppm.

## Peroxisomal Disorders

Peroxisomal disorders that manifest in the neonate are primarily a result of the failure to form viable peroxisomes (peroxisomal biogenesis disorders), resulting in multiple metabolic abnormalities. Zellweger syndrome and neonatal adrenoleukodystrophy are the most common peroxisomal disorders in the neonate, and both have pathognomonic findings on conventional MRI. Zellweger syndrome is characterized by delayed myelination, temporal and parietal polymicrogyria, and subependymal germolytic cysts adjacent to the frontal horns of the lateral ventricles. In contrast to Zellweger syndrome, neonatal adrenoleukodystrophy causes dysmyelination, mainly involving the occipital lobes, the splenium of the corpus callosum, and/or the cerebellum. Often these lesions demonstrate restricted water diffusion and peripheral enhancement. MRS in persons with Zellweger syndrome is not specific, showing a marked decrease in NAA levels in the gray-white matter, thalamus, and/or cerebellum, a decreased myoinositol level in the gray matter if concomitant hepatic dysfunction is present, and in some cases, elevated glutamine levels.

## Molybdenum Cofactor Deficiency

Molybdenum cofactor deficiency is a rare, usually underrecognized, autosomal-recessive disorder caused by genetic mutation of the genes that produce enzymes essential for the formation of molybdenum cofactor. The absence of molybdenum cofactor leads to toxic levels of sulphite, which may be detected by hypouricemia, elevated urine sulfate, and elevated S-sulfocysteine. Clinically, molybdenum cofactor deficiency manifests in the first few days of life with seizures and encephalopathy, and usually leads to death within months. Imaging shows edema and cystic changes involving predominantly the basal ganglia and severe volume loss of the gray-white matter. Reduced water diffusivity may be present in the affected areas.

## Mitochondrial Disorders

Mitochondrial disorders are a group of diseases caused by enzymatic defects leading to primary lactic acidosis and decreased ATP production. Pyruvate transcarboxylase, pyruvate dehydrogenase, and cytochrome c oxidase deficiencies are the most common enzymatic defects leading to primary lactic acidosis in the neonatal period. MRI is the imaging modality of choice for its capability to detect areas of reduced water diffusivity and the presence of lactate typically associated with these disorders. Characteristically, areas of increased T2 signal and reduced water diffusivity are found in the brainstem, the subthalamic nucleus, and the globus pallidum. MRS detects elevated lactate levels in the areas with abnormal signal, as well as in the normal-appearing brain. It should be noted, however, that elevated lactate is not always indicative of a mitochondrial disorder, and nondetectable lactate levels do not preclude the possibility of a mitochondrial disorder. Sometimes specific spectroscopic peaks can be detected—for example, elevated succinate peak at 2.4 ppm in persons with succinate dehydrogenase deficiency and an elevated pyruvate peak at 2.36 ppm in persons with pyruvate dehydrogenase complex deficiency.

### KEY POINTS

- MRI is the imaging modality with the highest sensitivity for detecting abnormalities in the neonatal brain.
- The central pattern of HIE usually occurs with profound asphyxia, when an abrupt interruption occurs in the oxygen supply to the neonatal brain.
- The peripheral pattern of HIE usually results from a period of decreased supply of oxygen to the neonatal brain.
- Arterial infarctions are more common in term neonates and most frequently involve the middle cerebral artery and its branches.
- Birth trauma is more common in vaginal delivery, particularly if forceps or vacuum extraction is used.
- Small subdural hematomas are seen in up to 46% of the newborns in the first week of life.
- The most common bacterial neonatal brain infections are caused by group B streptococcus, *Escherichia coli*, *Streptococcus pneumoniae*, *Haemophilus influenzae* type B, and *Listeria monocytogenes*.
- Kernicterus is caused by markedly elevated or sustained unconjugated hyperbilirubinemia.
- Neonatal encephalopathy resulting from hypoglycemia typically occurs when glucose concentrations are less than 30 mg/dL in the term infant and less than 20 mg/dL in the preterm infant.
- Inborn errors of metabolism are classified into organic acidemia, disorders of amino acid oxidation, disorders of fatty acid oxidation, primary lactic acidosis, mitochondria function, lysosomal storage disorders, and peroxisomal disorders.

# 31 Congenital Brain Malformations

Nancy Rollins

Advances in gene sequencing and genotype-phenotype profiling have furthered understanding of many brain malformations.[1–4] Some malformations previously considered disparate in terms of gestational timing and etiology are now considered phenotypic variants of common pathways while others previously considered variants of a specific malformation are now known to result from mutations affecting disparate molecular pathways (e.g., the lissencephalies).[1–4] Given the large number of congenital human brain malformations, the complexity of the molecular genetics, and the degree of anatomic variability, an in-depth discussion of some malformations is beyond the scope of this chapter. This chapter will address malformations seen most often in clinical practice and malformations that, although less common, are distinctive and have a profound impact on early childhood development. The malformations presented herein are grouped according to presumed dominant defect in embryologic or fetal development. Diffusion tensor imaging (DTI) is included for malformations in which aberrant white matter tracts are a dominant feature of the malformation.

A rudimentary description of relevant embryology is needed. Around 26 to 28 days after conception, primary neurulation occurs, in which the lateral edges of the neural plate elevate into neural folds under the control of signaling genes such as sonic hedgehog *(SHH)*, which is also important in prosencephalic differentiation.[5,6] The folds then fuse medially to form the neural tube; initial fusion is in the middle of the embryo with subsequent closure of the cranial and caudal ends (neuropores) of the neural tube.[5,6] The primitive brain vesicles (e.g., the prosencephalon, mesencephalon, and rhombencephalon) form at the cranial end of the neural tube.[5,6] The prosencephalon divides into the telencephalon, which gives rise to the cerebral hemispheres, lateral ventricles, and corpus striatum, and the diencephalon, which gives rise to the thalami and hypothalamus. The cerebral peduncles and midbrain arise from the mesencephalon while the rhombencephalon gives rise to the metencephalon, which forms the pons and cerebellum, and the myelencephalon from which arises the medulla[5,6].

## DEFECTS OF NEURULATION

***Clinical.*** Failure of closure of the cranial neuropore results in anencephaly (e.g., absent forebrain, skull, and scalp), a lethal malformation. Less severe disorders of cranial neuropore closure result in meningoceles and encephaloceles, which are protrusions of meninges or brain respectively through a congenital defect of the skull and dura occurring in about 1/5000 live births.[7] Encephaloceles in Asian children tend to be anterior,[1] whereas those in occidental children tend to be posterior and both are most often midline. Frontal encephaloceles include interorbital frontal, nasofrontal, nasoethmoidal, and nasoorbital lesions.[7–9] Interorbital frontal encephaloceles protrude through a defect in the frontal bone (Fig. 31.1). Nasofrontal encephaloceles involve the region of nasal bridge and/or the floor of the anterior cranial fossa (e-Fig. 31.2). Nasofrontal encephaloceles are also referred to as *nasal gliomas*, although they are not neoplastic. These masses of neuroglial tissue are categorized as extranasal (60%), intranasal (30%), or mixed (10%).[6] When there are telangiectasias on the skin overlaying an external nasal glioma, the lesion may be mistaken for a hemangioma. There is often hypertelorism with a broad nasal bridge. Intranasal glioma present as an intranasal mass; biopsy should be avoided before imaging due to the risk of meningitis. With nasoethmoidal encephaloceles, the frontal bone is intact. The neural tissue bulges into the ethmoid sinus through a defect in the floor of the anterior cranial fossa, and the nasal septum defines the posterior margin of the encephalocele. A defect in the medial orbital wall results in a nasoorbital encephalocele, which protrudes into the orbit with unilateral exophthalmos. Other facial anomalies seen with anterior encephaloceles include a bifid nasal tip or complete midline splitting of the nose in an uncommon malformation known as *frontonasal dysplasia*. Basal encephaloceles result from defects in the sphenoid bone (Fig. 31.3); the encephalocele herniates into the posterior nasopharynx anterior to the dorsum sella and may contain pituitary tissue, optic nerves, and/or branches of the circle of Willis. Parietal encephaloceles range from large, deforming, "towering" lesions to small meningoceles (e-Fig. 31.4). Atretic parietal encephaloceles or meningoceles present as a small vertex subcutaneous fibrofatty masses, often painful to palpation (e-Fig. 31.5).[8] Occipital encephaloceles may contain dysplastic cerebellar tissue alone or with cerebral cortex (Fig. 31.6). Rarely, the brainstem may be within the encephalocele making this malformation lethal. The prognosis depends on the severity of associated brain anomalies and the amount of dysplastic brain contained within the encephalocele.[6–9] Although dysplastic nonfunctional neural tissue is usually resected during encephalocele closure, major dural venous sinuses are preserved if possible. Hydrocephalus is common after closure of large parietal and occipital encephaloceles.

Occipital encephaloceles are seen in trisomy 13 and 18, amniotic band syndrome, Meckel-Gruber syndrome, dyssegmental dwarfism, Knobloch syndrome, Walker-Warburg (Type II lissencephaly) syndrome, cryptophthalmos, and Voss syndrome. Frontal encephaloceles are seen in morning glory syndrome includes midline facial defects, callosal agenesis, and characteristic eye anomalies.

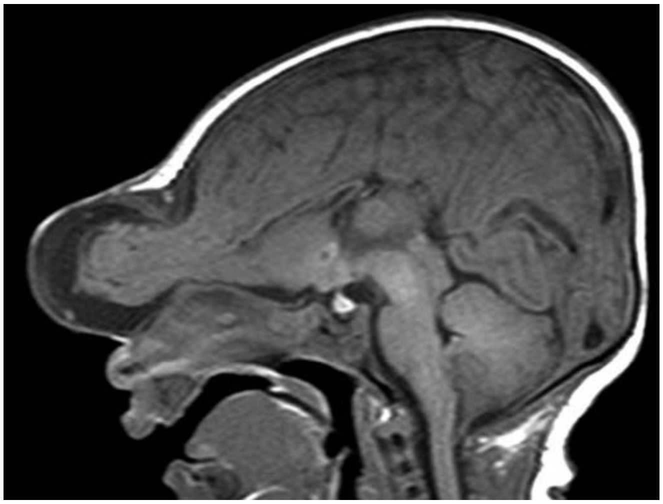

**Figure 31.1. Frontal encephalocele in a neonate.** Sagittal T1-weighted MR image shows agenesis of the corpus callosum associated with an encephalocele at the glabella.

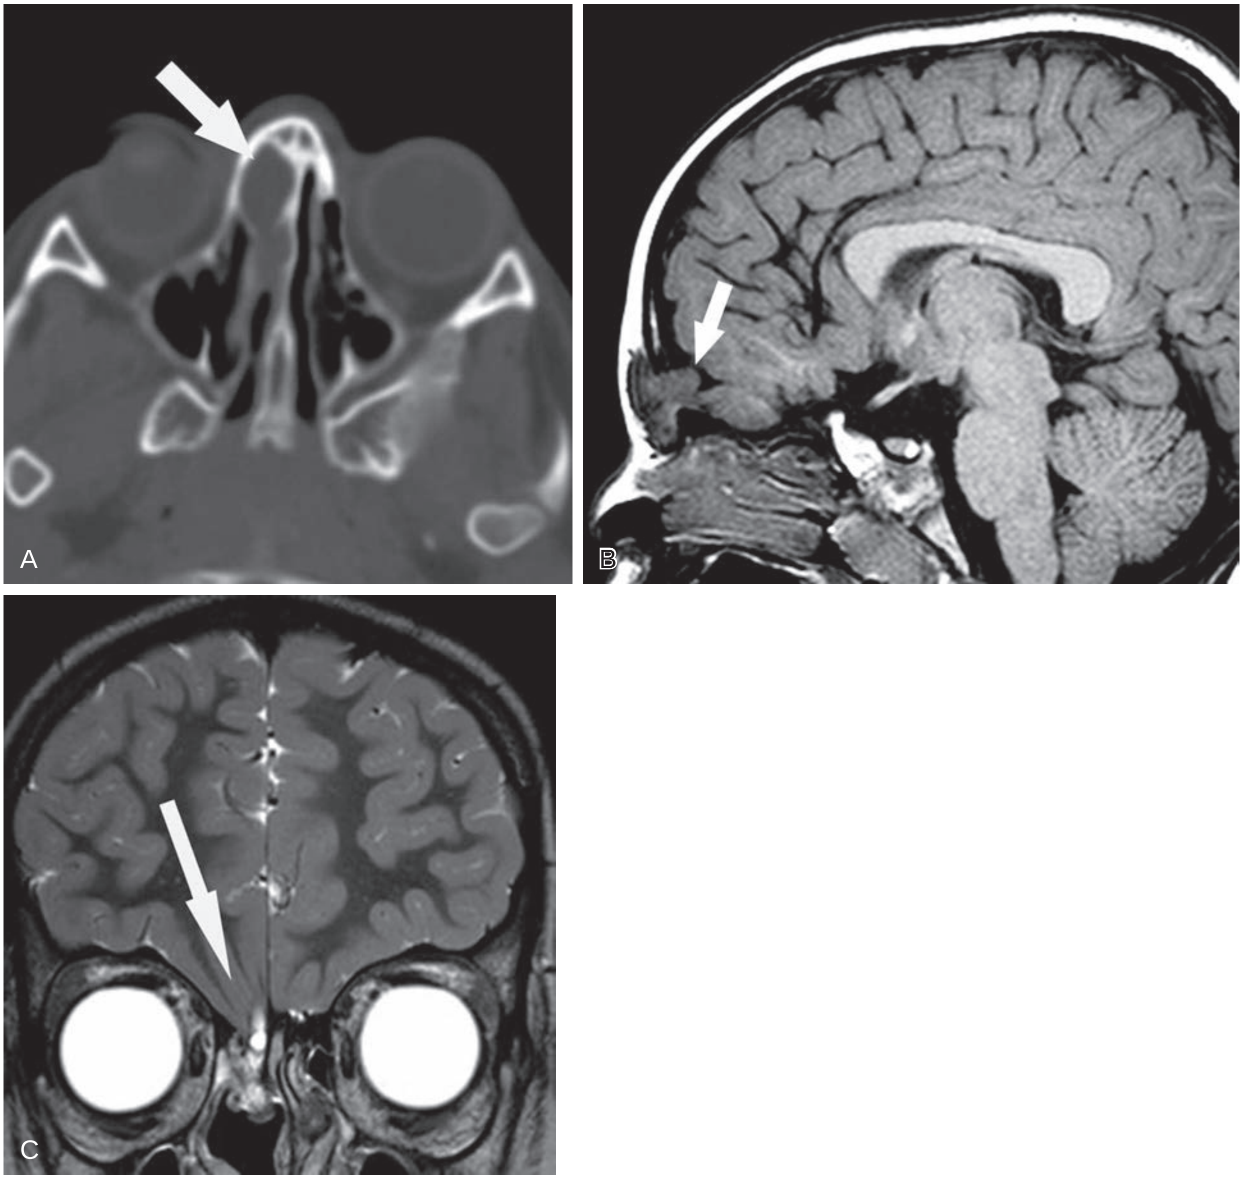
## Abstract:

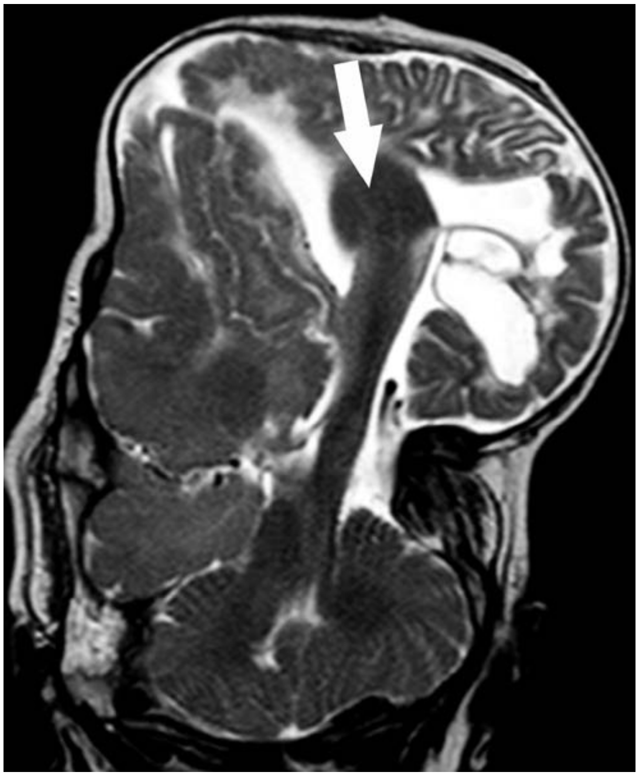
Advances in MR imaging, gene sequencing, and development of mouse models of congenital brain malformations have advanced the understanding of the etiologies and mechanisms of many congenital brain malformations. Congenital brain malformations have historically been grouped by gestational stage at time of teratogenic insult or expression of gene mutation; e.g. malformations of neural tube closure, malformations of diverticulation. However, malformations occurring at seemingly different gestational stages may have commonalities. Examples are the fused thalami seen in neural tube defects and holoprosencephaly and malformations of cortical development seen in many diverse malformations. Conventional MR imaging provides exquisite surface detail of the brain and allows white matter to be differentiated from grey matter. However, little information is provided about the white matter tracts that connect different regions of the brain. By virtue of sensitivity to different orientation of white matter tracts, diffusion imaging provides insight into malformations of axonal path finding and migration in diverse supra and infra tentorial brain malformations and expands the spectrum of anomalies in the malformed brain.

## Keywords:

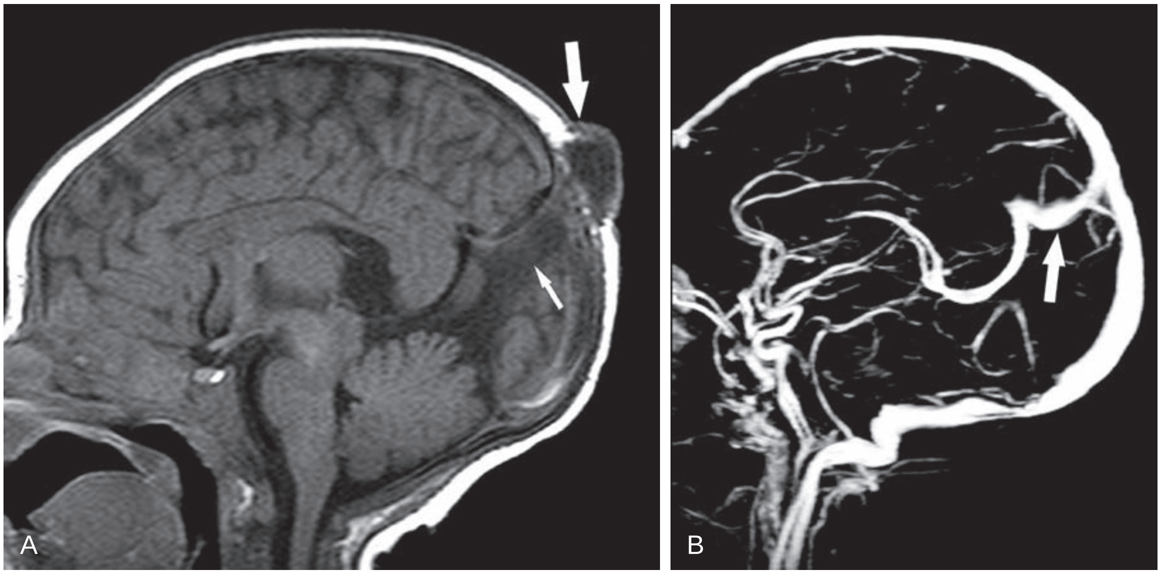
Congenital brain malformations
MRI
diffusion tensor imaging
mid hindbrain malformations



**e-Figure 31.2. Incident nasofrontal encephalocele found on CT done for trauma.** (A) Axial CT image shows a focally expansile lesion within the right ethmoid sinus *(arrow)*. (B) Sagittal T1-weighted MR image shows a small skin-covered mass *(arrow)* in the region of the glabella. (C) Coronal T2-weighted MR image shows hypertelorism and protrusion of brain and meninges *(arrow)* through a defect in the right cribriform plate.



**e-Figure 31.4. Large parietal encephalocele.** Coronal T2-weighted MR image shows extremely dysmorphic brain and diencephalic structures contained within the massive parietal encephalocele.



**e-Figure 31.5. Atretic parietal meningocele.** (A) Sagittal T1-weighted MR image shows the small meningocele *(arrow)* over the parietal vertex. There is focal expansion of the posterior interhemispheric subarachnoid space *(small arrow)*. (B) Sagittal view from gadolinium-enhanced MR venogram shows a persistent falcine sinus *(arrow)* draining the deep medullary venous system; there is no straight sinus.

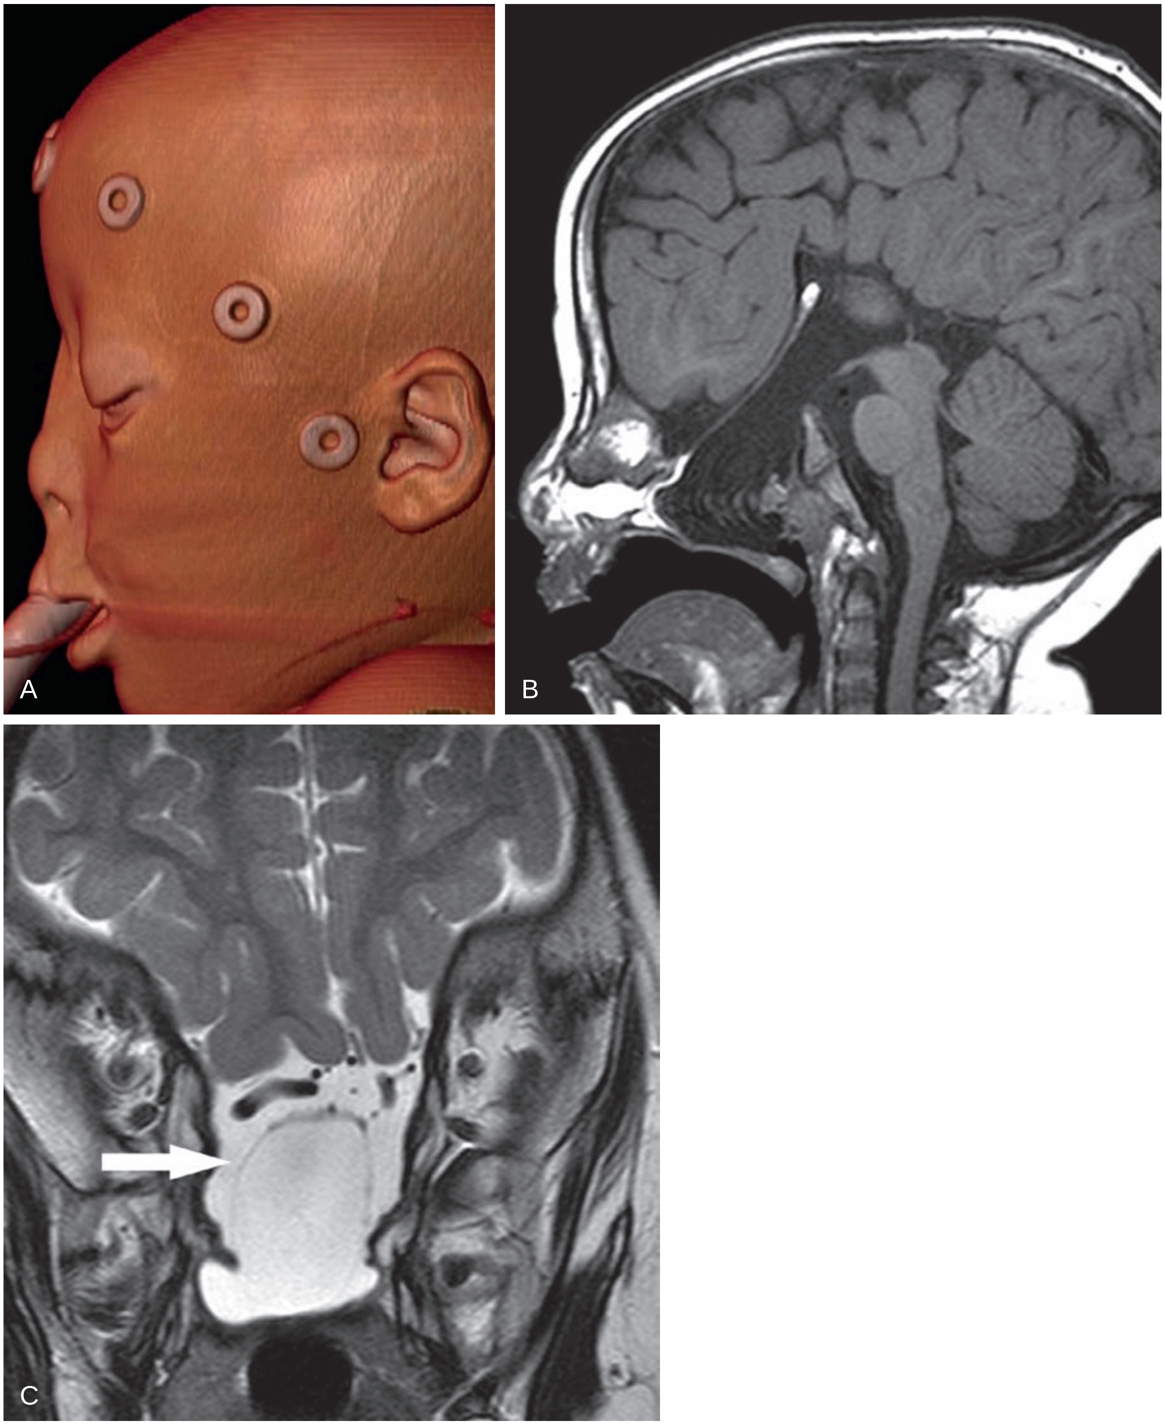


**Figure 31.3. Basal encephalocele.** (A) Lateral reformatted image from three-dimensional CT shows depressed nasal bridge. (B) Sagittal T1-weighted MR image shows callosal agenesis with a tiny lipoma. There is a large defect in the basisphenoid. Note absence of the pituitary, floor of the third ventricle, and optic pathways. (C) Coronal high-resolution T2-weighted MR image shows the pituitary-hypothalamic structures, and hypoplastic optic nerves *(arrow)* are contained within the encephalocele.

***Imaging.*** High-resolution magnetic resonance imaging (MRI) is performed soon after birth to define contents of the encephalocele and the severity of associated brain anomalies, which include callosal agenesis, malformations of cortical formation, and variable anomalies of the cerebellum, diencephalon, and brainstem. Magnetic resonance (MR) venography is essential with large occipital and midline parietal encephaloceles that may contain dural venous sinuses. Atretic parietal encephaloceles are characterized by posterior tenting of the tectal plate, a persistent falcine sinus with hypoplasia or atresia of the straight sinus, and focal expansion of posterior interhemispheric subarachnoid space.

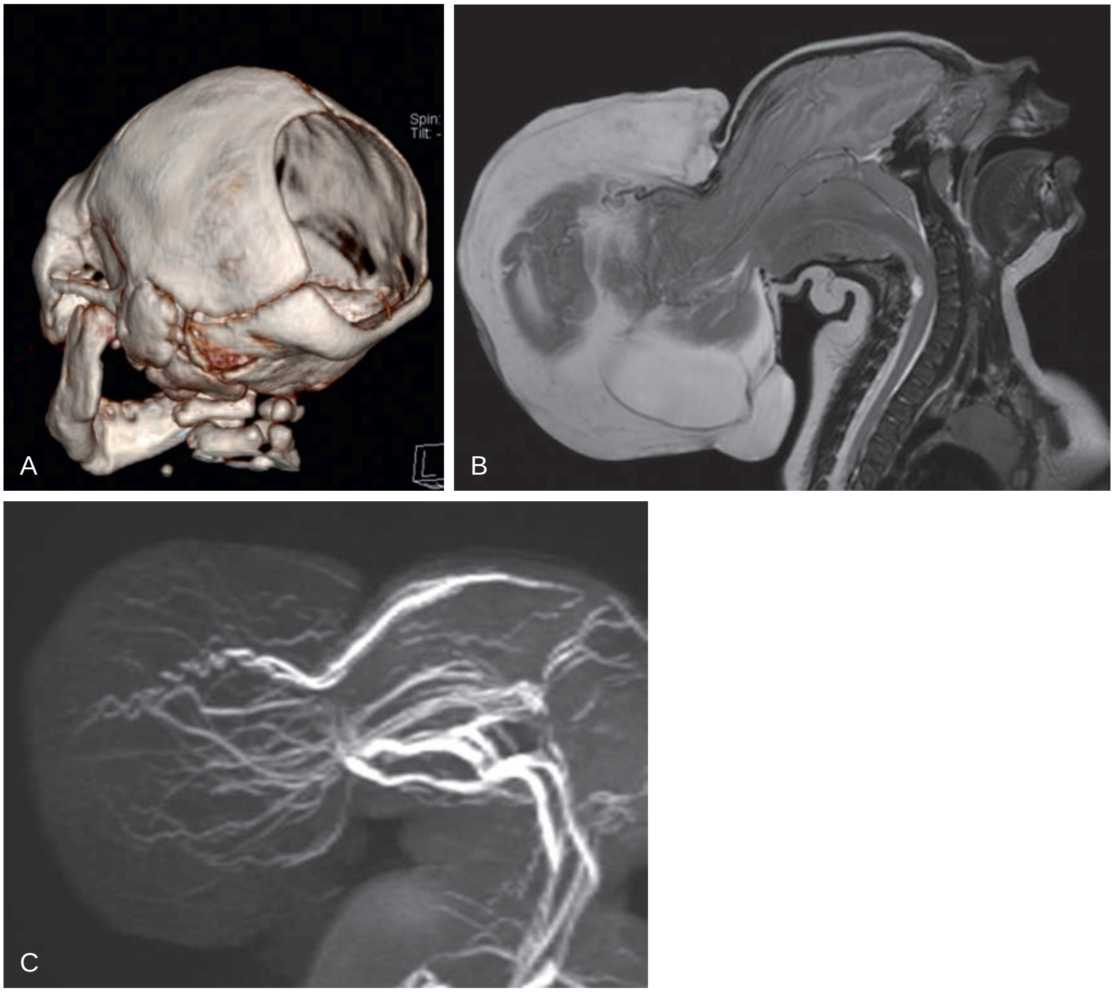

**Figure 31.6. Occipital encephalocele.** (A) Three-dimensional CT shows a large parietooccipital bony defect. (B) Sagittal T2-weighted MR image in this patient shows the encephalocele contains cerebellum and dysplastic cerebrum. (C) MR angiography shows numerous extracranial arteries and veins contained within the encephalocele.

## CHIARI II MALFORMATION

***Clinical.*** The Chiari II malformation is the intracranial manifestation of failure of closure of the caudal neuropore, which results in failure of the temporary occlusion of the neural tube needed to distend the primary brain vesicles.[10–14] Failure of distension of the primitive ventricular system results in premature fusion of the mesenchymal components that form the calvarium while the hindbrain manifestations result from leakage of cerebrospinal fluid (CSF) through the neural tube defect.[10–14]

Neural tube defects have been reported with multiple chromosomal abnormalities, including trisomies 18, 13, and 9, triploidies, unbalanced translocations and deletions, and in syndromes such as Turner, DiGeorge, and velocardiofacial syndrome.[15] The genes in the region of *22q11* have been implicated in the development of neural tube defects, although neural tube defects and the associated Chiari II malformation are probably due to a combination of genetic polymorphisms and environmental factors, including dietary folate intake and maternal folate metabolism.

The Chiari II malformation is characterized by mesodermal dysplasia, small and dysplastic lower cranial nerve ganglia, deficient tentorium cerebelli, hypoplastic and dysmorphic cerebellum, and thickened basal meninges.[10–14] As in holoprosencephaly (HPE), these anomalies are attributable to defective or deficient mesenchyme, which presumably deprived the skull base, hindbrain, and rhombencephalon of normal inductive effects.[4] Clinical problems related specifically to the malformed hindbrain include apnea, aspiration, feeding difficulties, and recurrent respiratory infections. Prenatal closure of myelomeningoceles reportedly decreases the need for ventricular shunting, decreases hindbrain herniation, and marginally improves the level of the motor deficit compared with those patients who undergo postnatal closure of the spinal dysraphic defect.[16]

***Imaging.*** The calvarial manifestations of the Chiari II malformation include a bifid frontal bone and lückenschädel or lacunar skull. Lückenschädel is due to nonossified fibrous bone in the inner and outer tables of the skull that results in the apparent scalloping of the cranium (Fig. 31.7); the affected cranium ossifies by 6 months of age. Lückenschädel is not the result of increased intracranial pressure and is not synonymous with the beaten copper skull.

The intracranial stigmata of the Chiari II malformation are typically infratentorial and less pronounced in patients who have undergone prenatal closure of the myelomeningocele.

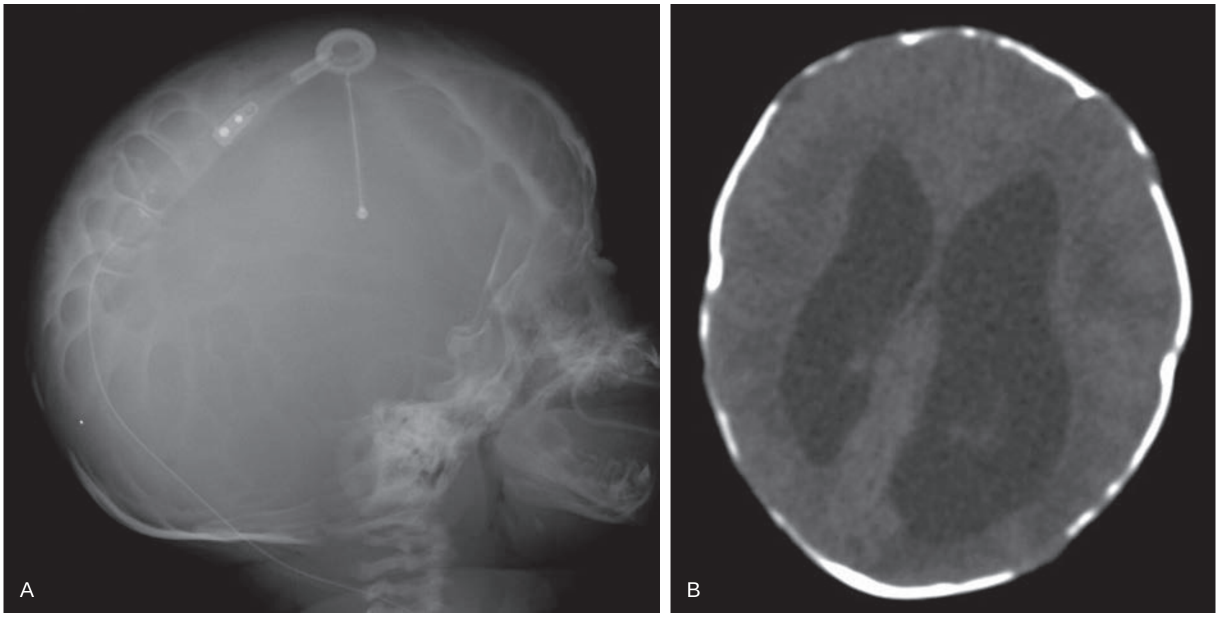

**Figure 31.7. Chiari II malformation and lückenschädel.** (A) Lateral skull radiograph shows a lacelike appearance to the cranium, which is a manifestation of mesodermal dysplasia not due to increased intracranial pressure. (B) Axial CT shows scalloping of the inner and outer tables of the calvarium.

MRI shows caudal displacement of dysplastic brainstem and hypoplastic cerebellum into the upper cervical canal with "kinking" of the cervicomedullary brainstem (Fig. 31.8). The fourth ventricle is effaced and caudally displaced. The torcula and transverse sinuses are low-lying, which presents a potential surgical hazard during decompressive suboccipital craniectomy performed for relief of symptomatic hindbrain compression. There is a "beaked" tectal plate and a variably thickened massa intermedia that may be so thick that the thalami appear virtually fused with partial atresia of the third ventricle.[6] There is an enlarged foramen magnum and constriction of the posterior cranial fossa with effacement of CSF spaces in the posterior cranial fossa; the cerebellum wraps around the ventral aspect of the brainstem, and the clivus and petrous ridges are concave. Common supratentorial abnormities include callosal dysgenesis, neuronal migration anomalies, and hydrocephalus seen in 95% of patients. After CSF diversion, the cerebral hemispheres drop away from the inner table of the skull, allowing the cortex to interdigitate across the midline under the hypoplastic falx while the superior cerebellar vermis projects upward across a widened tentorial incisura. These findings may also be seen after CSF diversion of severe congenital obstructive hydrocephalus. DTI of Chiari II malformations associated with more severe degrees of cerebellar hypoplasia show variable hypoplasia of the dorsal pontocerebellar tracts with preservation of the corticospinal tracts and medial-lateral lemniscus fibers (Fig. 31.9). The cingulum may be anomalous, crossing the midline above the corpus callosum (see Fig. 31.9).

The variants of Chiari malformations (e.g., Chiari III) are seen with high cervical/low occipital encephaloceles with variable cerebellar hypo- or aplasia. Defects of neurulation have been reported to coexist in patients with HPE; the latter malformation is considered a disorder of differentiation of the dorsal neural plate.[17] The coexistence of these malformations traditionally considered disparate in embryologic timing and insult may explained in part by mutations in genes implicated in both neural tube defects and HPE.

## DISORDERS OF DIFFERENTIATION OF DORSAL NEURAL PLATE

### Holoprosencephaly

***Clinical.*** HPE is the most common anomaly of the ventral forebrain, occurring in 1/250 embryos and 1/8300–16,000 live births.[4,18] HPE results from inductive failure of the median and paramedian structures, which are most pronounced in the ventral forebrain and declines in severity from rostral to caudal and from median to lateral.[19] HPE is due to a combination of genetic polymorphisms and environmental factors; the incidence of HPE is increased 200-fold in maternal diabetes mellitus and in prenatal retinoic acid and fetal alcohol exposure. HPE is notable for its genetic heterogeneity; at least 12 HPE loci are implicated in midline brain development.[19,20–23] Although 24% to 45% of affected live-born individuals have chromosomal abnormalities, there are no strong correlations between the type or severity of the holoprosencephalic defect and the specific mutation. Frequent facial anomalies include flattening of the nasal bridge, hypotelorism without metopic synostosis, a single central maxillary incisor, cleft lip/palate to facial clefting, and cyclopia with a central proboscis.[4,19–22] More severe facial anomalies are seen with more severe variants of HPE, whereas mild facial anomalies may occur in the absence of brain anomalies. Clinical problems include developmental delay, seizures, hypothalamic and brainstem dysfunction with swallowing problems, thermal instability and respiratory problems, pituitary dysfunction, and erratic sleeping.

***Imaging.*** There is considerable topographic variation in HPE, which is most often characterized as alobar, semilobar, or lobar.[19–22] The hallmark of HPE is incomplete separation of the forebrain, variable hypoplasia of the frontal lobes, absence of the anterior interhemispheric falx, and variable fusion of central grey nuclei with absent septum pellucidum.

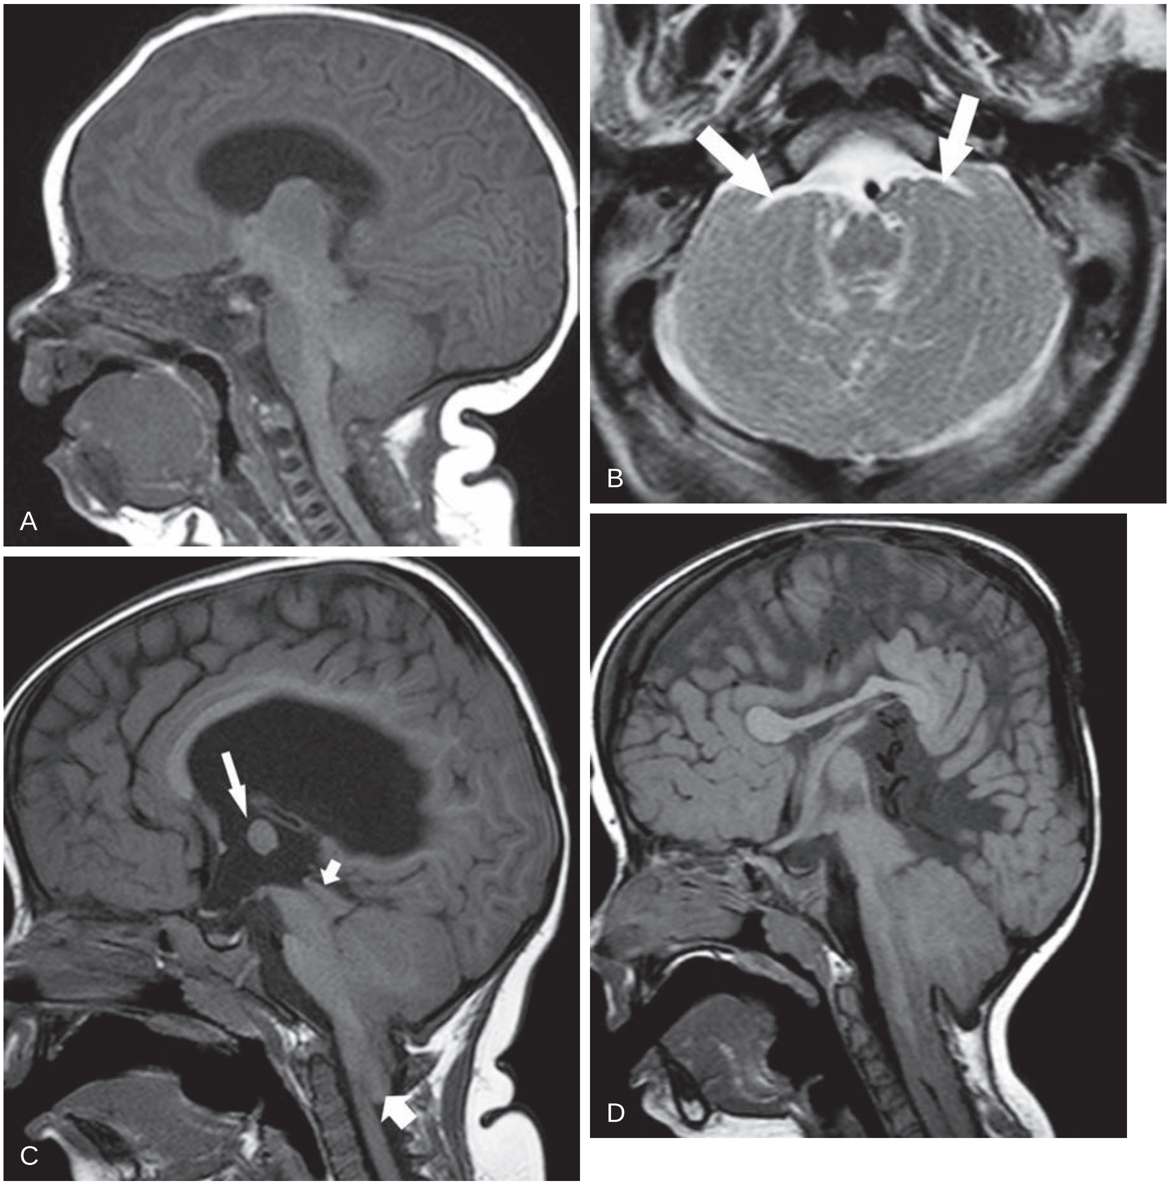

**Figure 31.8. Chiari II malformation.** (A) Neonate with Chiari II malformation. Sagittal T1-weighted MR image shows that the fourth ventricle is caudally displaced and effaced. The posterior cranial fossa is small. There is herniation of hindbrain into the upper cervical canal. (B) Axial T2-weighted MR image through the posterior fossa shows cerebellar tissue wrapping around the brainstem *(arrows)*. (C) Sagittal T1-weighted MR image in another patient shows the cerebellum and brainstem are more hypoplastic and the tectal plate *(small arrow)* is beaked. Note the large massa intermedia *(large arrow)* and the hydrocephalus. Hindbrain herniation is at the C2 level *(thick arrow)*. (D) Sagittal T1-weighted MR image shows a hypoplastic brainstem with absence of the ventral pons. The cerebellum is small, dysplastic, and caudally herniated. The fourth ventricle is not apparent.

## Alobar Holoprosencephaly

In this most severe form of HPE, there is complete lack of separation between the cerebral hemispheres with absence of the falx. The corpus callosum and septum pellucidum are absent, the central grey nuclei are fused, and the rudimentary single ventricle has a "U" configuration that may communicate with a dorsal cyst (Fig. 31.10A).[20–22]

## Semilobar Holoprosencephaly

There is relative preservation of the lateral and posterior cerebrum and the splenium (Fig. 31.10B-D). The posterior interhemispheric fissure and falx are present while the hypoplastic frontal lobe is undivided.[4,20–22] Frontal lobe hypoplasia results in the anterior position of the Sylvian fissures, termed a *wide Sylvian angle*.[23] The globus pallidi are absent or hypoplastic, and the caudate nuclei are fused, resulting in obliteration of or lack of formation of the septal region. The posterior limbs of the internal capsules are ventral to partially or totally fused thalami.[24] The hippocampus is virtually always present, although usually incompletely or abnormally developed. There may be a dorsal cyst. DTI shows fornices imbedded in dysplastic thalami and bands of anomalous white matter crossing the forebrain.[25]

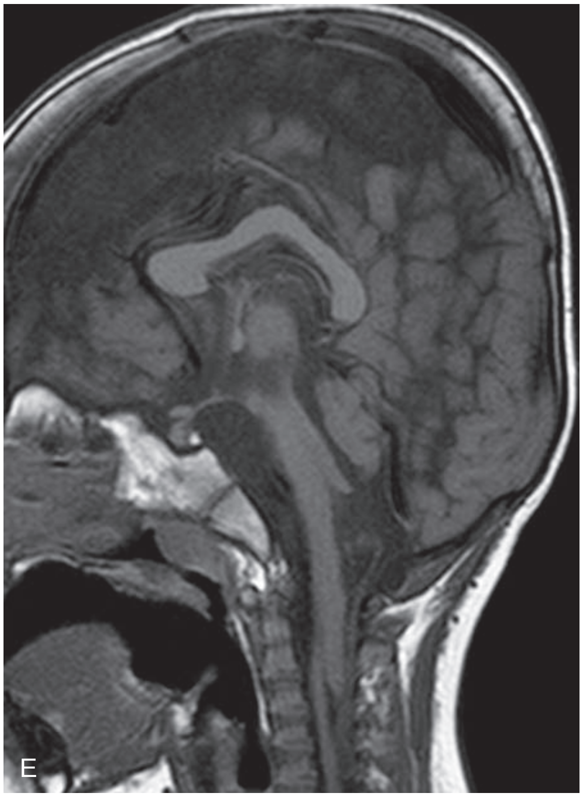

**Figure 31.8, cont'd.** (E) Sagittal T1-weighted MR image shows aplasia of the cerebellar hemispheres, sometimes referred to as *Chiari IV malformation*. This entity is probably best described as Chiari II malformation with cerebellar aplasia.

## Lobar Holoprosencephaly

In this mildest form of HPE, there is hypoplasia of the frontal poles, agenesis of the septal pellucidum, and incomplete separation of the basal forebrain, which is best depicted with high resolution coronal images (Fig. 31.11). The posterior frontal, parietal, and occipital lobes are more normally formed.[4,20–22] The callosal body and splenium are preserved.

## Syntelencephaly (Middle Frontal Variant)

The middle frontal variant is an unusual variant of lobar HPE characterized by separation of the frontal and occipital poles, fusion of the middle portions of the cerebral hemispheres (Fig. 31.12), preservation of portions of the commissural fibers of the corpus callosum, and neuronal migration anomalies; thalamic fusion is variable.[26,27]

## Septo-optic Dysplasia

***Clinical.*** Septo-optic dysplasia (SOD) is considered along the continuum of disorders of ventral forebrain differentiation.[4] Patients typically present in early childhood with nystagmus, optic nerve atrophy, short stature due to growth hormone deficiency, or panhypopituitarism with or without diabetes insipidus. Affected patients are at risk for Addisonian crisis due to subclinical adrenal insufficiency, which may become clinically apparent only during illness or severe stress. Most cases of isolated SOD are sporadic.

***Imaging.*** SOD is characterized by absence of the septum pellucidum and variable optic nerve hypoplasia (Fig. 31.13). The neurohypophysis may be ectopic and the pituitary stalk may be interrupted. However, agenesis of the septum pellucidum may be isolated with normal optic pathways and intact neuroendocrine function. Absence of the septal leaves results in downward displacement of the fornices into the third ventricle. SOD is seen in multiple malformations such as schizencephaly, neuronal migration anomalies, and neural tube defects.

## Corpus Callosal Agenesis/Dysgenesis

***Clinical.*** Agenesis of the corpus callosum (ACC), one of the most common central nervous system (CNS) malformations (0.5–70/10,000 live births), is genetically and phenotypically heterogeneous with clinical phenotype dependent on coexistent malformations and numerous chromosomal abnormalities and syndromes.[4,28] Affected patients have variable developmental delay, including speech, problems with vision and feeding, and seizures.[28]

Formation of the corpus callosum begins around 6 weeks' gestation, with initial axonal crossing around 11 to 12 weeks' gestation, and completion of callosal formation around 18 to 20 weeks. The first axons to cross the midline arise from neurons destined for the cingulate cortex and provide a path for subsequent migrating callosal axons arising elsewhere in the developing neocortex.[4,5,28–30] The crossing axons are controlled by the glial wedge composed of radial glial cells that geographically limits the passage of axons and then repel the axons away from the midline by expressing molecular guidance cues.[1,4,5,29] Other embryonic structures important in callosal formation include the indusium griseum above the callosal body and the subcallosal sling.[28] After crossing the midline, callosal axons grow into the contralateral hemisphere; their ultimate destination mirrors their region of origin and the cortical layer of the parent neuron.[28–30] Many of the crossing callosal axons undergo programmed cell death after reaching their final destination, which starts during the second trimester with postnatal pruning of axonal axons.[1,28] When the axons fail to cross the midline and remain in their hemisphere of origin, the misrouted callosal axons may course along the medial aspect of the lateral ventricle forming the longitudinal callosal bundles of Probst.[4,31,32] Alternately, aberrant axons may project to the contralateral hemisphere across a rudimentary callosal genu as nonhomotopic fibers.[33] Patients with isolated ACC and well-developed Probst bundles may be developmentally intact and processing deficits detected only with neurocognitive assessment.[34]

***Imaging.*** The anterior commissure (AC) is a variably sized tract embedded in the cranial aspect of the lamina terminalis, which demarcates the anterior wall of the third ventricle and may be enlarged, normal, or small in ACC. The hippocampal commissure is a thin sheet of white matter connecting the fornices, which is not routinely visualized on MRI of the normal brain. Absence of the corpus callosum, AC, and hippocampal commissure is described as "complete commissural agenesis" (Fig. 31.14).[4,31,32] Preservation of the AC in the absence of the corpus callosum and hippocampal commissure is "calloso-hippocampal agenesis," whereas the anterior and hippocampal commissures may be preserved, resulting in "isolated callosal agenesis." Calloso-hippocampal agenesis is the most common malformation, although it might be argued these classifications are somewhat academic. By MRI, the sulci over the mesial surface of the frontal lobes have a radial configuration and the lateral ventricles have a characteristic parallel orientation. Absence of the temporal segments of the cingulum results in dilatation of the temporal horns while hypoplasia of association fibers connecting the occipital and temporal lobe allows dilatation of trigones of the lateral ventricles, referred to as *colpocephaly*. Callosal agenesis may be associated with interhemispheric diencephalic pseudocyst (e.g. high-riding third ventricle) or interhemispheric cysts that do not communicate with the ventricles. In patients with a rudimentary callosal genu, diffusion tractography shows the nonhomotopic aberrant callosal connections described as "asymmetric sigmoid

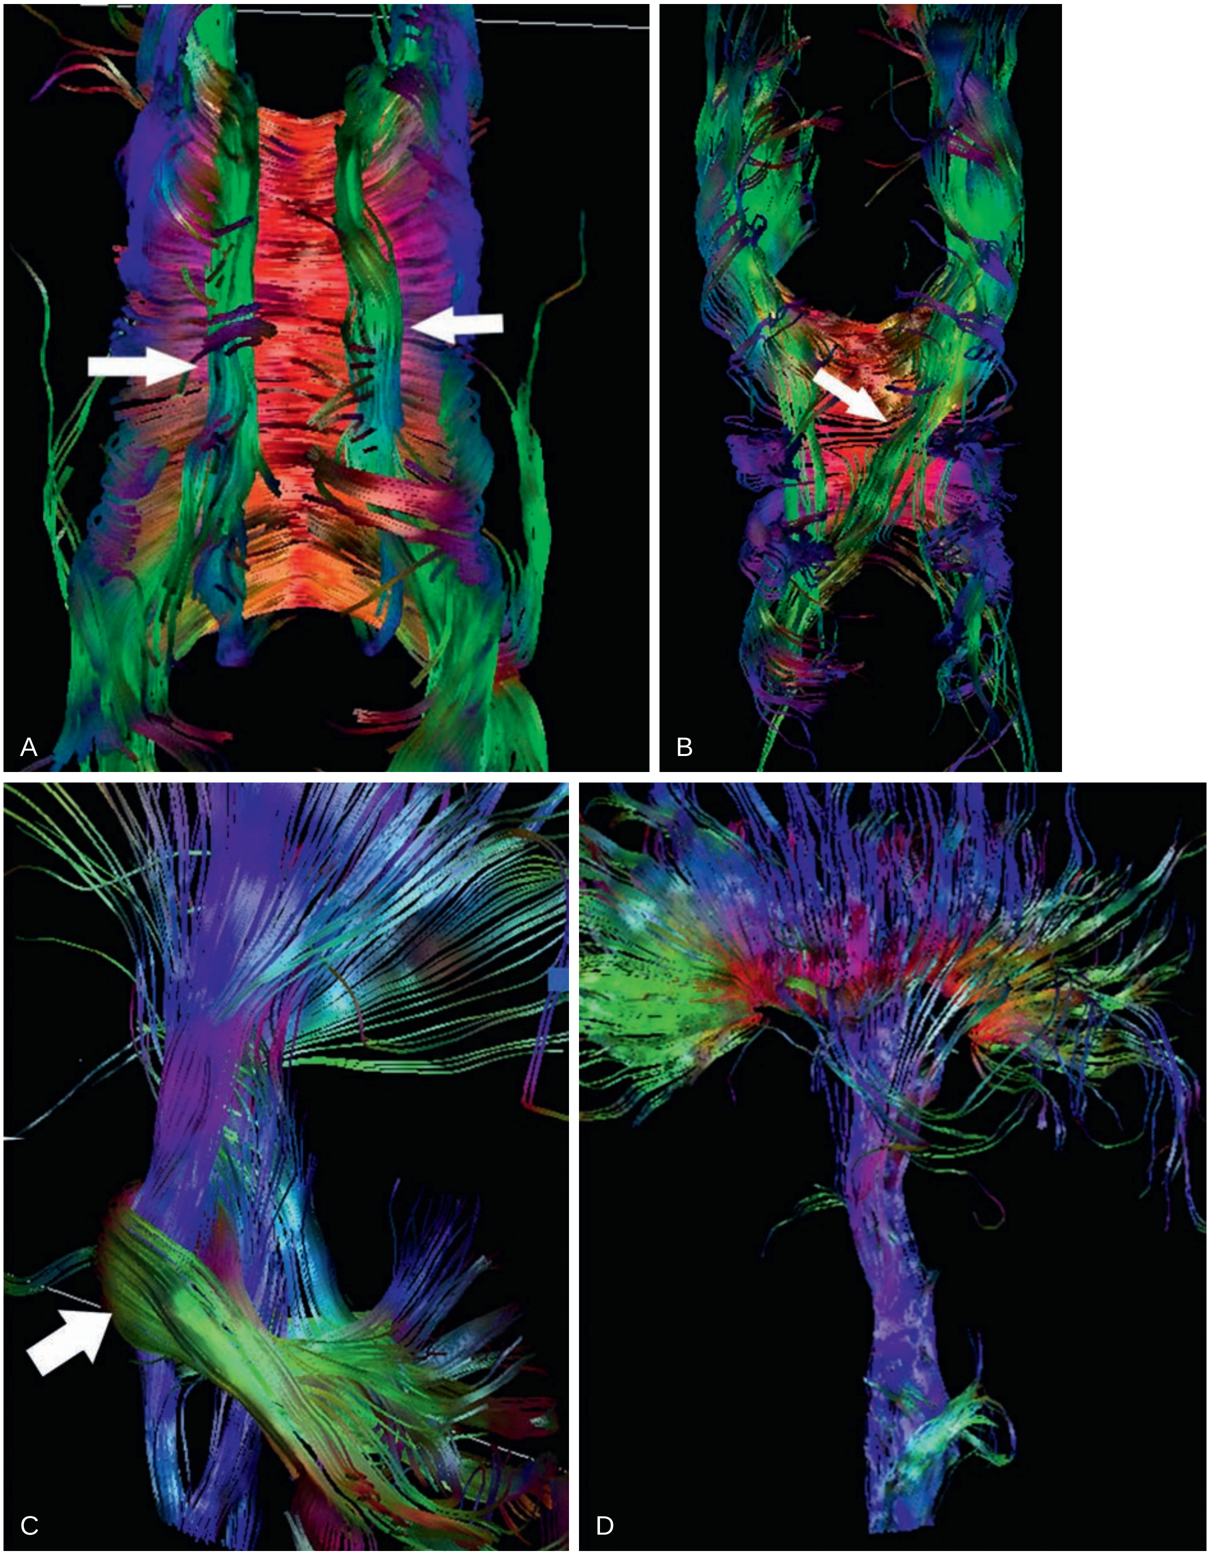

**Figure 31.9. Diffusion tensor imaging in Chiari II malformation.** (A) Diffusion tractography from a normal patient shows paired association fibers forming the cingulum *(arrows)* above the corpus callosum. The green orientation indicates the fibers are oriented back-front. By definition, association fibers do not cross the midline. (B) In a patient with Chiari II malformation, diffusion tractography shows the left cingulum is deficient and there are anomalous supracallosal fibers *(arrow)*. (C) Normal pontocerebellar tracts *(arrow)* in a normal patient. (D) Absence of the middle cerebellar peduncles and pontocerebellar tracts in patient illustrated in Fig. 31.8D.

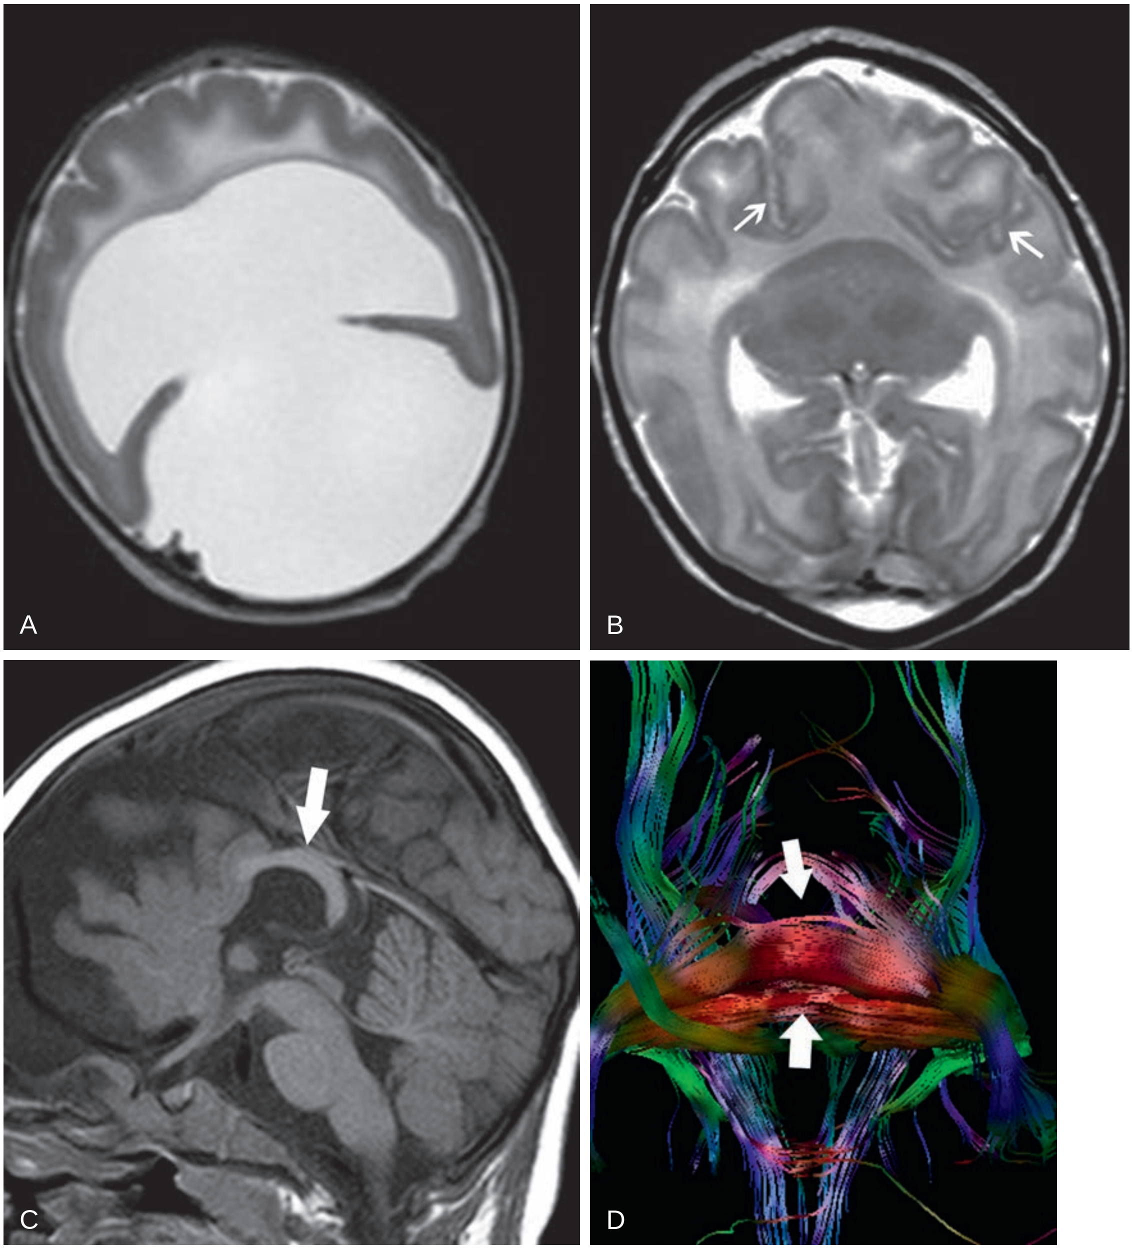

**Figure 31.10. Holoprosencephaly (HPE).** (A) Alobar HPE. Axial T2-weighted MR image shows a monoventricle with a large dorsal cyst. Note absence of an interhemispheric fissure and falx. (B) Semilobar HPE. Axial T2-weighted MR image shows the Sylvian fissures *(arrow)* are more anterior displaced in another patient with more severe frontal lobe hypoplasia. (C) Sagittal T1-weighted MR image shows underdeveloped frontal lobes. The splenium *(arrow)* is formed. (D) DTI of semilobar HPE. Tractography viewed in the coronal plane shows bands of anomalous white matter *(arrows)* crossing the midline.

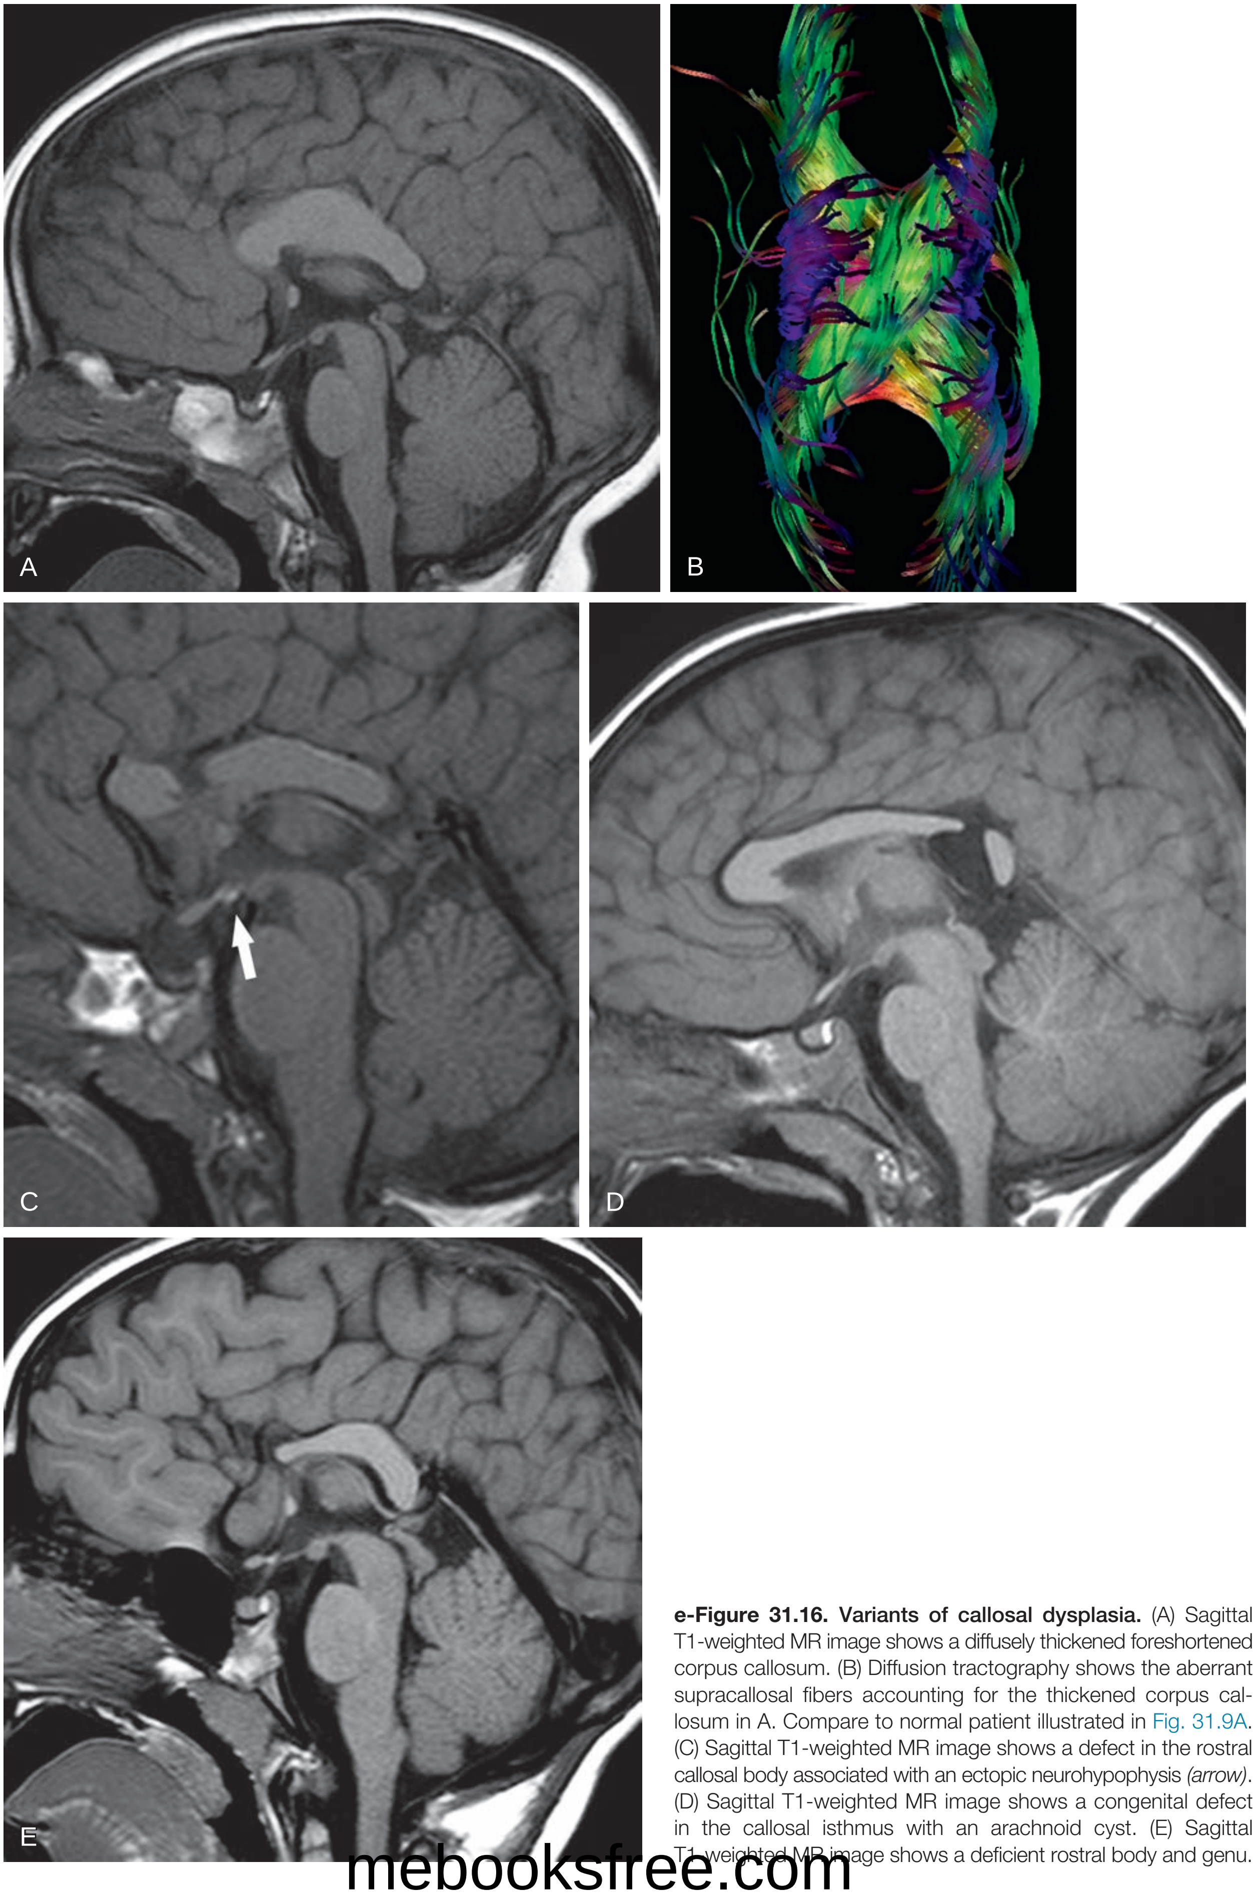
bundles" and have also been reported in patients with aberrantly shaped corpus callosum.[33]

Callosal agenesis may be isolated or associated with aqueductal stenosis, Chiari II malformations, and malformations of cortical development (MCD), brainstem, and cerebellum.[31,32] There are numerous syndromes associated with complete or partial ACC. Aicardi syndrome is a rare sporadic X-linked dominant malformation seen in females characterized by callosal agenesis, interhemispheric neuroepithelial cysts, and MCD (Fig. 31.15); affected males have Klinefelter syndrome (47,XXY). Ocular abnormalities include chorioretinal lacunae and coloboma; the cerebellum may be malformed. CRASH syndrome (corpus callosum agenesis, retardation, adducted thumbs, spastic paraplegia, and hydrocephalus) is caused by mutations in the L1 cell adhesion molecule gene that codes for a transmembrane cell adhesion protein involved in axonal migration.[4]

## Callosal Hypoplasia/Hyperplasia

The corpus callosum may be incompletely formed, diffusely hypoplastic, or segmentally deficient (e-Fig. 31.16). Partial callosal agenesis is usually characterized by absence of the splenium and dorsal body with relative preservation of the genu and rostral body, although the reverse may be seen. Diffuse callosal hypoplasia



**e-Figure 31.16. Variants of callosal dysplasia.** (A) Sagittal T1-weighted MR image shows a diffusely thickened foreshortened corpus callosum. (B) Diffusion tractography shows the aberrant supracallosal fibers accounting for the thickened corpus callosum in A. Compare to normal patient illustrated in Fig. 31.9A. (C) Sagittal T1-weighted MR image shows a defect in the rostral callosal body associated with an ectopic neurohypophysis *(arrow)*. (D) Sagittal T1-weighted MR image shows a congenital defect in the callosal isthmus with an arachnoid cyst. (E) Sagittal T1-weighted MR image shows a deficient rostral body and genu.

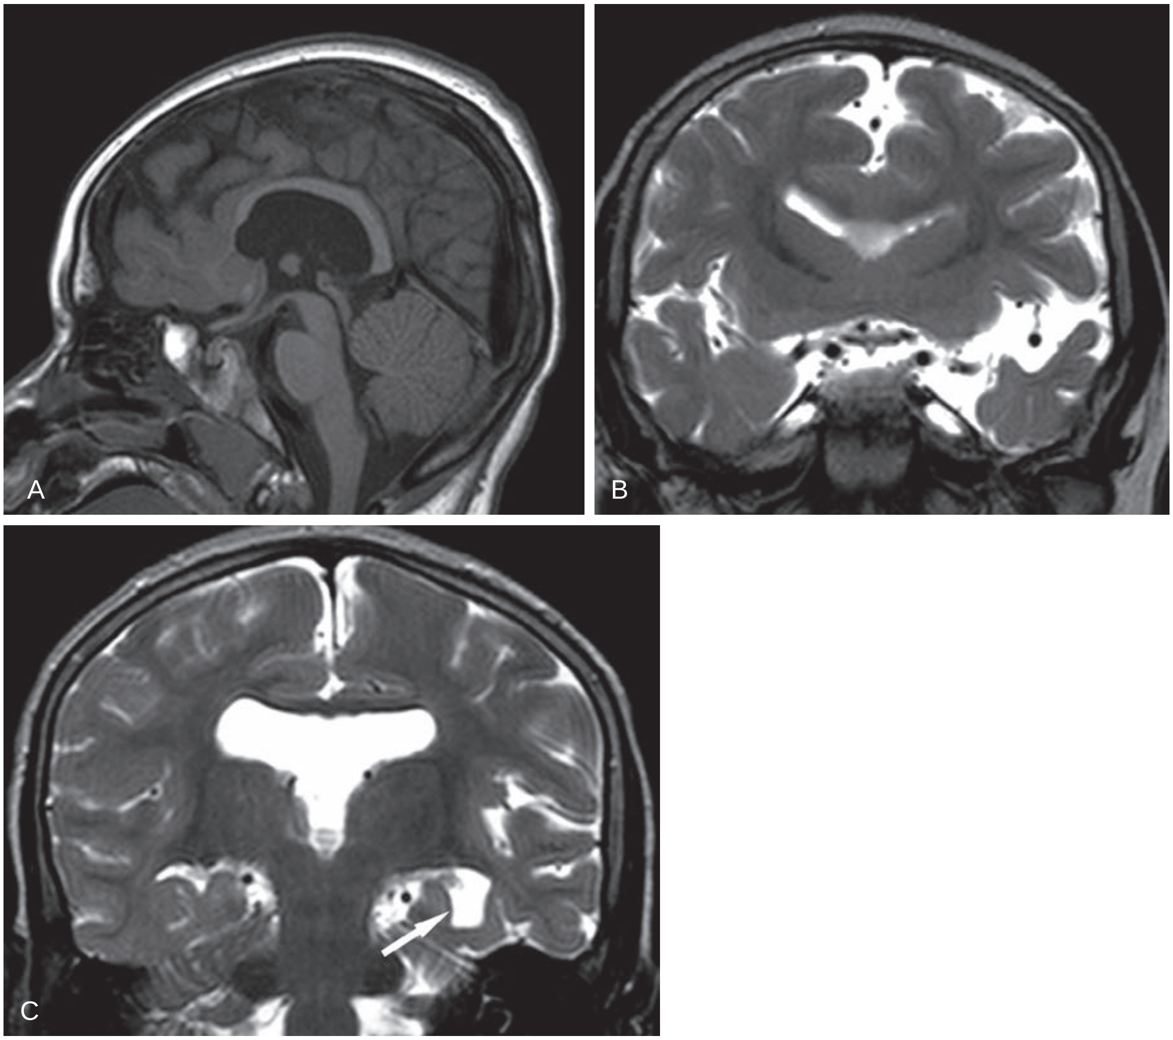


**Figure 31.11. Lobar holoprosencephaly.** (A) Sagittal T1-weighted MR image shows that the callosal rostrum and genu are deficient. (B) Coronal T2-weighted image shows a lack of separation of basal forebrain and caudate nuclei. (C) Coronal T2-weighted MR image shows that the septal leaves are absent. The hippocampi are globular with lateral insertion of the forniceal fimbria *(arrow)* onto the dysplastic hippocampus.

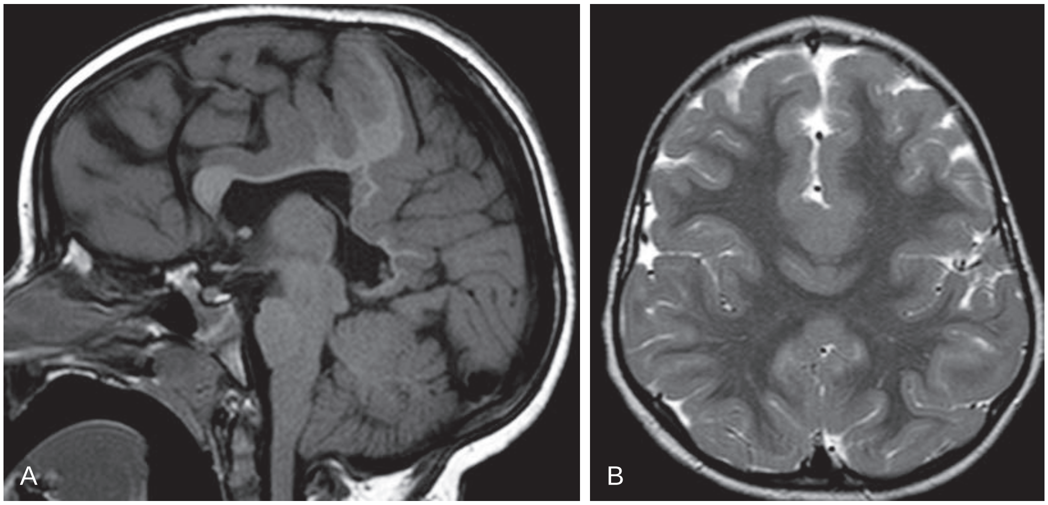

**Figure 31.12. Syntelencephaly (middle frontal variant of holoprosencephaly).** (A) Sagittal T1-weighted MR image shows the callosal genu is formed; the callosal body appears formed but is hypoplastic. There is partial fusion of the frontal lobes. (B) Axial T2-weighted MR image shows fusion of cortex and white matter in the middle frontal region. The anterior and posterior interhemispheric fissures are well developed.

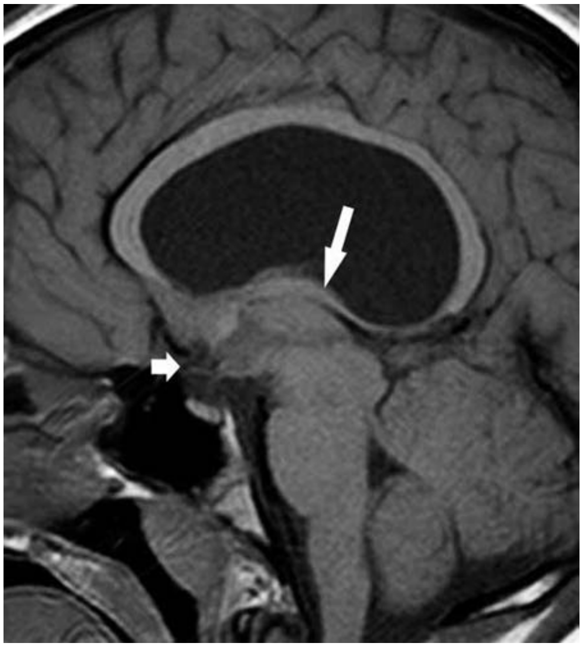

**Figure 31.13. Septo-optic dysplasia with agenesis of the septum pellucidum.** Sagittal T1-weighted MR image shows that fornices are inferiorly positioned *(arrow)*. The optic apparatus is hypoplastic *(short arrow)*; there is no identifiable neurohypophysis.

is characterized by diffuse thinning, while segmental callosal hypoplasia involves an intermediate portion of the corpus callosum. The segmental defects may result from a secondary callosal destruction or injury to regional white matter. Callosal hyperplasia may be diffuse, as seen in neurofibromatosis type 1, or limited to the midcallosal body, in which case the corpus callosal is often foreshortened. DTI of the congenitally thickened corpus callosum often shows anomalous longitudinal supracallosal fibers that represent misrouted callosal axons.[34]

Callosal lipomas are rare and are thought to result from abnormal differentiation of pluri-potential mesenchymal tissue.[4] Most of cases are associated with agenesis or incomplete formation of the corpus callosum. Anterior lipomas are more common than posterior. The lipoma itself is an incidental finding and may be seen with a fully formed corpus callosum.

## Primary Microcephaly

There are more than 400 phenotypes associated with microcephaly, discussion of which is beyond the scope of this chapter. Primary nonsyndromic microcephaly is autosomal recessive and genetically diverse. Genes implicated in primary microcephaly affect the centrosomes, centrioles, and spindle fibers of neuronal precursors adversely affecting neuronal proliferation and migration; the net result is diffuse thinning of the cerebral cortex.[35,36] Seizure disorders are uncommon; 15% of patients have normal neurodevelopmental outcomes.

MR may show a small, otherwise normal brain or diffuse undersulcation. DTI may show unsuspected anomalous white matter tracts, suggesting axonal migration defects in addition to defective neuronal proliferation and migration.

## Brain Overgrowth Syndromes (Megalencephaly)

***Clinical.*** Brain overgrowth may be diffuse or focal. Diffuse megalencephaly may be isolated or associated with polymicrogyria (PMG) and ventriculomegaly.[2,36] Megalencephaly is associated with gene mutations affecting protein products in the mammalian target of Rapamycin (mTOR) pathways, which regulate cell metabolism, growth, proliferation, and survival and are implicated in tuberous sclerosis and refractory epilepsy.[36–38] Hemimegalencephaly reflects focal megalencephaly with somatic mutations affecting only the dysmorphic overgrown tissues. Hemimegalencephaly may be isolated or associated with neurocutaneous syndromes such as epidermal nevus syndrome, Proteus syndrome, unilateral hypomelanosis of Ito, neurofibromatosis type I, Klippel-Trenaunay syndrome, and tuberous sclerosis.[36–38] Hemispherectomy may be required for relief of severe intractable epilepsy.

***Imaging.*** MRI of diffuse megalencephaly shows diffuse enlargement of the cerebrum and cerebellum with crowding of the posterior cranial fossa and secondary tonsillar herniation; there may be PMG (e-Fig. 31.17)

MRI of hemimegalencephaly shows diffusely enlarged hemisphere or lobe (Fig. 31.18) with abnormal sulcation pattern that may include PMG, agyria, and grey matter heterotopias. The regional white matter is thickened and gliotic. A hallmark is enlargement of the ipsilateral ventricle, which becomes more pronounced with age, with expansion of the overlaying hemicranium; the affected occipital lobe bulges across the midline. Lobar brain overgrowth may be subtle in the neonatal period. DTI shows anomalous white matter tracts that will be transected during hemispherotomy.

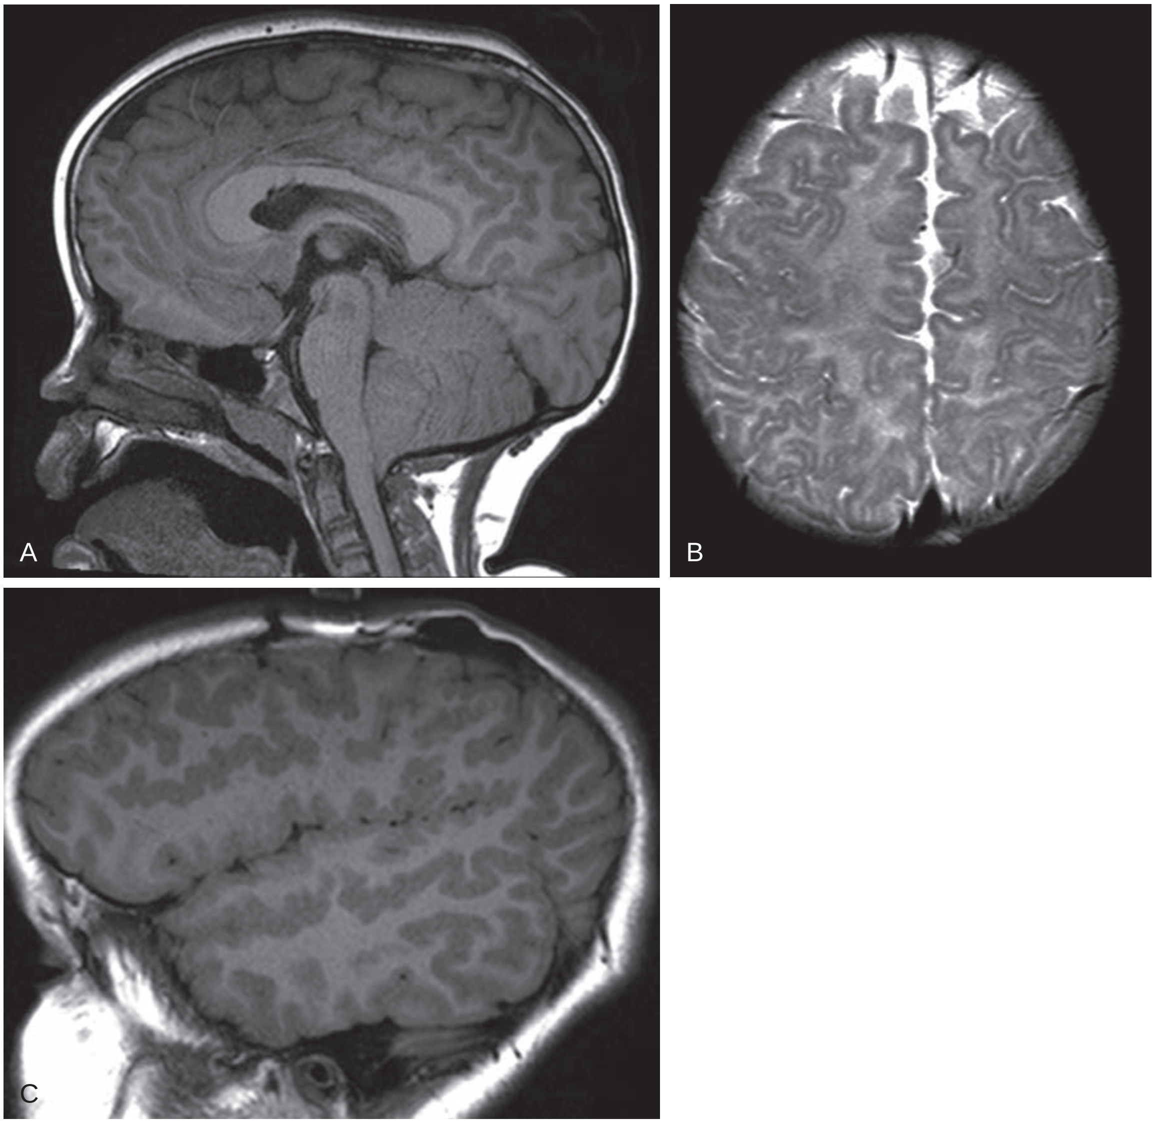
## Encephaloclastic/Destructive Lesions

Hydranencephaly describes near complete to total absence of the cerebral hemispheres with preservation of the brainstem, central grey nuclei, and cerebellum, and is thought to be due to intrauterine ischemic insult.[4] There may be remnants of the inferior frontal, anterior temporal, or occipital lobes (Fig. 31.19). Affected patients appear neurologically normal at birth due to the intact brainstem.

The differential diagnosis of hydranencephaly is aqueductal stenosis with severe hydrocephalus. In the latter conditions, CSF diversion results in variable reexpansion of the cerebral cortex, whereas shunt placement in patients with hydranencephaly serves to prevent progressive massive macrocephaly but does not affect the appearance of the rudimentary cerebral cortex. Other encephaloclastic lesions include porencephaly, which are CSF-containing spaces that usually communicate with the ventricular system. Porencephaly may occur from intrauterine vascular insult, trauma, infection, and nontraumatic hemorrhage. Unlike schizencephalic defects, porencephalic defects are not lined with dysplastic grey matter.

## MALFORMATIONS OF CORTICAL DEVELOPMENT

These malformations include a wide spectrum of developmental malformations of the cortex caused by disruption of neuronal cell proliferation, migration, and/or organization.[2,4,39] Neuronal proliferation commences in the germinal matrix along the subependymal layer of the walls of the lateral ventricles at 7 to 8 weeks' postconception.[2–4] The radial glia in the ventricular zone function as progenitor cells and also provide scaffolding on which the neurons migrate in waves out to the cortical plate.[2–4] Neurons in cortical layer VI are the first to reach the cortex followed by those destined for layers V, IV, III, etc. in an "inside-out" sequence. The trailing processes of the migrating neurons form the axons, which migrate away from the parent neuron toward their final destinations concurrent with the ventriculofugal migration of the parent neurons. Neuronal migration and axonal path finding are driven by complex molecular signaling controlled by genes that switch the signaling molecules on and off.[2,38,39] At the completion of migration, the cortex becomes organized with synaptic contacts developing between neurons throughout the six-layered cortex. Disruptions of neuronal proliferation,



**e-Figure 31.17. Diffuse megalencephaly.** (A) Sagittal T1-weighted MR image shows a diffusely enlarged cerebrum and cerebellum with secondary tonsillar herniation. (B) Axial T2 image shows asymmetric polymicrogyria. (C) Parasagittal T1 image shows extensive polymicrogyria.

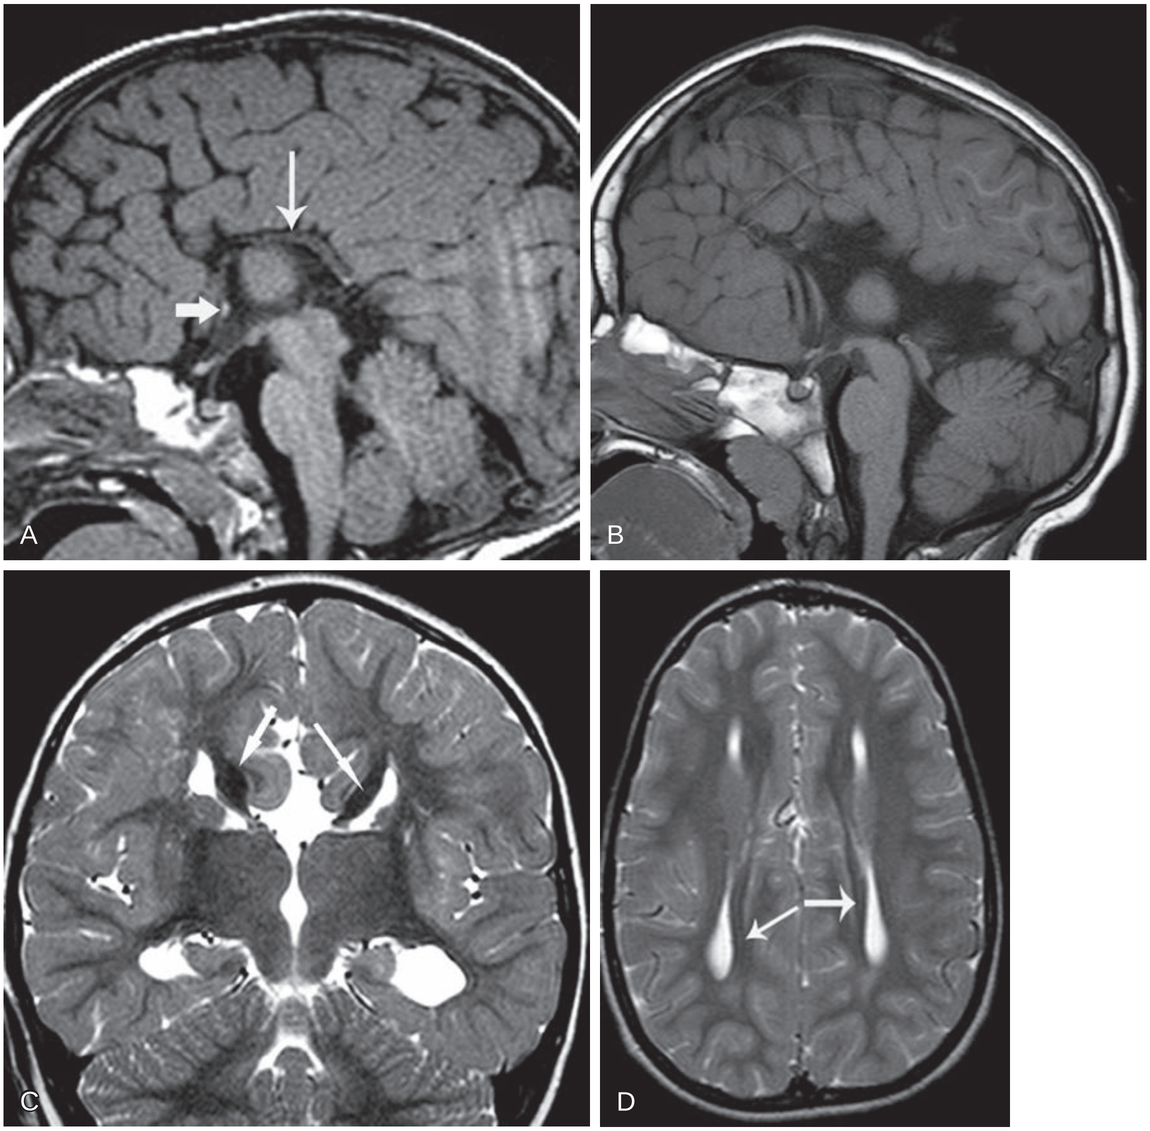


**Figure 31.14. Variants of corpus callosal agenesis.** (A) Sagittal T1-weighted MR image shows callosal agenesis with preservation of the anterior and hippocampal commissures. There is a thin midline commissural structure *(arrows)*, which represents the hippocampal commissure rather than a severely hypoplastic corpus callosum. (B) Sagittal T1-weighted MR image shows that the anterior and hippocampal commissures are also absent. (C) Coronal T2-weighted MR image shows the bundles of Probst *(arrows)* along the medial walls of the lateral ventricles. (D) Axial T2-weighted MR image shows that the ventricles have a characteristic parallel orientation in callosal agenesis. The variable enlargement of the ventricles is due to lack of regional white matter rather than to hydrocephalus. Note Probst bundles *(arrows)* along the lateral ventricles.

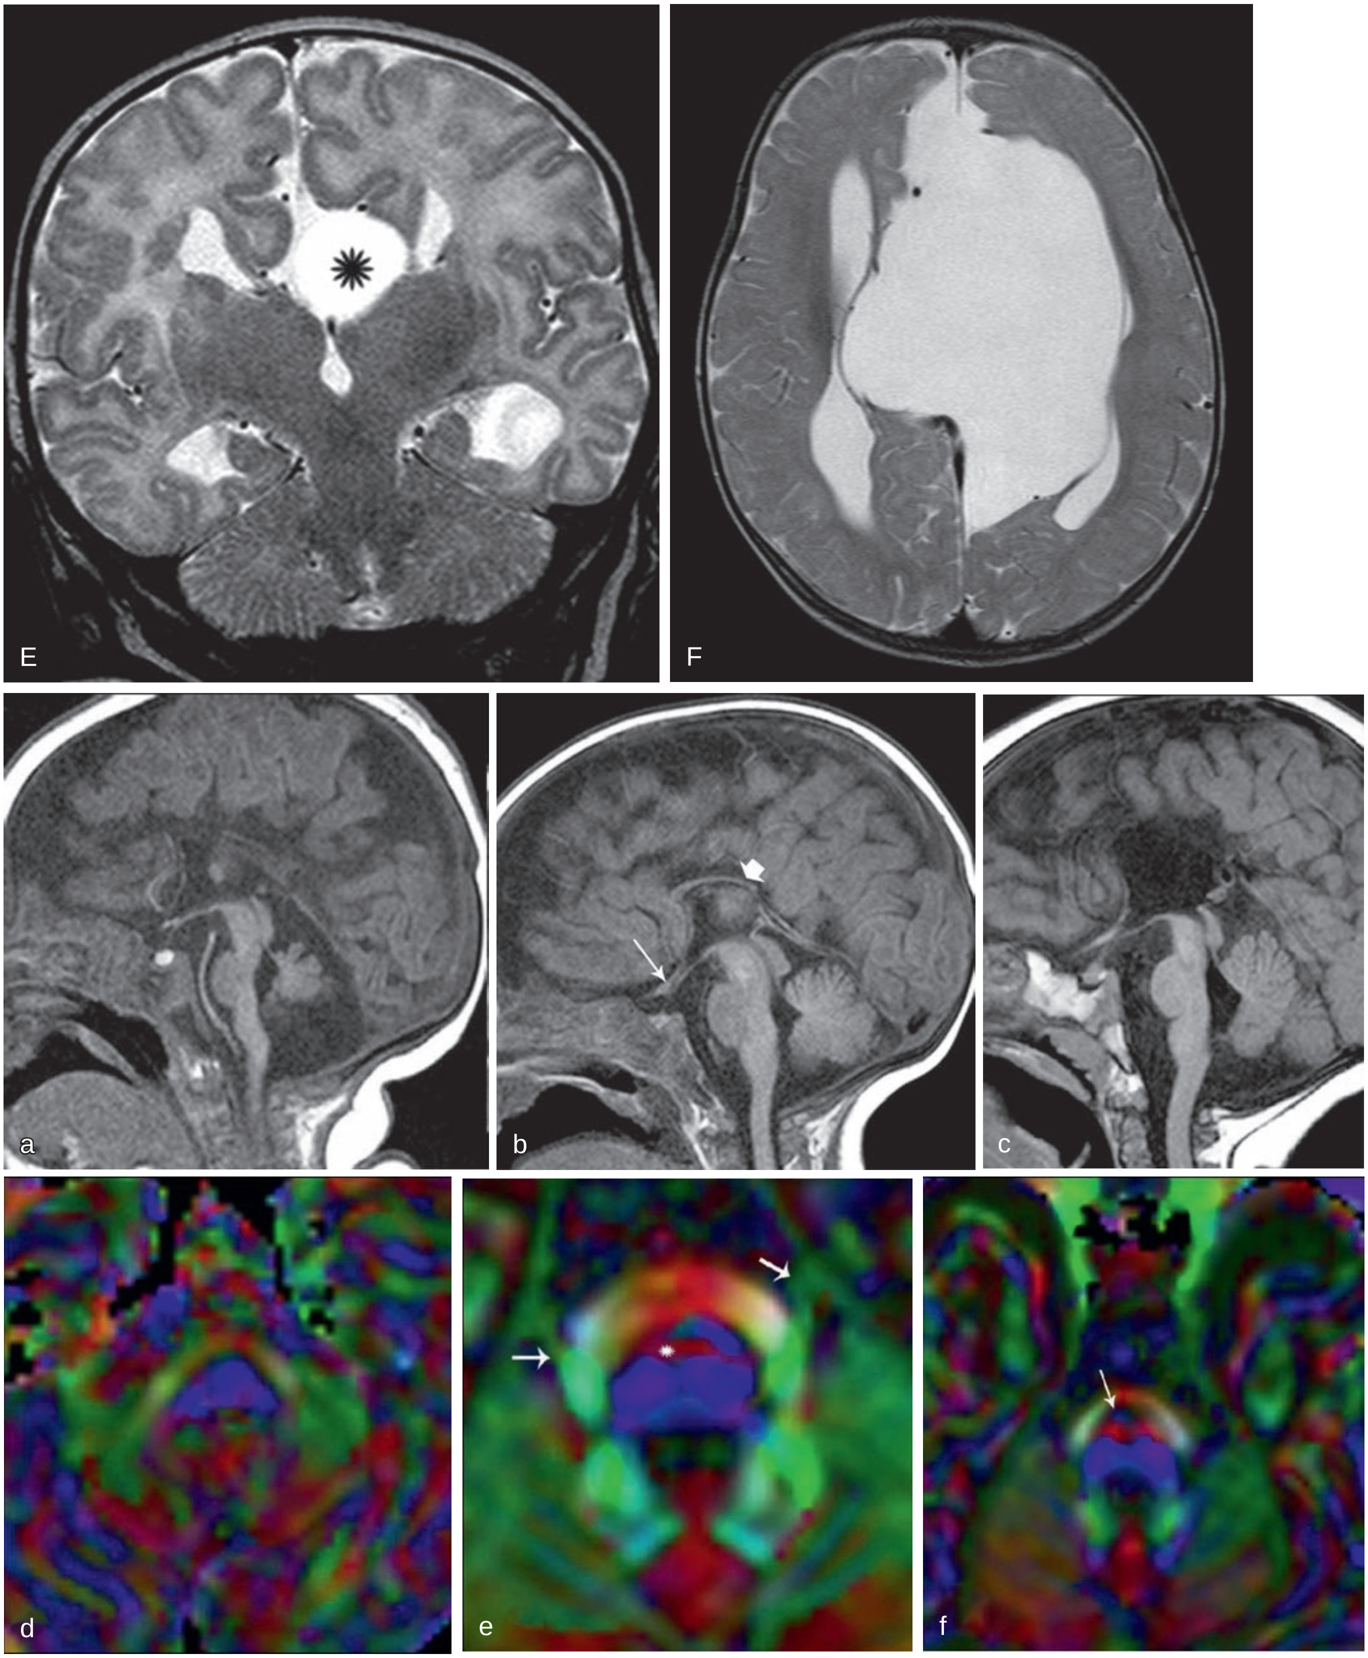
migration, and organization can result from infections (e.g., TORCH, Zika[39,40]), intrauterine ischemic insults, toxins, radiation exposure, genetic anomalies, and without known cause.[4] Affected patients have seizures, developmental delay, and variable focal neurologic deficits.

Based on advances in the understanding of cortical development, an updated classification has been proposed for MCD.[2]

- Group I: Malformations secondary to abnormal neuronal and glial proliferation or apoptosis, which includes microcephaly and diffuse megalencephalies, some forms of focal cortical dysplasia (FCD), and tuberous sclerosis complex.
- Group II: Malformations secondary to abnormal neuronal migration, which includes periventricular heterotopia, the various complete and incomplete lissencephalies, subcortical heterotopia, and the cobblestone lissencephalies.
- Group III: Malformations secondary to abnormal postmigrational development, which includes PMG, schizencephaly, some forms of FCD, and microcephaly.

## Microlissencephaly

***Clinical.*** Unlike lissencephaly, patients with microlissencephaly have severe microcephaly (<3 SD) at birth often with dysmorphic craniofacial features, abnormal genitalia, and arthrogryposis.[4] Developmental delay is pervasive and profound with accompanying epilepsy. Mode of inheritance is thought to be autosomal recessive, related in some patients to the *RELN* gene. Mutations in ACTG1, a cytoplasmic



**e-Figure 31.14.** (E) Coronal T2-weighted MR image shows a small interhemispheric cyst *(asterisk)* versus high-riding third ventricle. (F) Axial T2-weighted MR image shows a large interhemispheric cyst in ACC. Patient is developmentally normal. (G) Composite of pontine anomalies by DTI in ACC. a, d; pontocerebellar dysplasia with a single ventral pontocerebellar tract. b, e; persistent hippocampal commissure *(short arrow)* and optic pathway *(arrow)* hypoplasia, with hyperplastic ventral pontocerebellar tract, hypoplastic dorsal pontocerebellar tract *(asterisk)*, and dislocated hypoplastic corticospinal tracts. *Arrows* indicate Vth nerves. c, f; ACC with a single hypoplastic corticospinal tract *(arrow)*. Patients b and c had absent gag and respiratory drive.

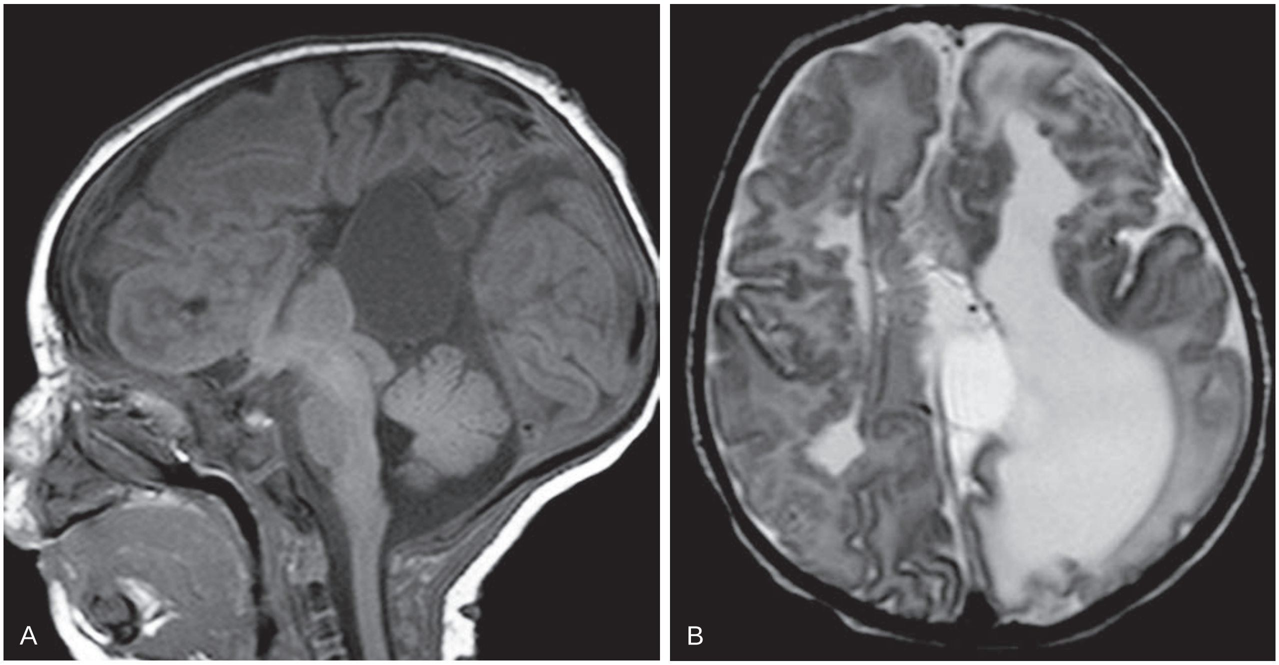


**Figure 31.15. Aicardi syndrome.** (A) Sagittal T1-weighted MR image shows callosal agenesis with an interhemispheric cyst. (B) Axial T2-weighted MR image shows extensive asymmetric cortical dysplasia, interhemispheric cyst, and asymmetric ventriculomegaly.

actin, are implicated in Baraitser-Winter syndrome characterized by microlissencephaly and distinctive facies in addition to congenital nonsyndromic neurosensory hearing loss.[40,41] Prenatal infections causing microlissencephaly include cytomegalovirus (CMV) and Zika.[42,43]

***Imaging.*** MRI shows diffuse cortical thinning with agyria-pachygyria and/or PMG (Fig. 31.20) and variable hypoplasia of the corpus callosum, brainstem, and cerebellum. Imaging abnormalities in congenital Zika infection include microlissencephaly with cortical-subcortical dystrophic calcifications, pachygyria and PMG, and ex vacuo ventriculomegaly often with cerebellar hypoplasia.[43] The calvarium is collapsed around the atrophic brain; there may be a prominent occipital ridge.[43]

## Focal Cortical Dysplasia (FCD)

***Clinical.*** FCD is probably caused by mutations in multiple genes but is not associated with a known single genetic mutation.[2,44,45] The histologic hallmark of FCD is lack of normal cortical lamination. FCD is classified into types I, II, and more recently type III, based on cortical laminar structure, cytoarchitectural disruption, cell composition, and the presence of associated destructive brain lesions.[44] Type I FCD has alterations in cortical layering, with distortion of the normal radial cortical lamination and lack of the normal six-layered neocortex, but by definition, type I FCD has no balloon cells. Type II FCD is characterized by cortical dyslamination and dysmorphic neurons without or with balloon cells and is considered a malformation resulting from abnormal proliferation.[2] Type III FCD is found in association with encephaloclastic lesions such as traumatic brain injury, perinatal ischemia, Rasmussen encephalitis, or low-grade tumors and is considered a malformation resulting from abnormal postmigrational development reflecting cortical injury during later stages of cortical development.[2,44] FCD presents as medication-resistant focal epilepsy and/or variable cognitive impairment.[44,45]

***Imaging.*** Even with high-resolution MRI and knowledge of the seizure semiology, FCD may not be detected. The most common histopathologic finding in surgical specimens removed for cryptogenic epilepsy (e.g., no lesion is identifiable by imaging) is type I FCD.[44] Findings of type I FCD include focal cortical thickening often within the depth of a sulcus and blurring of the gray–white junction. MRI of type II FCD may show focal thickening of cortex with regional subcortical increased signal on T2-weighted and FLAIR sequences viewed with using narrow tissue contrast windowing (Fig. 31.21). There may be radial extension of balloon cells and ectopic neurons into the deep white matter (e.g., "transmantle sign" of FCD), which may be the sole visible evidence of FCD.[44] The differential diagnosis of type II FCD is low-grade tumor. Although type II FCD can be suggested on the basis of MR findings, there is overlap in imaging findings between type I and II, and the ultimate diagnosis is based on histopathology.[44]

## Grey Matter Heterotopias

***Clinical.*** Grey matter heterotopias include periventricular nodular heterotopias (PNH), subcortical heterotopia, and subcortical band heterotopia. PNH results from mutations in the genes that code for proteins involved in neuronal migration including the *FLNA* gene on Xq28.[2,44,45] These nodular masses of normal neurons and glial cells devoid of laminar organization are intrinsically epileptogenic; seizures result from hyperexcitable circuitries between the ectopic neurons and the overlaying cortex and may not manifest until adolescence.[2,44–46] More severe and generalized seizure activity and cognitive delay are seen with bilateral PNH.

***Imaging.*** MRI of PNH shows variable-sized nodules in the subependymal periventricular white matter (Fig. 31.22) with the same signal intensity as cortex.

## Polymicrogyria

***Clinical.*** PMG results from disruption of normal terminal neuronal migration and organization and is defined by excessive convolutions of the cerebral cortex.[47–51] PMG is seen in conjunction with inborn errors of metabolism (e.g., cobblestone lissencephaly,

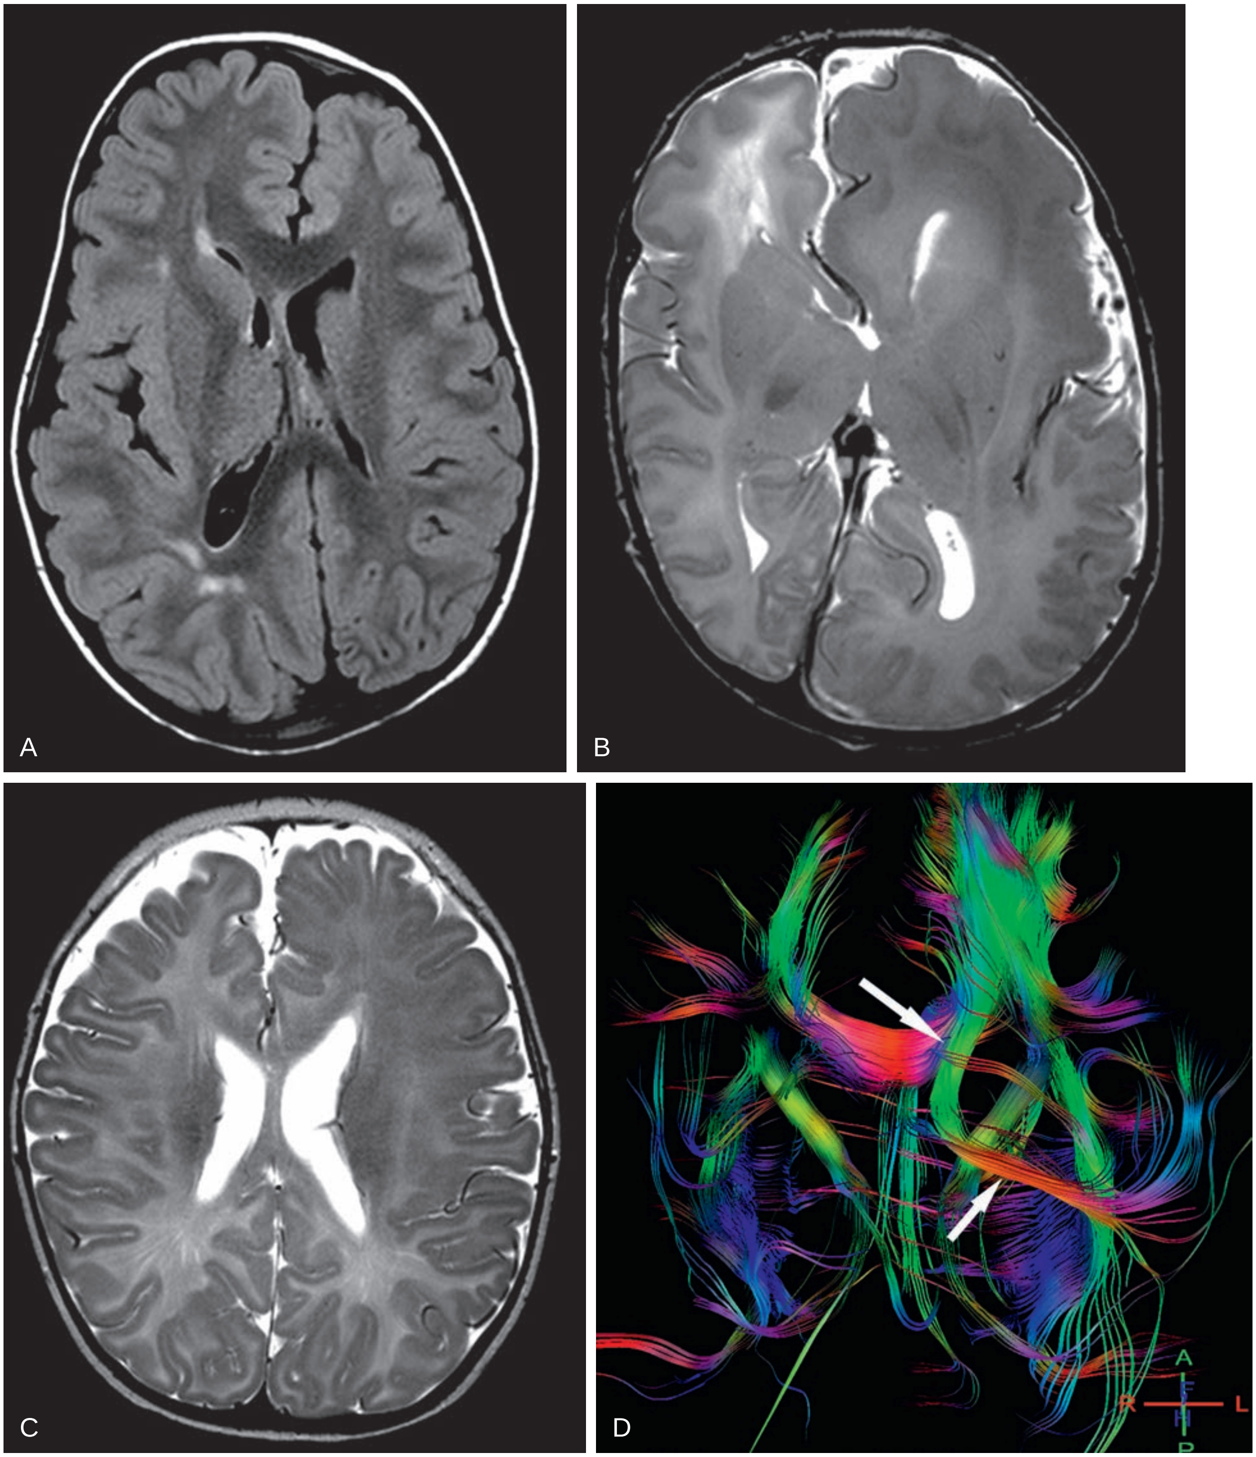

**Figure 31.18. Hemimegalencephaly.** (A) Axial FLAIR MR image shows an overgrown dysplastic right hemisphere with ipsilateral ventriculomegaly. The white matter is thickened and focally gliotic. (B) Axial T2-weighted MR image in another patient shows more striking hamartomatous overgrowth of the left hemisphere, particularly the frontal lobe. (C) Axial T2-weighted MR image in a neonate with intractable seizures shows subtle hamartomatous overgrowth of the left frontal pole. (D) DTI of patient in C shows anomalous white matter tracts *(arrows)*. The left frontal pole is composed of bands of grey and white matter that are in a highly parallel configuration, resulting in high anisotropy.

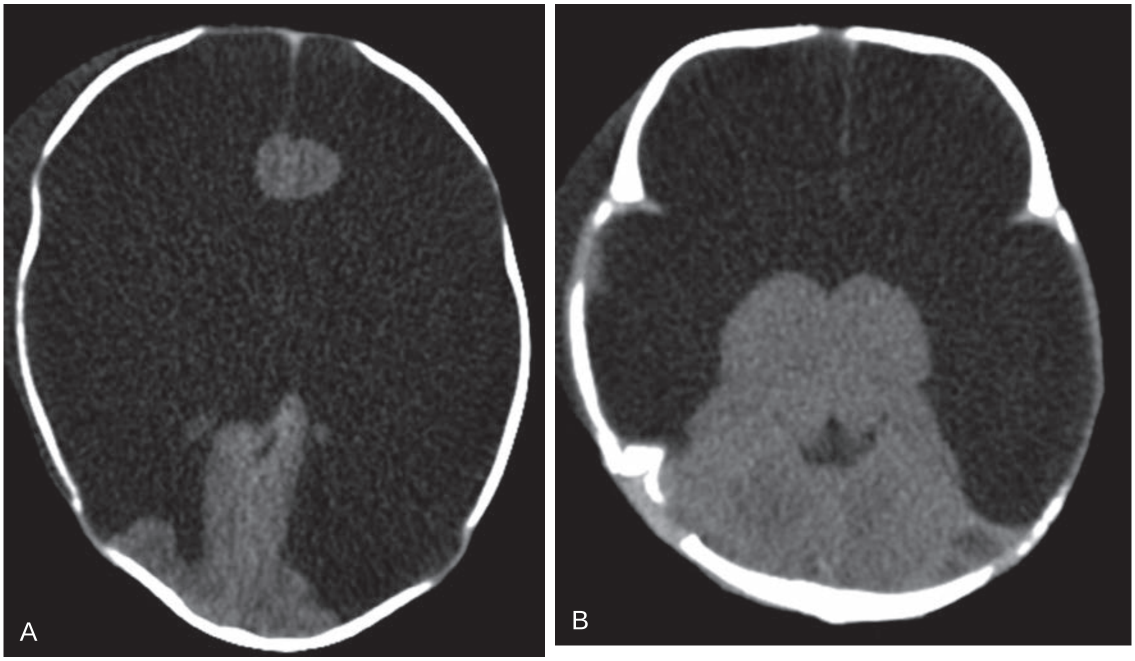

**Figure 31.19. Hydranencephaly.** (A) Axial CT image shows hydrocephalus with split sutures and absence of large portions of the cortical mantle. (B) The basal ganglia are compressed by the supratentorial ventriculomegaly.

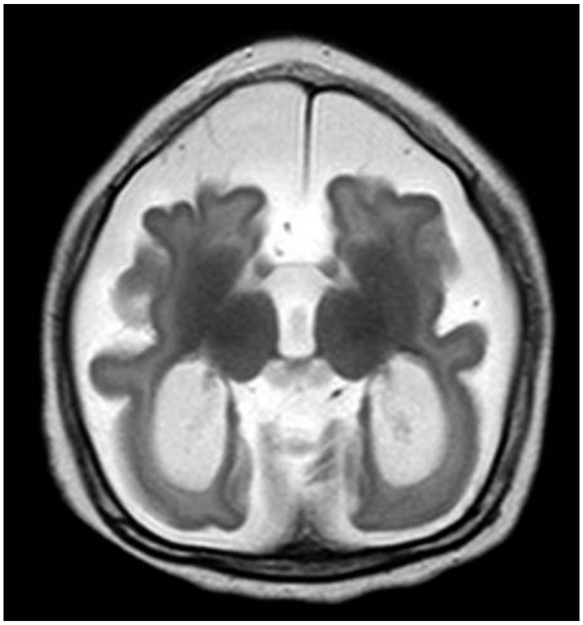

**Figure 31.20. Microlissencephaly.** Axial T2-weighted MR image shows that the brain is diffusely undersulcated with callosal agenesis and dilated ventricles.

Zellweger) and with multiple congenital anomalies, including schizencephaly, callosal agenesis, Aicardi syndrome, and Joubert syndrome and related disorders (JSRD).[2,47–51] PMG may also occur from CMV infection and intrauterine ischemic injury. Regardless of etiology, PMG is associated with thickened dysplastic overlaying leptomeninges.[43–44] The severity of seizures and developmental impairment correlates with the location and severity of the malformation. Focal PMG may be clinically occult or associated with seizures, often medically uncontrollable. Bilateral perisylvian PMG is associated with epilepsy, delayed development, strabismus, dysphagia and speech problems, and paresis.

***Imaging.*** MRI shows increased cortical thickness and irregularity at the cortical–white matter junction (Fig. 31.23). PMG may be focal, bilateral but asymmetric, or symmetric, most often bifrontal or biparietal; the pattern of the PMG appears to differ with location.[2,48] The appearance of the PMG may change with brain maturation, and PMG visible in the unmyelinated brain as T2 hypointensity may be less conspicuous as myelination progresses.

### Schizencephaly

***Clinical.*** Schizencephaly is a congenital cleft extending from the pial surface to the ventricles.[46] Affected patients may present with seizures and/or motor deficits or may be asymptomatic. Larger or bilateral defects are associated with poorer neurodevelopmental outcome.[4,52]

***Imaging.*** The lips of the defects may be in apposition (closed lip) or separated (open lip). The clefts are lined with dysplastic grey matter that extends the full length of the cleft. Discontinuity of the ventricular ependyma and the subpial membrane in open lip schizencephaly results in communication between the lateral ventricles and the subarachnoid space. The pulsations of the CSF may cause remodeling and outward expansion of the calvarium overlaying the open cleft (Fig. 31.24). The septum pellucidum is absent in most cases of schizencephaly involving the frontoparietal regions. Unilateral schizencephaly is often associated with contralateral peri-Sylvian PMG.[48] With open-lip defects, the corticospinal tract ipsilateral to the defect is hypoplastic by DTI.

## DIFFUSE MALFORMATIONS OF CORTICAL DEVELOPMENT

### Type I (Classic) Lissencephaly

Type 1 or classic lissencephaly (LIS1) is considered a malformation due to generalized abnormal transmantle migration,[2,53,54]

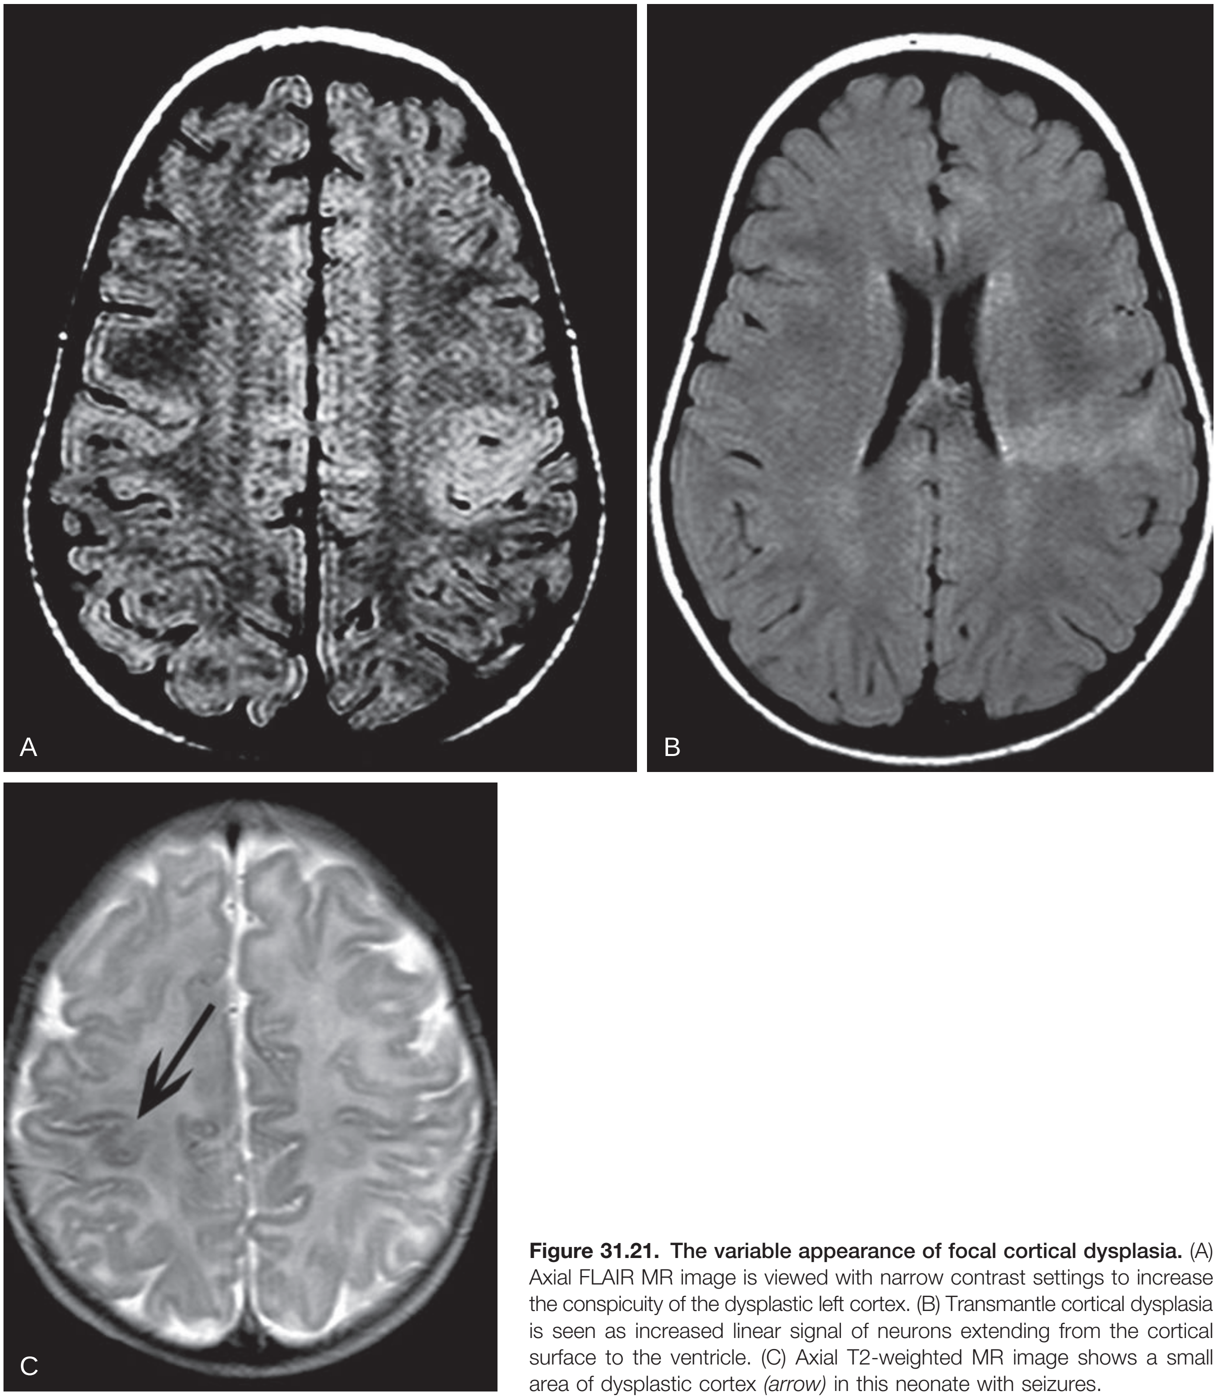

**Figure 31.21. The variable appearance of focal cortical dysplasia.** (A) Axial FLAIR MR image is viewed with narrow contrast settings to increase the conspicuity of the dysplastic left cortex. (B) Transmantle cortical dysplasia is seen as increased linear signal of neurons extending from the cortical surface to the ventricle. (C) Axial T2-weighted MR image shows a small area of dysplastic cortex *(arrow)* in this neonate with seizures.

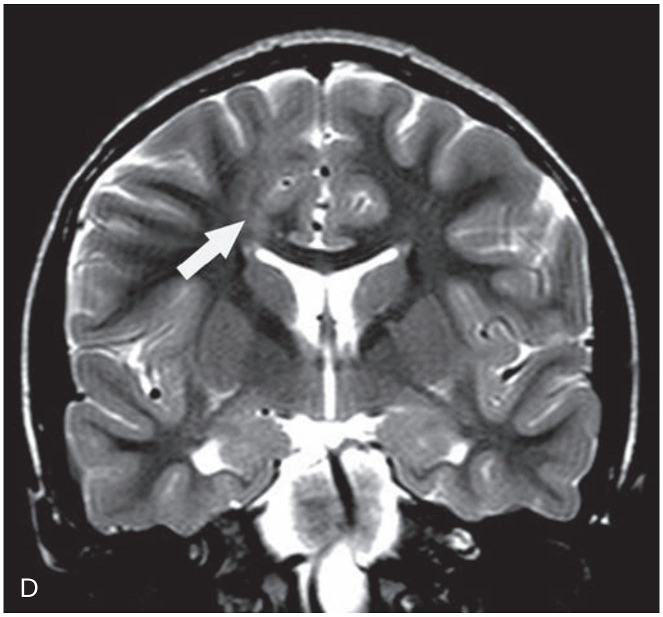
and the phenotype includes classic anterior, posterior, or diffuse LIS1 with and without known genetic causes, and agyria/pachygyria with and without cerebellar hypoplasia.[2,53,54] LIS1 occurs in 1/500,000 live births with gender predominance only in the less-common X-linked forms. The most common mutations in LIS1 occur in the *PAFAH1B1* (platelet-activating factor acetylhydrolase isoform 1b regulatory subunit 1) of 17p13.3 (LIS1 gene), Xq22.3–q23 DCS, and in tubulinopathies such as *TUBA1A*, *TUBB2B*, and *TUBB3*.[56–58] *PAFAH1B1* is integral to neuronal division and migration by coupling the nucleus to centrosomes. The tubulinopathies disrupt centrosome and nuclear movement and the integrity of the microtubules, growth cones, filaments, and other components of the cytoskeleton required for normal migration of cerebral, precerebellar, and cerebellar neurons, which also affect axonal path finding and migration.[39,54]

Histopathology of LIS1 shows inversion of cortical laminar architecture; the normal six-layered cortex is replaced with a two-, three-, or four-layered cortex.[48] The four layers include a superficial molecular layer, layer II of pyramidal cells resembling the fifth and sixth layers of the normal neocortex, followed by a sparse cellular layer (layer III), and a thick band of disorganized neurons



**e-Figure 31.21.** (D) Coronal T2-weighted MR image shows transmantle cortical dysplasia *(arrow)*.

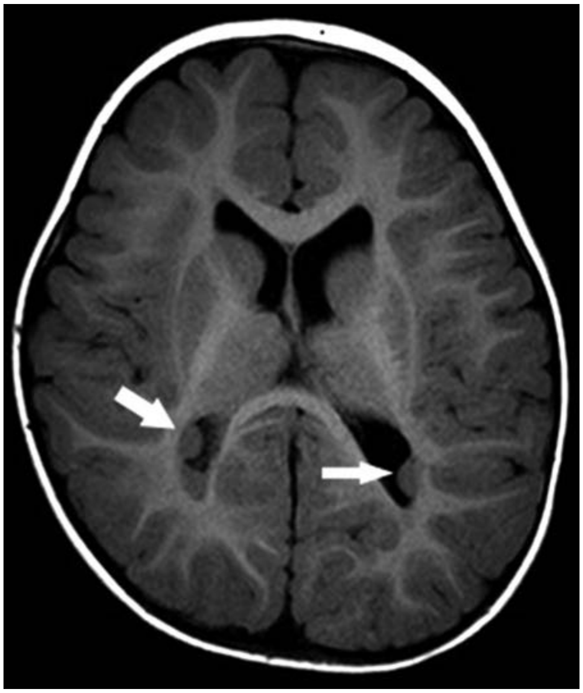


**Figure 31.22. Grey matter heterotopia.** Axial T1-weighted MR image shows variable-sized nodules of grey matter along the surface of the ventricle *(arrows)*.

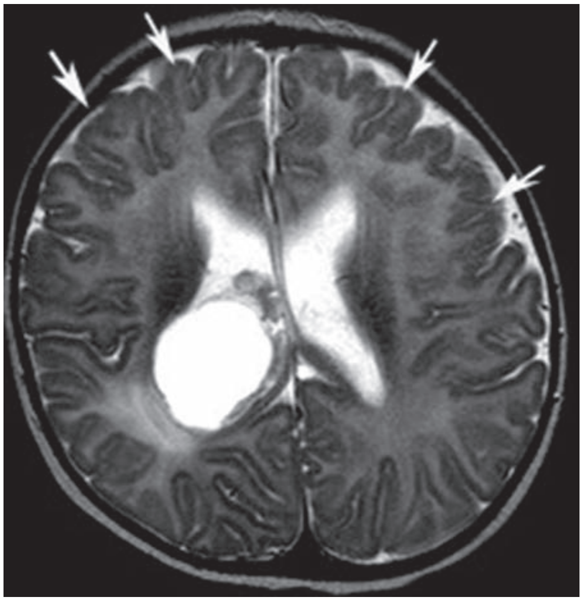

**Figure 31.23. Polymicrogyria.** Axial T2-weighted MR image shows bifrontal polymicrogyria *(arrows)* and large intraventricular cyst.

of variable size (layer IV), which extends into the regional white matter.[48]

***Clinical.*** The hallmarks of LIS1 are profound mental retardation with a normal to small head size, intractable seizures, hypertonia, and hyperreflexia. LIS is classified according to brain and extra-CNS anomalies.[2,4] Patients with Miller-Dieker syndrome have LIS1 and abnormal facies. Males with the X-linked *DCX* mutation have classic LIS1 by MRI, whereas females will have variable cognitive delay and subcortical band heterotopias (SBH) by MRI without seizures. The presence of an unexplained seizure disorder or cognitive problems in the mother of a male child with lissencephaly should trigger a screening MRI of the mother for possible SBH. Females with the *ARX* mutation have ambiguous genitalia without lissencephaly; males have lissencephaly with ambiguous genitalia (XLAG) syndrome. Lissencephaly due to the *RELN* mutation is associated with congenital lymphedema.

***Imaging.*** The most severe LIS1 is diffuse agyria with no gradient in severity from anterior to posterior.[2,4] There may be posterior predominant agyria with variable frontal pachygyria; posterior predominant pachygyria, or SBH.[48] DTI of classic LIS1 shows a highly organized laminated pattern reflecting the persistent radial pattern of the neurons arrested during migration (Fig. 31.25). The lissencephalic pattern in males with the sex-linked *DCX* mutation is similar to L1S1 but more severe anteriorly. Females with the *DCX* mutation have SBH (e.g., the "double cortex"[2,4]) with bands of heterotopic neurons embedded in white matter between normal appearing cortex and the ventricles. *TUBA1A* LIS is posterior predominant with variable cerebellar and callosal hypoplasia, dysplastic basal ganglia, and ventriculomegaly.[57]

The severe supratentorial malformation in LIS1 overshadows the infratentorial anomalies. The severity of the lissencephaly is reflected by the degree of brainstem hypoplasia on MRI.[58] DTI shows derangement of pontine fibers in LIS1, which does not appear to correlate with the severity of the LIS or the brainstem hypoplasia.[59]

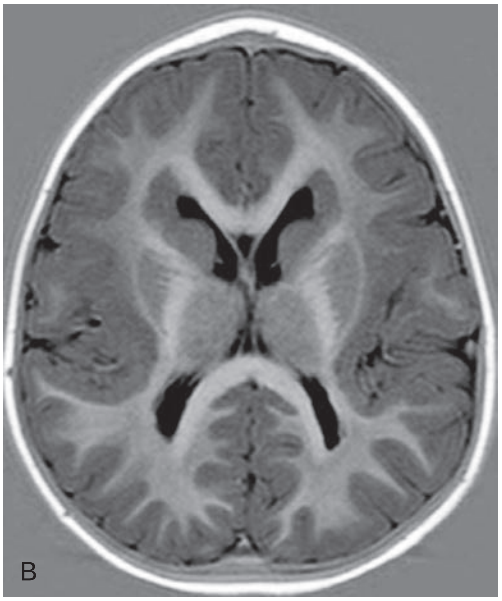
The other tubulinopathies have marked phenotypic variability including congenital fibrosis of the extraocular muscles type 3 (CFEOM3), MCD including PMG, gyral disorganization, fusion of the basal ganglia with thin corpus callosum, hypoplastic brainstem and corticospinal tracts (e-Fig. 31.26), and dysplastic cerebellar vermis.[56,57]

## Type II Cobblestone Lissencephaly

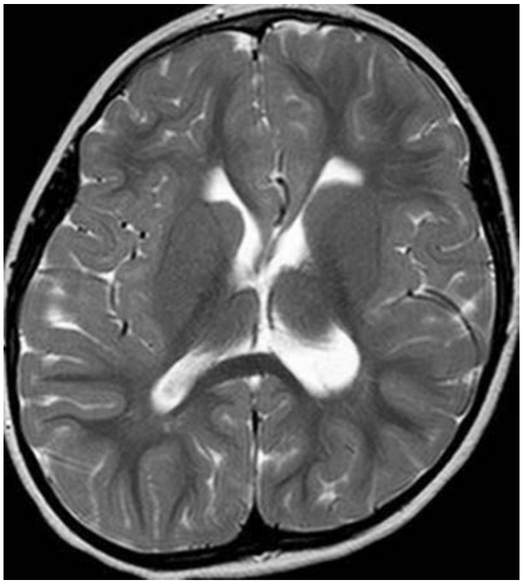
Cobblestone lissencephaly reflects abnormal glycosylation of α-dystroglycan due to *DAG* gene mutations.[2,39,51,60] The nodular surface of the brain reflects the structural defects in the glial-pial limiting membrane that normally prevent migrating neurons from traversing the pial surface and accumulating on the surface of the brain. There is variable pachygyria and PMG with thickened cortex lacking the normal six-layered cortex, fibroglial proliferation of the leptomeninges, and focal interhemispheric fusion.

***Clinical.*** *DAG* is also expressed in skeletal muscle and the eye. The clinical presentation of the cobblestone lissencephalies is congenital muscular dystrophy (CMD), which is a heterogeneous group of inherited disorders presenting with diffuse symmetric hypotonia at birth or in infancy.[2,39,51,60] CMD is categorized as CMD without and with CNS abnormalities; the latter includes Fukuyama congenital muscular dystrophy (FCMD), muscle-eye-brain disease (MEBD), and Walker-Warburg syndrome (WWS).[2] Depending on the specific syndrome, affected patients also have psychomotor retardation, seizures, micropthalmia, optic nerve hypoplasia, and colobomas. Scoliosis and contractures develop during early childhood. Death is often respiratory due to chest wall rigidity and weakness of the diaphragm or aspiration, or from cardiomyopathy. The specific diagnosis is made based on clinical findings, serum creatine kinase, neuroimaging, muscle and/or skin biopsy, and molecular genetic testing.[60]

Fukuyama CMD is an autosomal recessive disorder most common in Japan, where the incidence approaches 3/100,000 individuals.[60] The syndrome results from mutations in the *FKTN* gene on chromosome 9, which codes for the protein fukutin that interacts with α-dystroglycan in the extracellular matrix. MEBD is an autosomal recessive disorder rare outside of Finland caused by mutations in the *POMT1*, *POMT2*, *POMGnT1*, *fukutin*, and *FKRP* genes; phenotypes may overlap with FCMD. WWS is the



**e-Figure 31.23.** (B) Axial T1-weighted image shows bifrontal polymicrogyria and periventricular grey matter heterotopia.



**e-Figure 31.26.** The tubulinopathies can result in phenotypes identical to LIS1. There is phenotypic heterogeneity. This patient with a TUBB3 mutation has dysmorphic basal ganglia, asymmetric ventriculomegaly, and gyral disorganization.

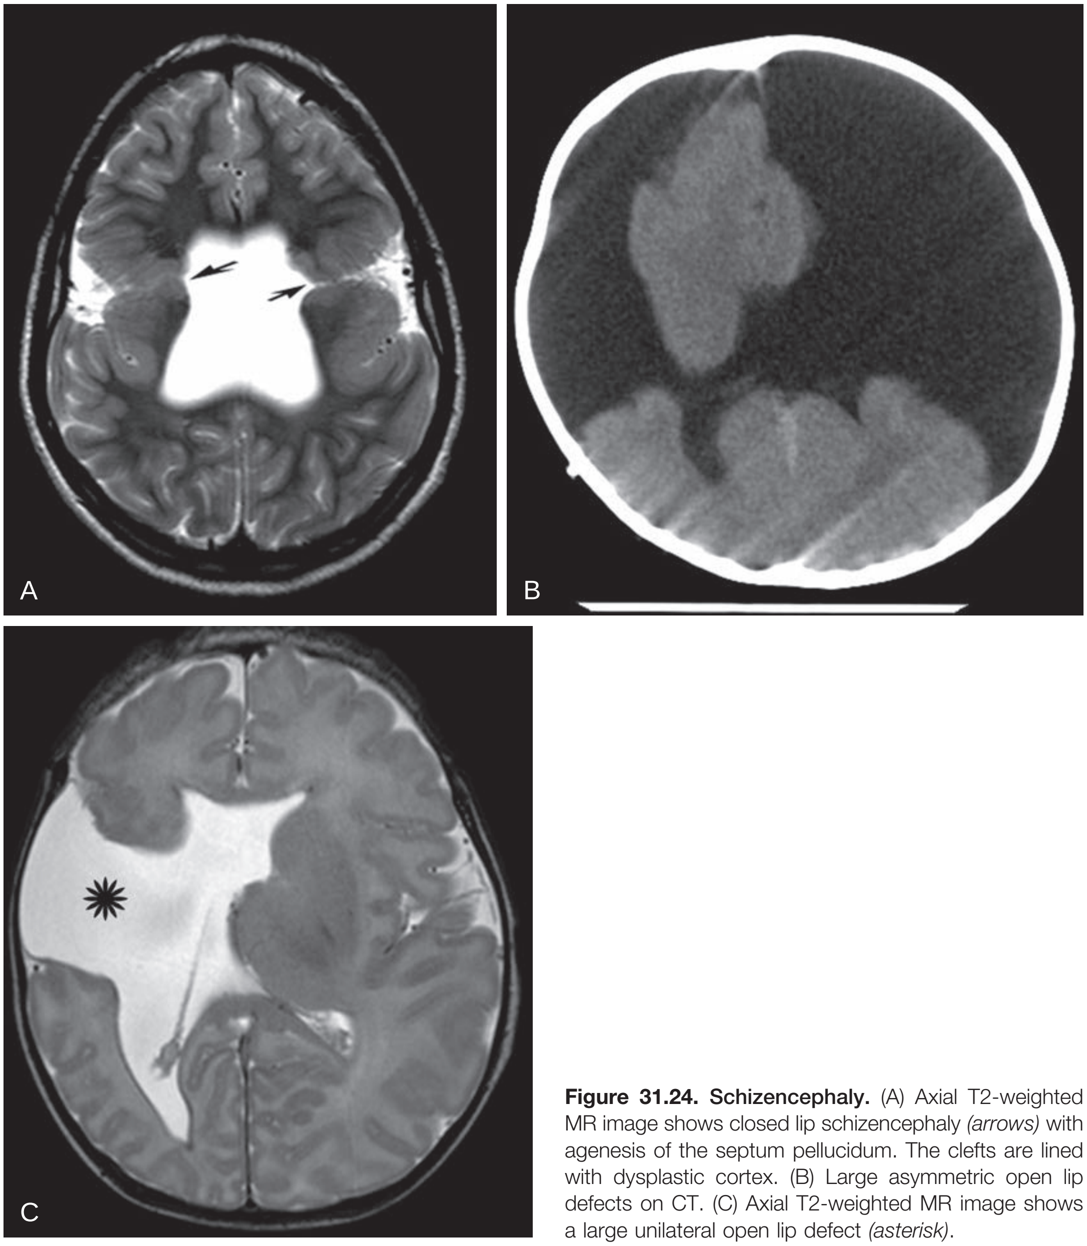


**Figure 31.24. Schizencephaly.** (A) Axial T2-weighted MR image shows closed lip schizencephaly *(arrows)* with agenesis of the septum pellucidum. The clefts are lined with dysplastic cortex. (B) Large asymmetric open lip defects on CT. (C) Axial T2-weighted MR image shows a large unilateral open lip defect *(asterisk)*.

most severe form of CMD with CNS manifestations and is also associated with mutations in the *POMT1*, *POMT2*, *fukutin*, and fukutin-related protein genes.[2,60]

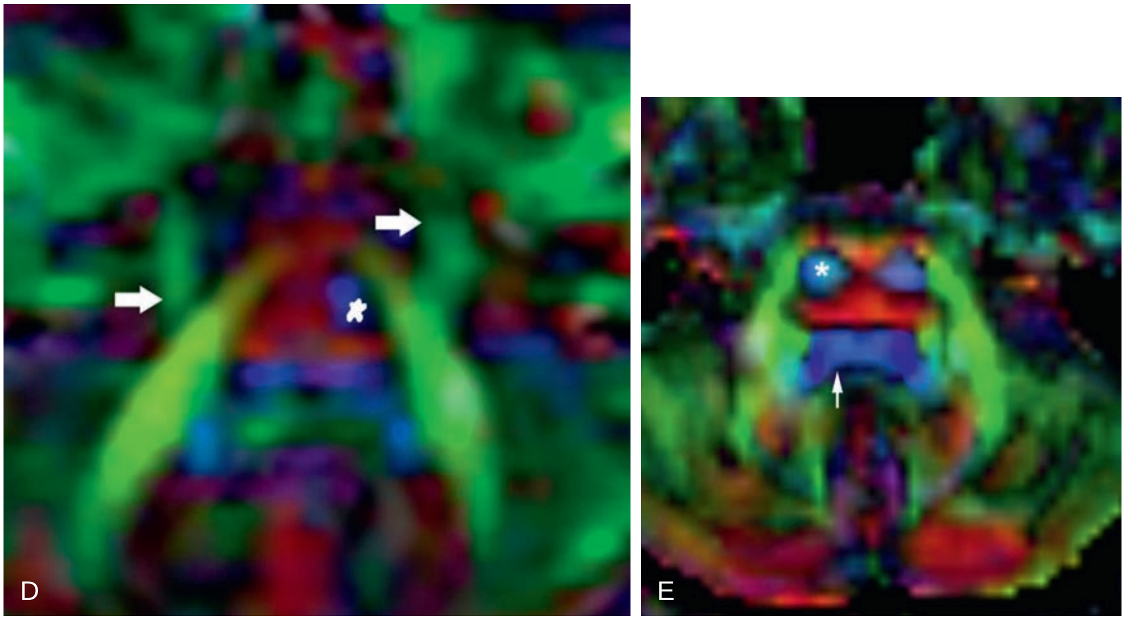
***Imaging.*** The MR abnormalities are less severe in FCMD than in WWS and MEBD.[2,4,60] In mild cases of FCMD, the cerebrum may be relatively normal or have a simplified gyral pattern. More severe malformations have variable pachygyria and PMG; the white matter is gliotic with cysts. Neurons may be seen lining the ependymal surface of the ventricle, contrasted on T2-weighted images by hyperintense signal of the CSF and the abnormal white matter (Fig. 31.27). The lateral ventricles are enlarged. The cerebellum consistently shows small cysts with variable PMG. The most severe cerebellar hypoplasia is seen with WWS, which is also associated with occipital encephalocele (Fig. 31.28). The brainstem is usually normal in FCMD, hypoplastic in MEBD, and small and kinked posteriorly in WWS. Hydrocephalus is rare in FCMD, common in MEBD, and almost invariable in WWS; the hydrocephalus may mask the malformation.

## HINDBRAIN AND CEREBELLAR MALFORMATIONS

### Brainstem Malformations

The embryonic hindbrain is transiently divided into distinct segments or rhombomeres (r1-8), giving rise to rhombomeric-specific neurons and physiologic regulatory circuits.[61,62] The pontine nuclei are populated by mossy fibers that arise from the rhombic lip of the hindbrain and traverse the pons tangentially along the subpial surfaces of the developing brainstem changing migration from tangential to radial at the site where precerebellar nuclei develop.[63] The pontine nuclei are the primary targets for the corticopontine tracts, most of which of cross the midline in the basal pons, terminating in the contralateral cerebellar hemisphere.

A malformed brainstem may occur as a relatively localized developmental defect or in conjunction with and overshadowed by cerebral malformations.[61,62] Localized malformations affecting



**e-Figure 31.24.** (D) DTI of the pons from patient in C shows severe hypoplasia of the corticospinal tract ipsilateral to the schizencephaly. Note normal contralateral corticospinal tract *(asterisk)*. *Arrows* indicates the fifth cranial nerves. (E) DTI of normal pons. Asterisk *(asterisk)* denotes the normal corticospinal tract, and the *arrow* indicates the dorsal column medial lemniscus complex.

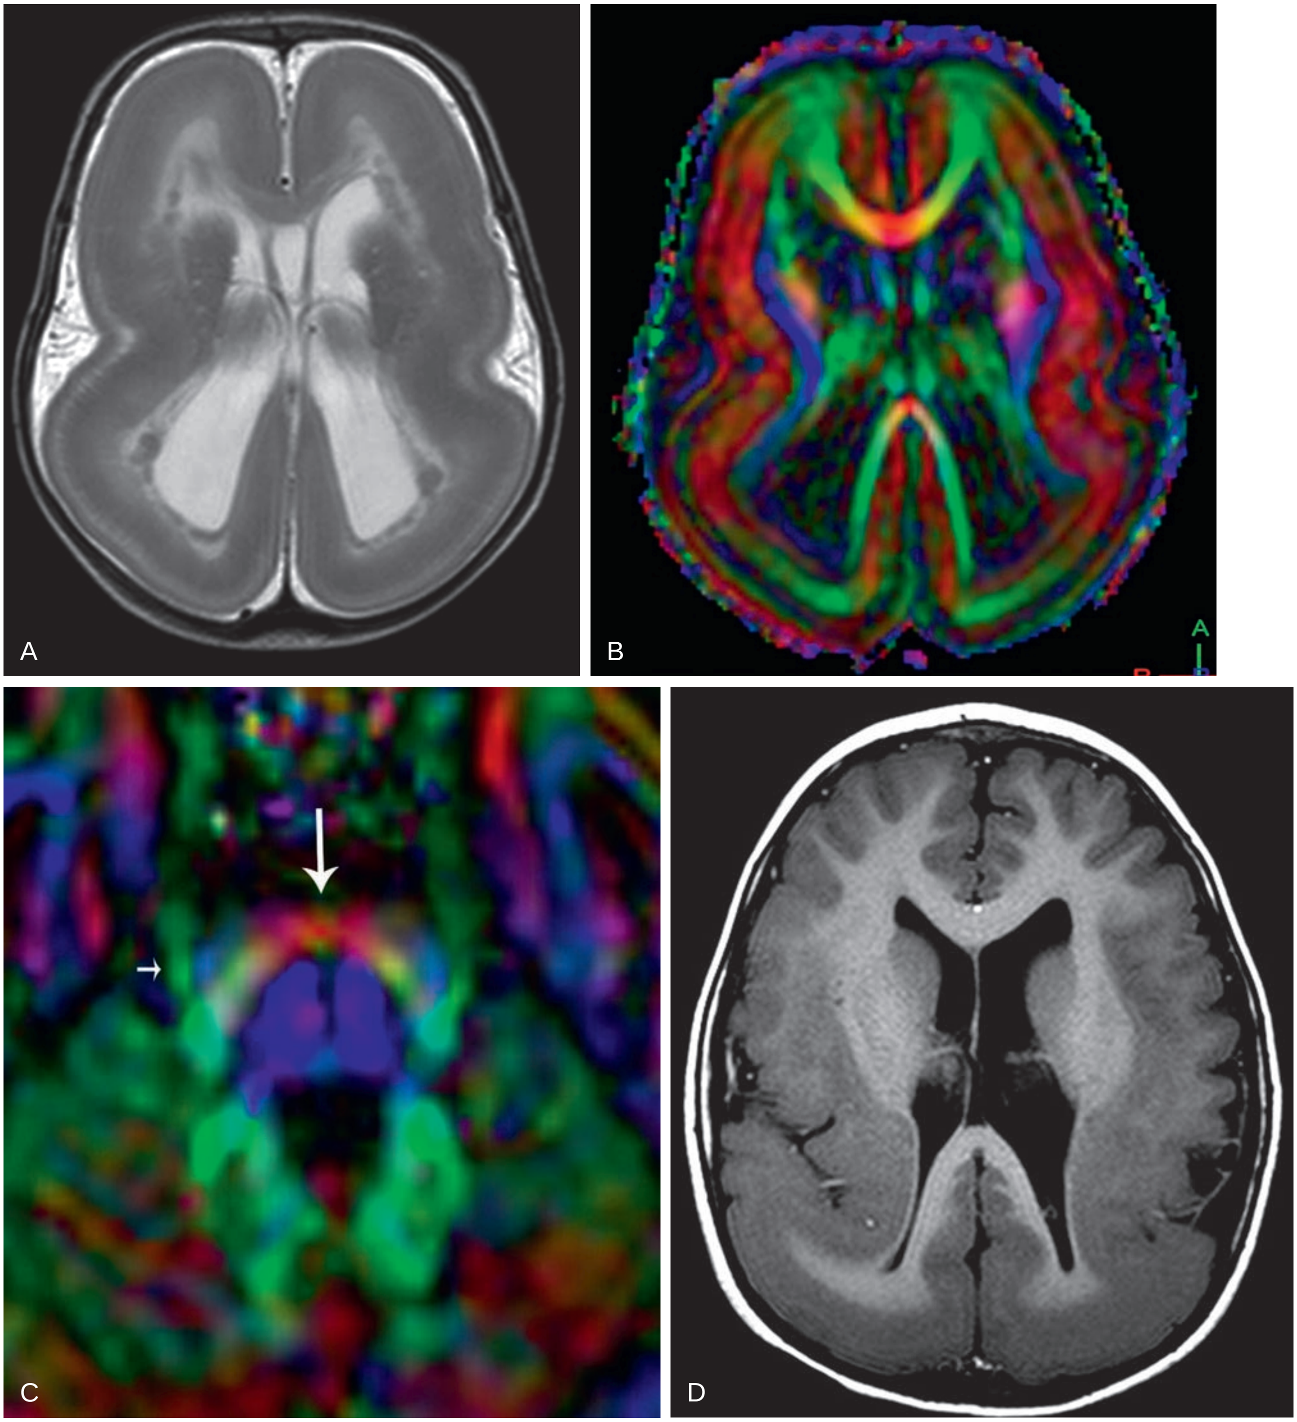


**Figure 31.25. Lissencephaly type I.** (A) Axial t2 MR image showed complete agyria. The brain is smooth with bands of arrested neurons imbedded in the hemispheres. There are subependymal grey matter heteropias. (B) DTI shows the bands of grey matter *(arrows)* in arrested migration. (C) Axial DTI through pons from the patient illustrated in A and B. There is a single red band of pontine fibers *(arrow)* instead of the 2 red bands seen in the normal pons (compare to e-Fig 31.24c). Small arrow indicates the Vth cranial nerve. (D) Axial T1 image in another patient shows posterior predominant agyria.

*Continued*

the brainstem and cerebellum are uncommon, characterized by deficient or defective formation of cranial nerve nuclei resulting in problems with ocular movement and lid control, facial palsy, and/or neurosensory hearing loss. Conventional MR imaging is useful in the diagnosis of brainstem malformations in which brainstem surface morphology and size are affected, although DTI provides more information about white matter tracts and may show absence or hypoplasia of dorsal pontocerebellar tracts.[59] The Chiari I malformation is included here for convenience, although it is not considered a true brainstem malformation.

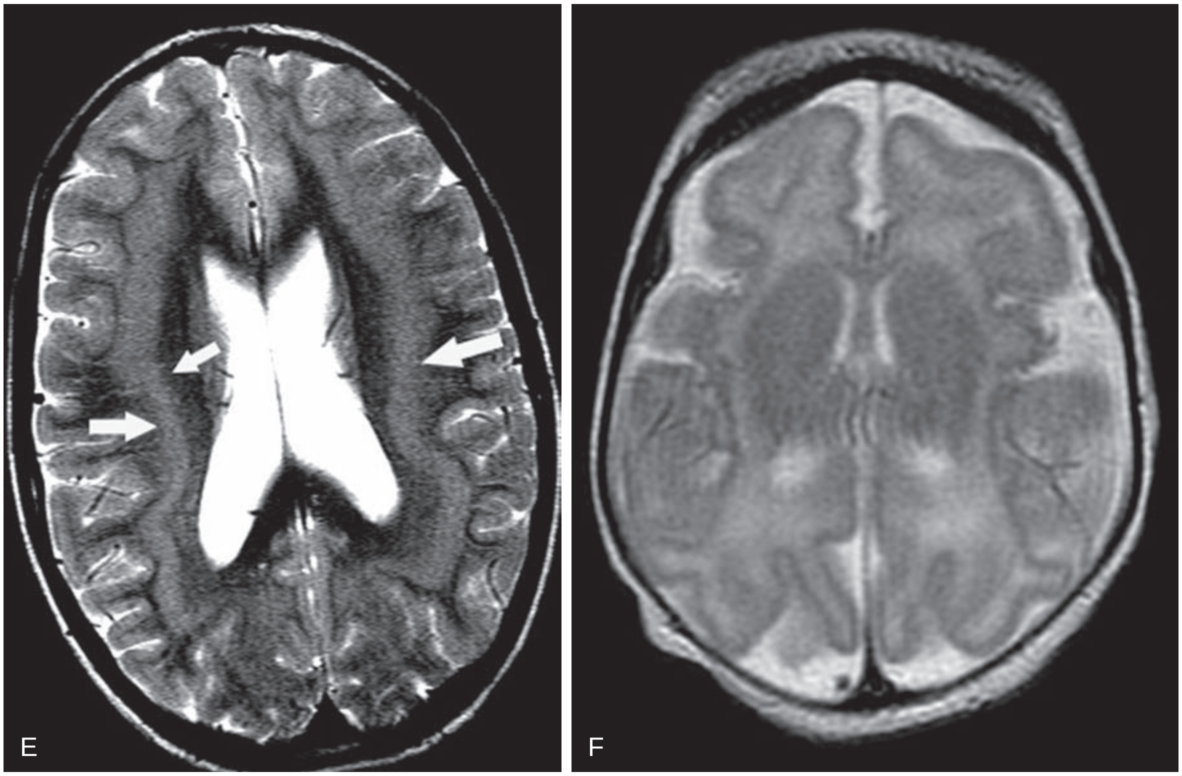

**Figure 31.25, cont'd.** (E) Axial T2-weighted image shows subocrtical band heterotopia. Bands of grey matter arrested during radial ventriculofugal migration are imbedded in the deep white matter. (F) Axial T2-weighted image shows diffuse pachygyria.

## Molar Tooth Syndrome (Joubert Syndrome and Related Disorders)

***Clinical.*** JSRD-causing mutations are usually autosomal recessive and involve one of multiple genes involved in the nonmotile cilia integral to neuronal and axonal migration. The clinical syndrome is markedly diverse and characterized by hypotonia; episodic hypo- and hyperventilation, which tend to improve with age; truncal ataxia that develops during early childhood; oculomotor apraxia; nystagmus; pigmentary retinopathy; endocrinopathies; and abnormal facial features, which include ptosis, hypertelorism, and low-set ears.[64] There may be hepatic and/or kidney dysfunction reflecting the extra CNS role of nonmotile cilia.

***Imaging.*** MR findings include variable hypoplasia of the superior vermis with enlargement of the superior aspect of the fourth ventricle and elevation of the fastigium. The superior cerebellar peduncles are thickened and elevated, forming the "molar tooth" seen in the axial plane at the pontomesencephalic junction.[4,64,65] DTI of Joubert syndrome shows consistent absence of both the decussation of the superior cerebellar peduncle within the midbrain (e.g., the "red dot") and the pyramidal tracts in the medulla with variable anomalies of pontocerebellar fibers (Fig. 31.29).[65–67]

## Horizontal Gaze Palsy With Progression Scoliosis

***Clinical.*** Horizontal gaze palsy with progression scoliosis (HGPPS) is the expression of mutation of the *ROBO3* gene, which codes for proteins involved in axonal guidance and neuronal migration.[61,62] Expression of the defective gene appears to be limited to decussating fibers in the brainstem. Patients with HGPPS tend to be cognitively normal but have congenital nystagmus and are unable to perform lateral eye movements due to lack of decussating fibers in the brainstem. Progressive scoliosis develops during early childhood.

***Imaging.*** MRI shows pontine hypoplasia with a dorsal midsagittal cleft.[66,67] The facial colliculi are absent, the inferior olivary nuclei prominent, and the medulla lacks the normal dorsal convexities formed by the gracile and cuneate nuclei (Fig. 31.30). DTI of HGPPS shows hypoplasia of the ventral transverse pontine fibers and absence of the dorsal transverse pontine fibers with small middle cerebellar peduncles, and small superior cerebellar peduncles with absent decussating fibers within the midbrain.[66,67]

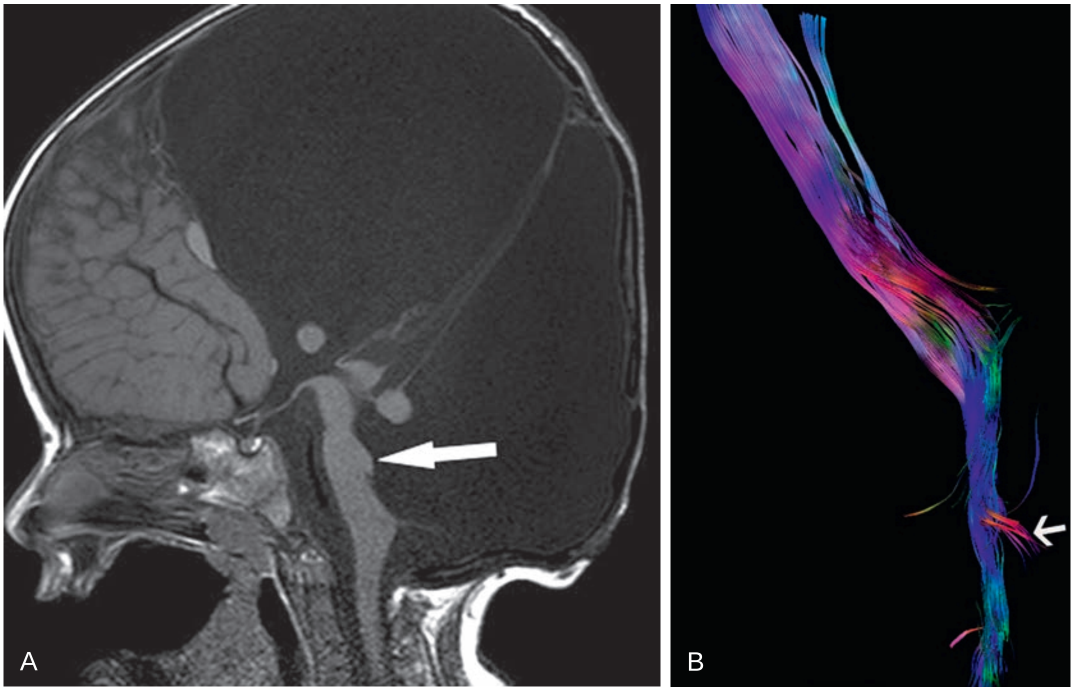
## Pontine Tegmental Cap Dysplasia

***Clinical.*** Pontine tegmental cap dysplasia is a rare brainstem malformation associated with variable developmental delay, ataxia, and restricted horizontal gaze, failure initiating fast eye movements, facial weakness, deafness, and swallowing problems, which reflect deficient lower cranial nerves.[68]

***Imaging.*** MRI shows pontine hypoplastic; the ventral surface is flattened and there is ectopic tissue protruding dorsally into the fourth ventricle referred to as the *tegmental cap*. The superior cerebellar vermis is hypoplastic, which along with the elongated and laterally misplaced superior cerebellar peduncle results in a molar-tooth-like deformity. By DTI, the tegmental cap is transversely oriented ectopic pontine fibers (e-Fig. 31.31). DTI shows absence of the normal decussations of the superior and middle cerebellar peduncles.[66–68]

## Brainstem Disconnection Syndrome

***Clinical.*** This is a rare and usually lethal malformation for which no gene mutations have been identified; intrauterine ischemia has been postulated as etiology.[61,62]



**e-Figure 31.31. Pontine tegmental cap dysplasia.** (A) The pons is severely hypoplastic with a dorsal cap *(arrow)*. There is hydrocephalus and a Dandy-Walker malformation; rare in this entity. (B) DTI shows absence of crossing brainstem fibers with the exception of a transverse band of dorsal fibers corresponding to the cap *(arrow)*.

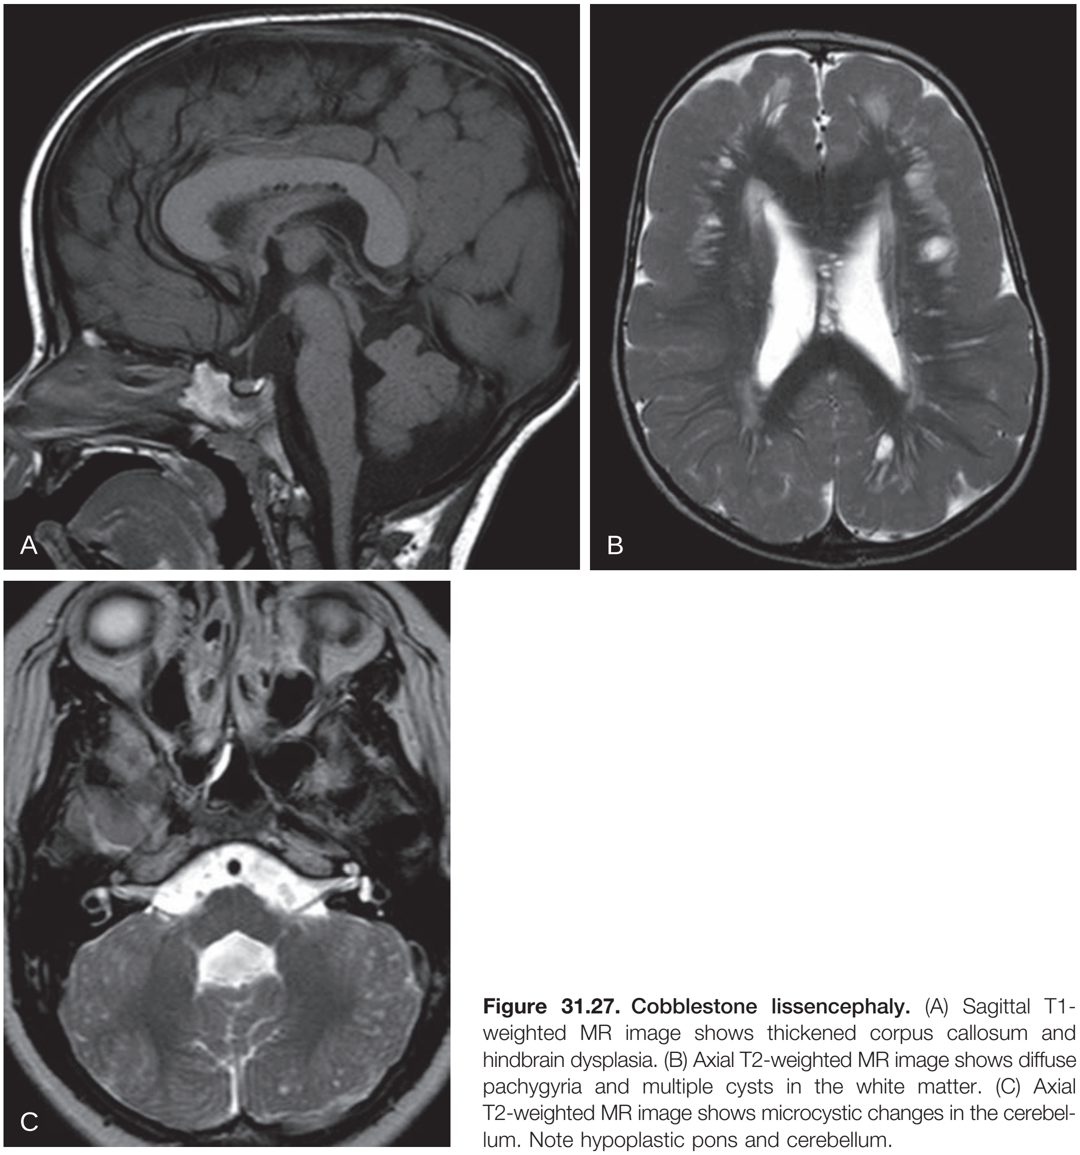


**Figure 31.27. Cobblestone lissencephaly.** (A) Sagittal T1-weighted MR image shows thickened corpus callosum and hindbrain dysplasia. (B) Axial T2-weighted MR image shows diffuse pachygyria and multiple cysts in the white matter. (C) Axial T2-weighted MR image shows microcystic changes in the cerebellum. Note hypoplastic pons and cerebellum.

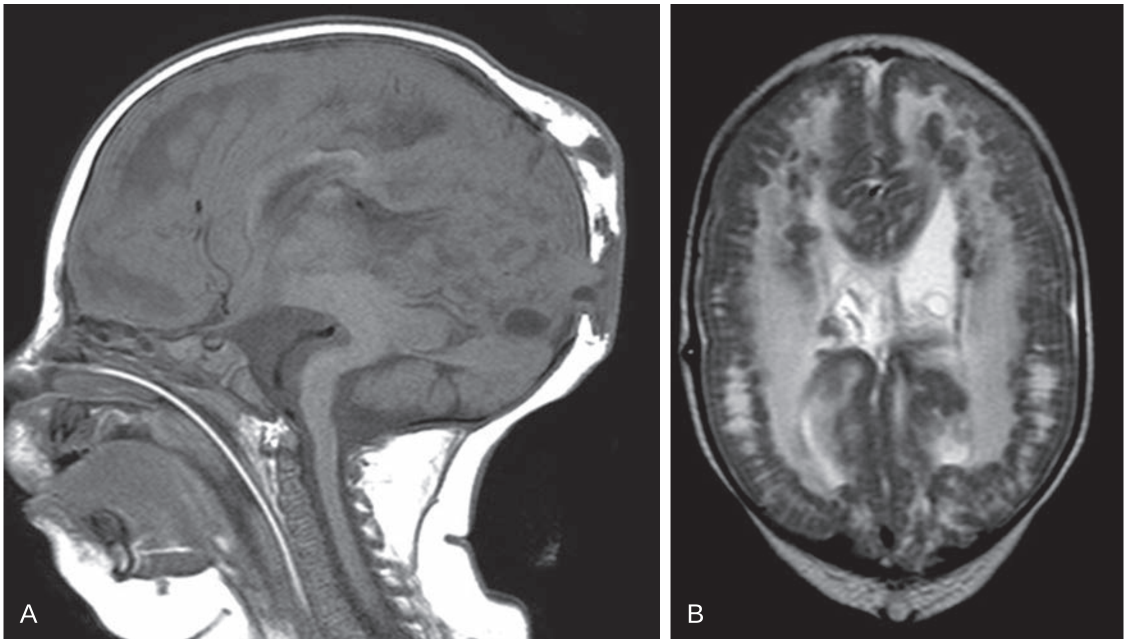

**Figure 31.28. Walker-Warburg type II cobblestone lissencephaly.** (A) Sagittal T1-weighted MR image shows "Z-shaped" configuration to the brainstem. There is severe cortical dysplasia. Note multiple atretic parieto-occipital encephaloceles. (B) Axial T2-weighted MR image shows severe hemispheric dysplasia with microcysts and grey matter heterotopias within the deep white matter.

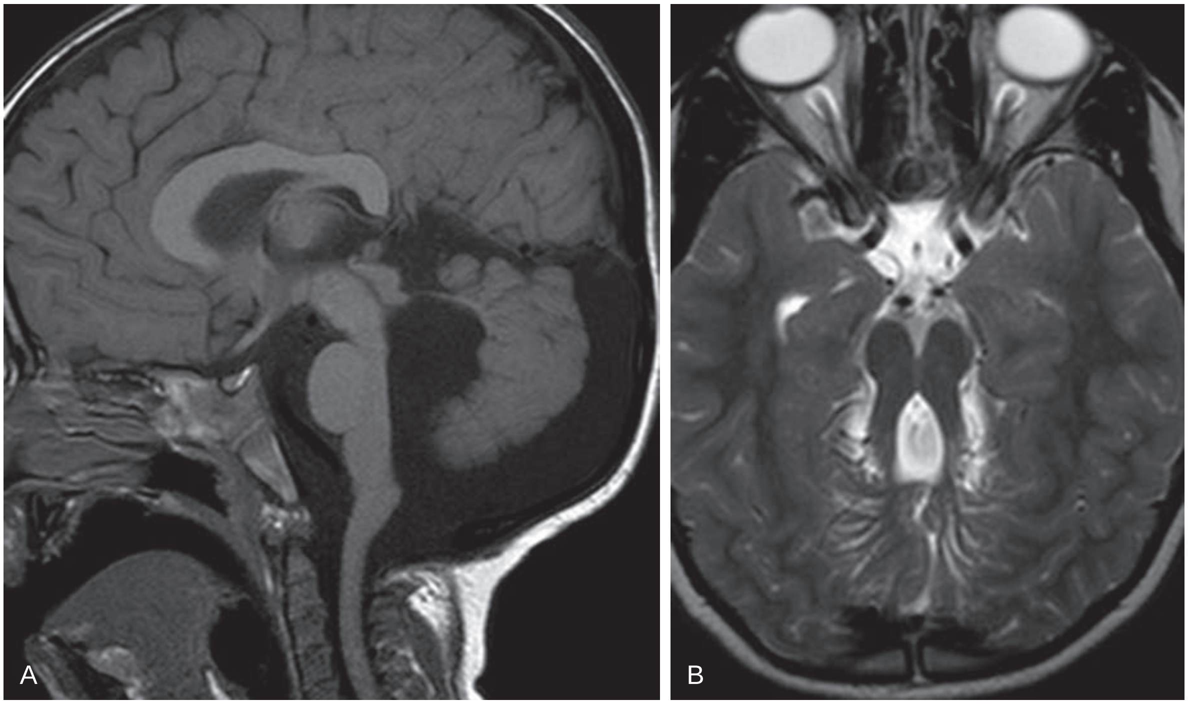

**Figure 31.29. Molar tooth syndrome.** (A) Sagittal T1-weighted MR image shows hypoplasia of the superior cerebellar vermis with upward bowing of the roof of the fourth ventricle. (B) Axial T2-weighted image shows the molar tooth at the level of the midbrain, the hallmark of Joubert syndrome and related disorders (JSRD).

***Imaging.*** MRI shows a severely constricted hindbrain with cerebellar dysplasia; the basilar artery is absent (e-Fig. 31.32). The clivus may be dysplastic. There are usually no supratentorial anomalies.

## Chiari I Malformation

***Clinical.*** Chiari I malformation is defined as downward displacement of cerebellar tonsils below the foramen magnum and may be acquired or spontaneously resolve.[4,11,13] It is not associated with defective neural tube closure. Although many patients with Chiari I malformations are asymptomatic, some patients experience suboccipital headaches, neck pain, ataxia, dysmetria, nystagmus, and disequilibrium due to brainstem or cerebellar compression and/or upper extremity weakness and pain due to cervical cord myelopathy.[69] Treatment of a symptomatic Chiari I malformation with or without syrinx is a suboccipital decompressive craniectomy with duraplasty; the cerebellar tonsils may be resected.

***Imaging.*** The Chiari I malformation is defined by cerebellar tonsils greater than 6 mm below the posterior lip of the foramen magnum. In symptomatic patients, the low-lying tonsils disrupt CSF flow across the foramen magnum, which predisposes to syringomyelia in the thoracic or cervical spinal cord (Fig. 31.33). Flow of CSF across the foramen magnum is further impaired when the odontoid is elongated and dorsally angulated or with platybasia (e.g., the complex Chiari I variant). The dynamic significance of the low-lying tonsils is best depicted using single slice multiple phase gated two-dimensional (2D) phase contrast MR images in the sagittal and/or axial plane with a velocity encoding of 5 cm/sec. Obstruction of CSF flow results in abnormal bidirectional movement of hindbrain across the foramen magnum seen as changes in signal intensity on the phase contrast sequence. In patients with a Chiari I malformation, increased intracranial pressure resulting from a tumor or hydrocephalus resulting in secondary tonsillar herniation should be excluded with screening images through the brain.

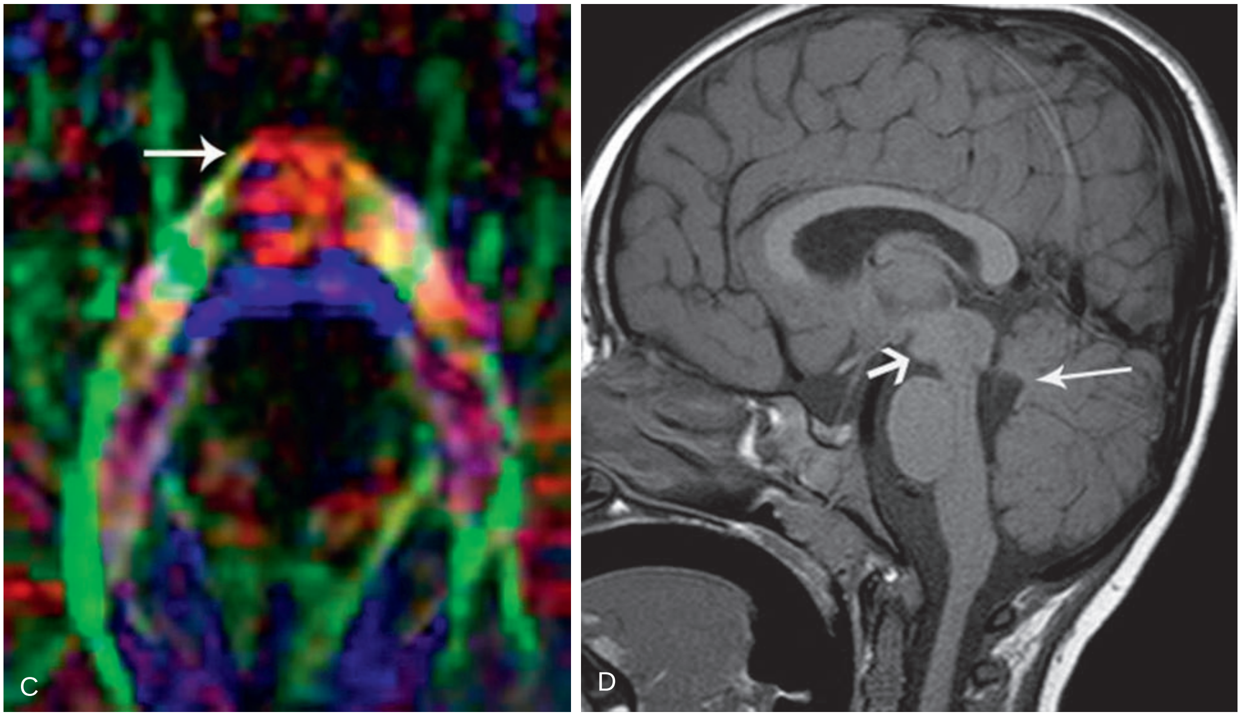
Bony anomalies of the craniovertebral junction may be seen with low-lying cerebellar tonsils including an elongated retroflexed odontoid and a short clivus (e.g., platybasia) with impingement on the ventral surface of the cervicomedullary brainstem by the high-riding odontoid (Table 31.1).[69]

## Cerebellar Malformations

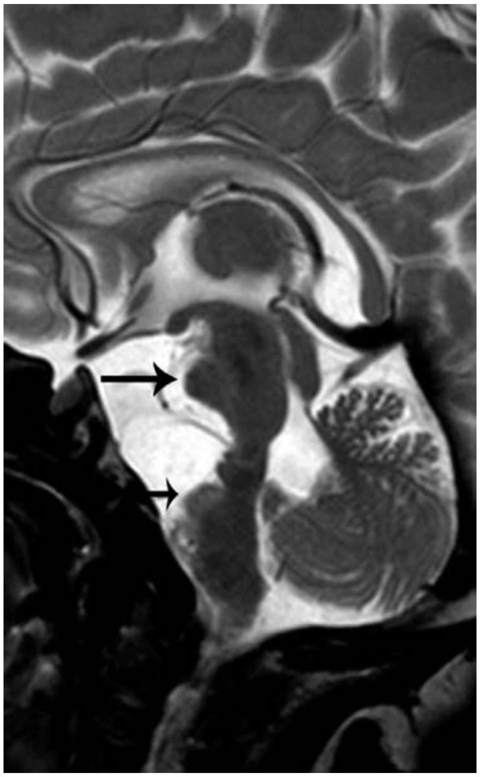
This section addresses malformations of the cerebellum in which the cerebellum is hypoplastic or dysplastic but not cerebellar atrophy.[70] Cerebellar hypoplasia is defined by a small cerebellum with fissures of normal size compared with the folia. Cerebellar dysplasia describes disorganized development and includes an abnormal folial pattern or cerebellar grey

**TABLE 31.1** Comparison of Chiari I and II Malformations

| Chiari I | Chiari II |
|---|---|
| Headache and neck pain increased by cough or Valsalva; dysarthria, dysphagia, downbeat nystagmus, upper extremity weakness/numbness | Brainstem dysfunction; swallowing/feeding difficulties, stridor, apnea, weak cry, nystagmus |
| Downward herniation of cerebellar tonsils resulting in compression of cervicomedullary brainstem; impeded CSF flow. Odontoid may be elongated and retroflexed | Downward herniation of dysplastic lower brainstem and cerebellar vermis |
| Brain usually normal<br>Syringomyelia 30%-70% | Callosal dysgenesis, neuronal migration anomalies, hydrocephalus ~95% |



**e-Figure 31.29, cont'd.** (C) Axial DTI shows the decussation of the cerebellar peduncles (e.g. the red dot) is absent in JSRD and several other hindbrain malformations, along with the decussation of the pyramidal tracts. DTI may also show pontine dysplasia. The right CST is fragmented *(arrow)* and the left CST is absent. (D) Sagittal T1-weighted MR image from another patient with JSRD shows elevation of the fastigium *(long arrow)* of the 4th ventricle and a dysplastic midbrain with ventral cap *(arrow)*.



**e-Figure 31.32. Brainstem disconnection syndrome.** Sagittal T2-weighted image shows the cranial and caudal limits of the severely constricted pons *(arrows)*. The basilar artery is absent and the clivus is dysplastic.

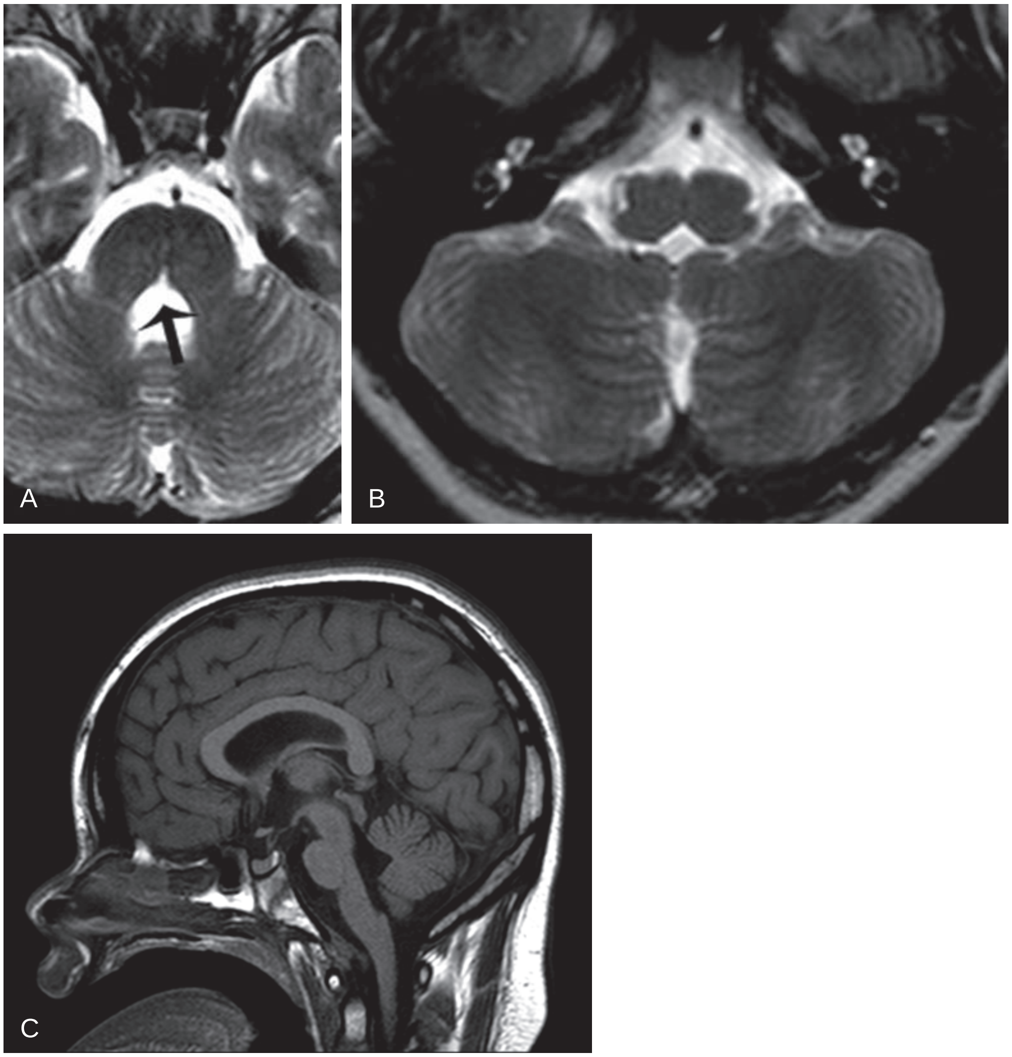


**Figure 31.30. Horizontal gaze palsy with progression scoliosis.** (A) Axial T2-weighted MR image shows a cleft *(arrow)* along the dorsal pons. (B) Axial T2-weighted MR image and (C) sagittal T1-weighted MR image show that the medulla lacks the normal dorsal convexities and the facial nerve colliculi are absent.

matter heterotopias, which may be generalized and involving cerebellar hemispheres and vermis, or focal and limited to a hemisphere or vermis. Cerebellar hypoplasia includes the Dandy-Walker continuum and isolated focal cerebellar hypoplasia.[70,71]

## Dandy-Walker Continuum

The Dandy-Walker malformation is defined by complete or partial agenesis of the vermis, cystic dilatation of the fourth ventricle, and an enlarged posterior fossa with cranial displacement of the torcular (Fig. 31.34), often associated with supratentorial hydrocephalus. Associated anomalies occurring in 70% of patients include an abnormal or absent corpus callosum, callosal lipoma, and neuronal migration anomalies.[70,71] The Dandy-Walker variants are controversial and defined by inferior vermian hypoplasia with nonobstructive cystic dilatation of the fourth ventricle; the posterior fossa is not enlarged. In contrast to the Dandy-Walker continuum, the posterior fossa arachnoid cyst and mega cisterna magna are associated with a fully formed cerebellum. Retrocerebellar arachnoid cysts (Fig. 31.35) cause anterior displacement of the fourth ventricle and cerebellum. The mega cisterna magna consists of enlarged retrocerebellar CSF spaces with no mass effect on the normally formed cerebellum.

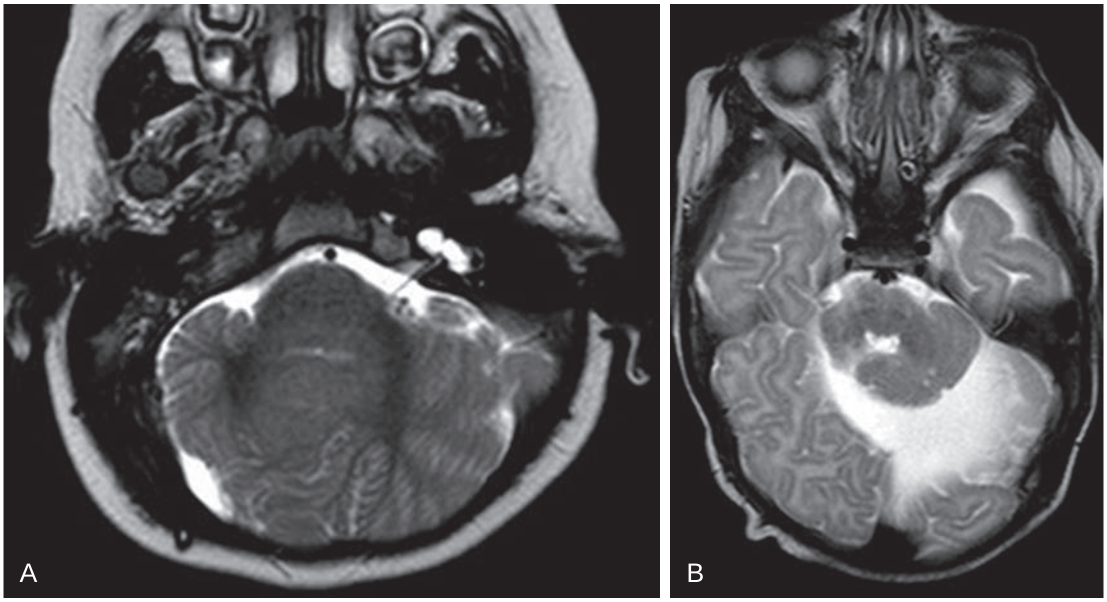
## Cerebellar Dysplasia

Unlike focal cerebellar dysplasia, diffuse cerebellar dysplasia is usually associated with severe supratentorial MCD such as LIS1 and cobblestone LIS (e-Fig. 31.36).[70]

## Rhombencephalosynapsis

***Clinical.*** This is a relatively rare major malformation of the cerebellum in which the two halves of the cerebellum fail to form.

***Imaging.*** The hallmark of this malformation is fusion of the cerebellar hemispheres (Fig. 31.37).[70–72] Associated brainstem abnormalities include fused colliculi, atresia or dilatation of the fourth ventricle, and cranial nerve and inferior olivary nuclei abnormalities. The corpus callosum may be hypoplastic or absent, and there may be failure of formation of diencephalic structures



**e-Figure 31.36. Cerebellar dysplasia.** (A and B) Axial T2-weighted MR images shows asymmetric cerebellar hemispheres and vermian dysplasia.

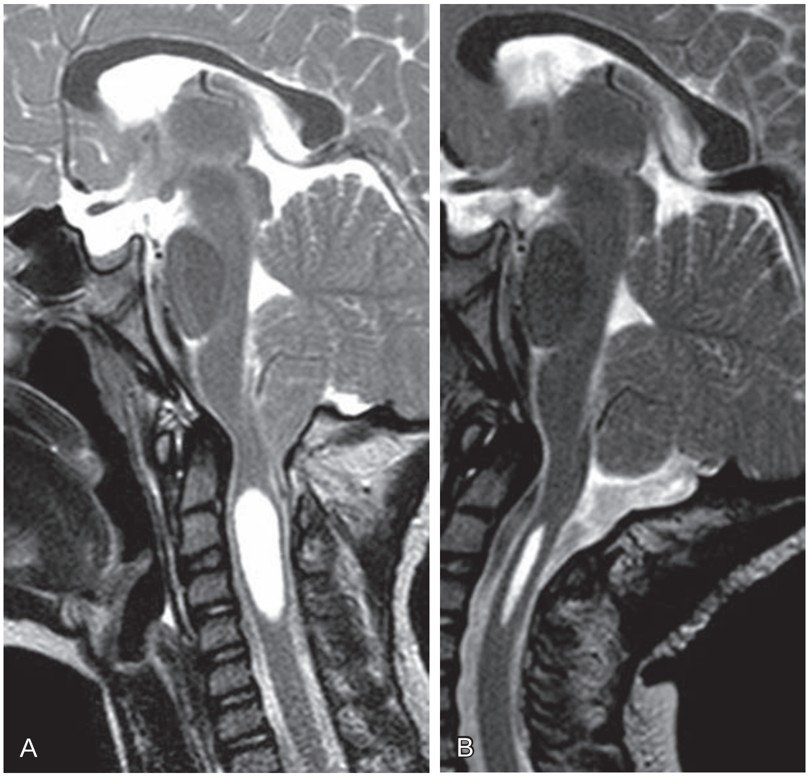


**Figure 31.33. Chiari I malformation.** (A) Sagittal T2-weighted image shows that the cerebellar tonsils are caudally displaced. The blockage to the flow of CSF across the foramen magnum has resulted in dilatation of the central spinal canal and syrinx formation. Previous decompressive suboccipital craniectomy was inadequate. (B) Sagittal T2-weighted image after repeat surgery reestablished normal CSF flow across the foramen magnum shows that the syrinx has improved.

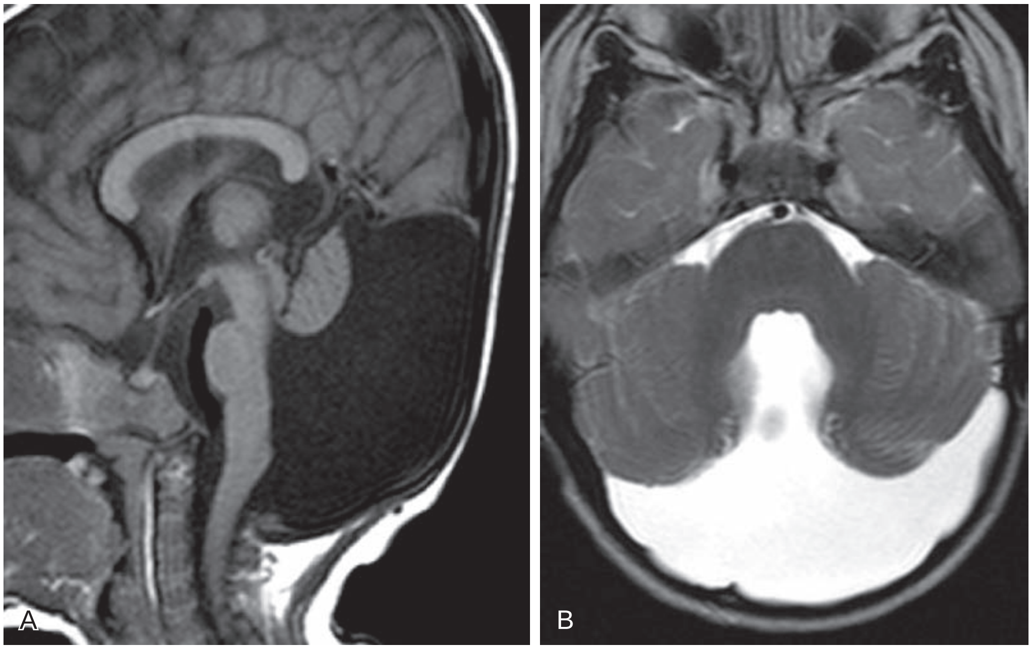

**Figure 31.34. Dandy-Walker malformation.** (A) Sagittal T1-weighted MR image shows an elevated torcular and cerebellar hypoplasia. (B) Axial T2-weighted MR image shows that the vermis is deficient and the retrocerebellar fluid communicates with the fourth ventricle; the hemispheres are relatively normal.

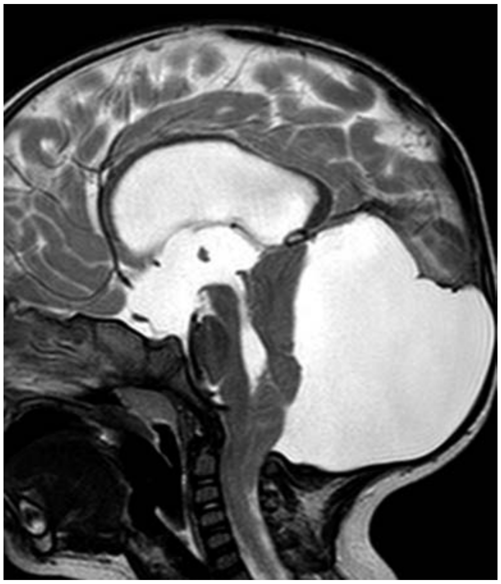

**Figure 31.35. Retrocerebellar arachnoid cyst.** Sagittal T2-weighted MR shows that the cerebellum is compressed by a large CSF collection causing obstruction to fourth ventricle outflow and resultant hydrocephalus.

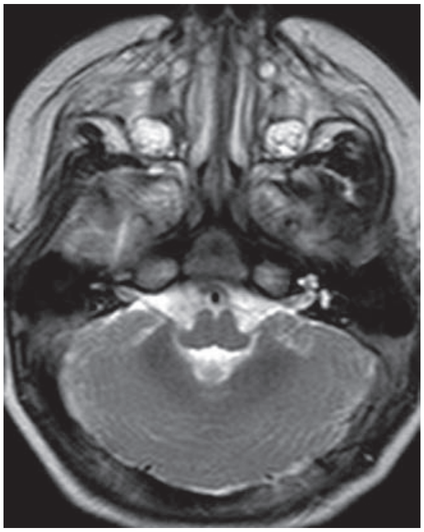

**Figure 31.37. Rhombencephalosynapsis.** Axial T2-weighted MR image shows fusion of the cerebellar hemispheres and absent vermis. A band of white matter is seen posterior to the third ventricle.

with thalamic fusion, hydrocephalus, and malformations of cortical development. Clinical problems vary with the severity of associated malformations. Isolated rhombencephalosynapsis may be associated with normal cognition or behavioral disorders, hypotonia, and ataxia.

## KEY POINTS

- Advances in developmental genetics have furthered understanding of many congenital brain malformations and their associated extra CNS manifestations.
- DTI shows anomalies of white matter tracts in malformations dominated by cortical anomalies by conventional MR techniques.
- The relative contribution of genetics versus epigenetics in some brain malformations remains poorly defined.
- A given gene mutation may have variable phenotypic expression.

# 32 Hydrocephalus

Giulio Zuccoli and Subramanian Subramanian

Hydrocephalus means "water in the brain." It is the morphologic end result of many different processes related to enlarging ventricles with compression on brain parenchyma and subarachnoid spaces leading to raised intracranial pressure (ICP). The active enlargement of cerebrospinal fluid (CSF) space in the ventricles eventually leads to loss of brain tissue. By convention, ventriculomegaly associated with increased ICP is termed *hydrocephalus*. It is crucial to differentiate it from *ex vacuo* enlargement of the ventricles secondary to volume loss or from anomalies that may alter the morphology of the ventricular system thus mimicking hydrocephalus.

Hydrocephalus is one of the most common sequelae of any insult to a child's central nervous system (CNS). Hydrocephalus occurs in 1 in 2000 live births and is associated with one-third of all CNS malformations. Since the 1970s, the incidence of spinal dysraphism–related hydrocephalus has declined[1] primarily due to maternal folate therapy, and vaccinations have decreased the number of patients with meningitis who may have been progressed to hydrocephalus.

## PHYSIOLOGY OF CEREBROSPINAL FLUID

CSF appears in response to degeneration of the primitive mesenchyma that surrounds the brain. Although the precise timing of CSF formation is not clear, CSF circulation from the ventricles to the subarachnoid space does not occur until after formation of the fourth ventricle outlet foramina at the ninth to tenth week of gestation.

Approximately 60% of CSF is produced by the choroid plexus, and the rest is produced extrachoroidally, possibly across parenchymal capillaries or by the ependyma itself. The rate of choroid plexus CSF production in adults is approximately 500 mL/24 hr. Normal CSF volume in an adult is estimated to be approximately 150 mL. The CSF volume in a neonate is approximately 50 mL.

The sites of CSF absorption remain controversial. It is widely accepted that arachnoid villi are one of the major sites in adults and older children.[2] The arachnoid villi (pacchionian granulations) are not developed in children until the closure of the fontanels. Studies suggest that a portion of CSF drains through the perivascular and perineural spaces into the lymphatic system or through the capillaries of the brain and spinal cord.[3] Others suggest that the arachnoid villi and granulation are poorly formed in neonates and that the majority of CSF absorption occurs through the lymphatic and venous system.[4]

## MECHANISMS OF HYDROCEPHALUS

Several theories have been used to explain the pathophysiology of hydrocephalus. Two widely accepted theories include the bulk flow theory and the Greitz model (hydrodynamic theory).

### Bulk Flow Theory

According to the bulk flow theory, hydrocephalus occurs as a result of imbalance between the production and the absorption of CSF. An obstruction inside the ventricular system proximal to fourth ventricle foramen of Lushka and Magendie causes obstructive hydrocephalus, whereas an obstruction outside the ventricular system causes communicating hydrocephalus.

Increased CSF production is rare but may occur with choroid plexus papilloma. Decreased CSF uptake occurs as a result of obstruction to CSF flow anywhere along the CSF pathway. The common sites of obstruction along the CSF pathway are the foramen of Monro, the aqueduct of Sylvius, the fourth ventricle outlet foramina, the basal cisterns, and the arachnoid villi.

### Hydrodynamic Model for Cerebrospinal Fluid Circulation

The hydrodynamic model is based on the concept that the absorption of CSF occurs through the capillaries in the CNS rather than through the arachnoid granulations and villi.[3] The skull is a nonelastic housing for brain tissue; blood, CSF, and brain tissue are almost incompressible. As stated by the Monro-Kellie doctrine, the total volume of arteries, veins, CSF, and brain confined within the skull cavity and dura mater is constant, and any increase in volume in one or more compartments causes a decrease in volume in the others. The skull and dura mater of children are more compliant. The elasticity of these structures plays a pivotal role in the hydrodynamic theory of hydrocephalus. During the cardiac systole, the expansion of the intracranial arteries increases the ICP, causing CSF displacement into the spinal canal and an increase in the venous outflow. During the cardiac diastole, there is inflow of CSF from the spinal canal, which causes elevation of pressure in the subarachnoid space. Therefore there is increased pressure in the CSF spaces during the entire cardiac cycle, which in turn compresses the venous outlets, causing an increase in outlet resistance and venous "counter" pressure. This pressure is necessary to keep the intracerebral veins sufficiently distended to accommodate the normal cerebral flow.

## CLASSIFICATION

Tully and colleagues identified five subtypes of hydrocephalus without evident extrinsic cause: "developmental hydrocephalus." This new classification is based on the apparent level of obstruction identified on magnetic resonance imaging (MRI): (1) hydrocephalus associated with myelomeningocele; (2) hydrocephalus with apparent aqueductal obstruction; (3) hydrocephalus associated with posterior fossa crowding; (4) hydrocephalus associated with cysts or cephaloceles; and (5) communicating hydrocephalus.[5]

## IMAGING

### Computed Tomography and Magnetic Resonance Imaging

Computed tomography (CT) and MRI are the primary modalities to assess ventricular size. Head ultrasound (US) is used as the initial study in infants with macrocephaly. Several parameters can help in differentiating between hydrocephalus and *ex vacuo* dilatation of ventricles from cerebral atrophy in infants. The parameters that favor the diagnosis of hydrocephalus are listed in Box 32.1.

The most reliable sign of hydrocephalus is the enlargement of anterior and posterior recesses of the third ventricle (Fig. 32.1). This does not occur in *ex vacuo* enlargement of the ventricles and strongly favors a diagnosis of hydrocephalus. The disproportionate enlargement of the recesses occurs because the thin hypothalamus

## Abstract:

Hydrocephalus is the most common end result of insult to pediatric central nervous system. The physiology of cerebrospinal fluid production and mechanism of development of hydrocephalus including bulk flow theory and hydrodynamic model for cerebrospinal fluid circulation has been discussed. The newer classification system of developmental hydrocephalus is based on MRI including hydrocephalus associated with myelomeningocele, hydrocephalus with apparent aqueduct obstruction, hydrocephalus associated with posterior fossa crowding, hydrocephalus associated with cyst or cephaloceles and communicating hydrocephalus. The various imaging findings in hydrocephalus on ultrasound, CT and MRI has been reviewed with emphasis on differentiating ventriculomegaly from hydrocephalus. Genetic factors have a role in development of hydrocephalus and role of ciliary dyskinesia, L1CAM mutation and X-linked inheritance has been discussed. Ultrasound is preferred modality when anterior fontanelle is open. Radiographs and CT scan play an important role in evaluation of shunt malfunction. Rapid MRI protocol is increasingly used to assess shunt malfunction resulting in substantial reduction of radiation. Use of third ventriculostomy in hydrocephalus and assessment of patency of third ventriculostomy by imaging techniques have been discussed.

### **BOX 32.1** Imaging Characteristics of Hydrocephalus*

Enlargement of the third ventricle, particularly the anterior and posterior recesses
Commensurate dilation of the temporal horn with the lateral ventricles
Narrowing of the mamillopontine distance
Narrowing of the ventricular angle
Widening of the frontal horn radius
Periventricular interstitial edema
Effacement of cortical sulci

*From Barkovich AJ. Hydrocephalus. In Barkovich AJ, ed.* Pediatric Neuroimaging, *4th ed, Philadelphia: Lippincott Williams & Wilkins; 2005:663.*
*Listed in order of diagnostic value.

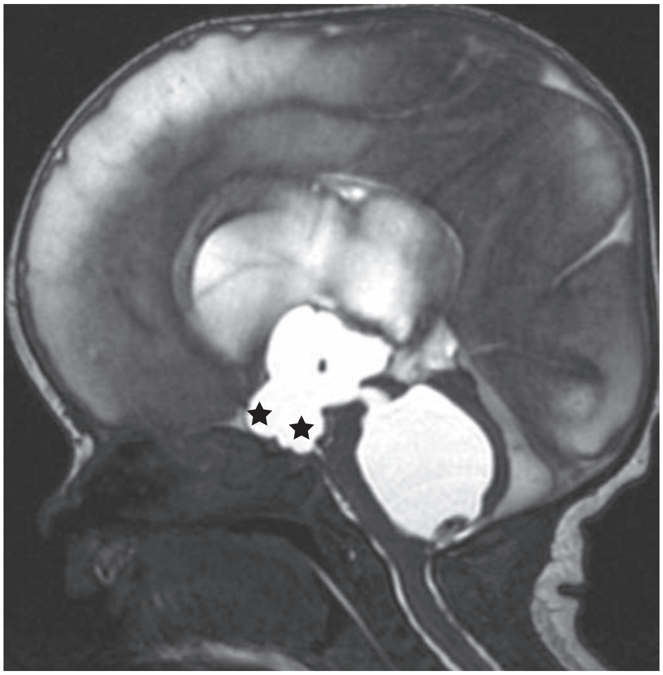

**Figure 32.1. Hydrocephalus and third ventricular enlargement.** Midline sagittal balanced steady-state free precession (SSFP) MR image demonstrates the dilatation of the chiasmatic and infundibular recess of the third ventricle *(asterisks)*. A dilated fourth ventricle is also noted in this patient with fourth ventricular outflow obstruction (entrapped fourth ventricle) from neonatal hemorrhage.

and cisterns surrounding these recesses provide relatively little resistance to expansion. In contrast, the body of the third ventricle is restricted by the rigid thalami, which provide more resistance to expansion. The anterior recesses (i.e., the chiasmal and infundibular) expand earlier than the posterior recesses (i.e., the pineal and suprapineal).[6] These findings are best appreciated on midsagittal magnetic resonance (MR) images.[5] On axial CT, dilation of the anterior recesses of the third ventricle is detected when the third ventricle is larger at the level of the optic chiasm than at the middle of the ventricle.

The enlargement and inferior displacement of the anterior recesses may cause flattening of the pituitary gland with erosion of the dorsum sellae, giving the classical plain film appearance of increased ICP in older children and adults. The recesses may compress the infundibulum and decrease the flow in the hypothalamic-pituitary portal venous system, resulting in hypothalamic-pituitary dysfunction. The enlargement of the suprapineal and pineal recesses may displace the pineal gland inferiorly, and it occasionally elevates the vein of Galen. A large diverticulum of this recess may compress the tectum inferiorly and shorten it in the rostrocaudal direction, mimicking a neoplasm.

Commensurate dilation of the temporal horns with the lateral ventricles is also a strong indicator of hydrocephalus. Temporal horn dilation is best viewed on coronal T2-weighted MR images. The choroidal fissure is enlarged, and the hippocampus is compressed and displaced inferomedially (Fig. 32.2). Studies have suggested that temporal horns dilate less than the bodies of the lateral ventricles in generalized atrophy.[7] This may be related to the small size of the temporal lobes and to their relatively small volume of white matter.

In *ex vacuo* dilatation of ventricles associated with cerebral atrophy, the superior and inferior walls of temporal horns remain parallel and are smaller than the lateral ventricle body. The hippocampus is normally placed, and the choroidal fissures are not enlarged. The Sylvian fissure is enlarged in patients with temporal lobe atrophy. In children with temporal lobe atrophy, temporal horn enlargement is not a reliable sign of hydrocephalus.

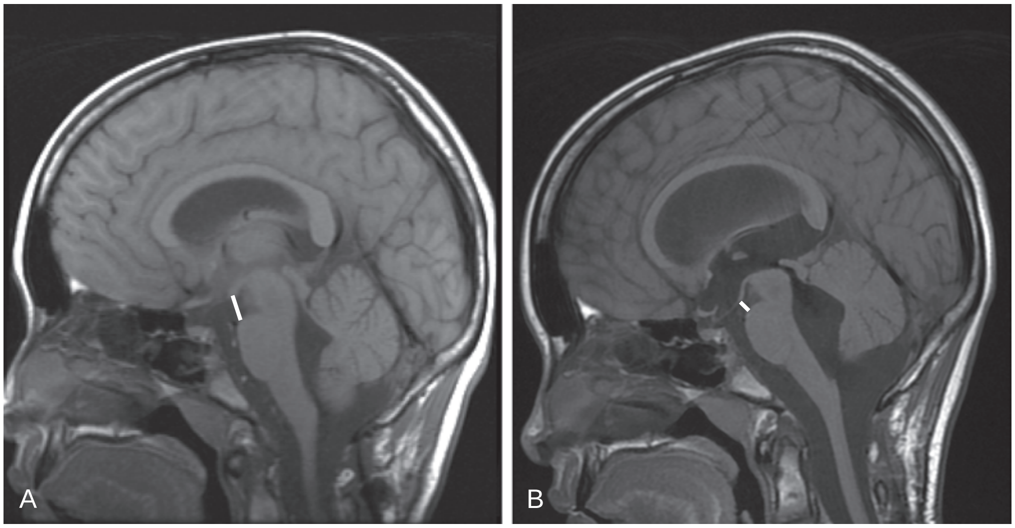
The mamillopontine distance is measured on sagittal MRI from the anterior root of the mamillary body to the top of the pons parallel to the anterior mesencephalon (e-Fig. 32.3).[6] The normal average distance is 3.8 mm. The floor of the third ventricle as seen on a sagittal MR images is usually concave downward. With enlargement of the third ventricle, it becomes straightened or convex downward, resulting in reduction of the mamillopontine distance.

The ventricular angle, as defined by Heinz and colleagues, measures the divergence of the frontal horns (e-Fig. 32.4).[7] Concentric enlargement of the frontal horns in hydrocephalus causes diminution of this angle as seen on axial or coronal images and produces an enlargement of the frontal horn radius with a rounded configuration of the frontal horns, or a “Mickey Mouse ears” appearance.

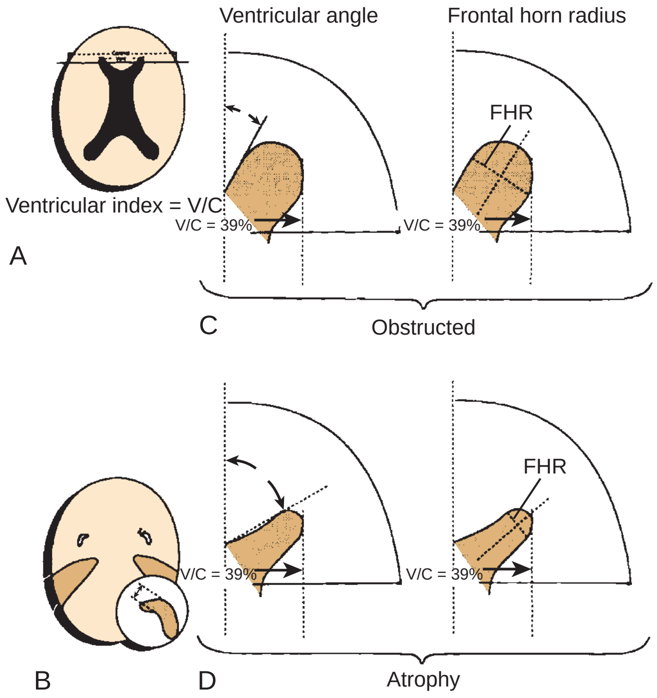
Enlargement of the ventricles disproportionate to enlargement of the cortical sulci favors a diagnosis of hydrocephalus. This parameter is not reliable in children, especially in the first couple of years of life, because patients with communicating hydrocephalus and atrophy have enlargement of both the fluid spaces. Also, the sizes of the ventricles and the subarachnoid spaces may vary tremendously, as seen in infants with benign macrocephaly. Therefore it is important to evaluate ventricular size in conjunction with the patient’s neurologic evaluation and serial head circumference measurements. A large or rapidly enlarging head would favor a diagnosis of hydrocephalus, whereas a small or diminishing head circumference would suggest atrophy.

The presence of periventricular interstitial edema is indicative of hydrocephalus (Fig. 32.5). With elevation of pressure within the ventricles, the normal centripetal flow toward the ventricles is reversed. The CSF is forced out through the ependyma into the surrounding extracellular spaces to be absorbed by alternative routes. This increase in periventricular fluid constitutes interstitial edema. It is best recognized on MRI with fluid-attenuated inversion–recovery (FLAIR) and proton density sequences. It is more difficult to appreciate on T2-weighted images because of the bright signal from the ventricles. Periventricular interstitial edema is difficult to appreciate in neonates and young infants because it is masked by bright signal from immature myelin, with its high water content. On CT, periventricular interstitial edema is seen as hypoattenuation in the periventricular region, with indistinct ventricular margins.

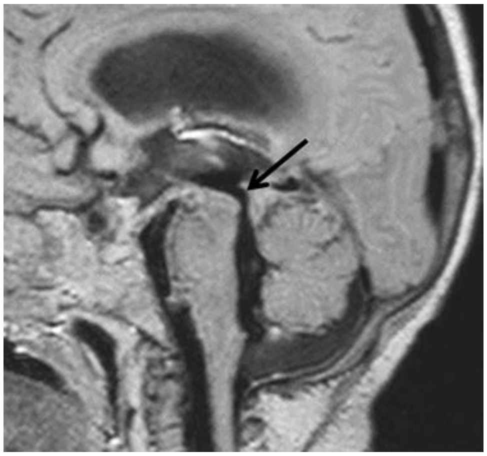
A CSF “flow void” in the third ventricle, aqueduct of Sylvius, and fourth ventricle is accentuated in hydrocephalus as a result of hyperdynamic flow (e-Fig. 32.6). The specificity of this finding has been disputed by some authors.



**e-Figure 32.3. Mamillopontine distance.** (A) Baseline MRI in this 11-year-old patient demonstrates normal mamillopontine distance on T1-weighted sagittal midline image. The distance *(bar)* is measured from the anterior base of the mamillary body to the top of the pons parallel to the anterior aspect of the mesencephalon. (B) Reduction in the mamillopontine distance within 6 months due to interval development of hydrocephalus from intraventricular hemorrhage. Note the stretching of corpus callosum and the third ventricular dilatation.



**e-Figure 32.4. Methods of radiographically diagnosing hydrocephalus.** (A) The ventricular index is the ratio of the ventricular diameter at the level of the frontal horns to the diameter of the brain measured at the same level. This is not very sensitive because the ventricular index is enlarged in cerebral atrophy as well as in hydrocephalus. (B) Temporal horns that have enlarged commensurately with the bodies of the lateral ventricles are probably the most sensitive and reliable sign in the differentiation of hydrocephalus from atrophy. There is significantly less dilation of the temporal horns than of the bodies of the lateral ventricles in cerebral atrophy. (C) The ventricular angle measures the divergence of the frontal horn. In theory, the angle made by the anterior or superior margins of the frontal horn at the level of the foramina of Monro is diminished when concentric enlargement of the frontal horns occurs. Compare the illustration of hydrocephalus (top) with that of atrophy (bottom). The ventricular index in both cases is 39%, but the ventricular angle is markedly reduced in hydrocephalus. (D) Concentric dilation produces an enlargement of the frontal horn radius *(FHR)* with a rounded configuration of the frontal horns, or a "Mickey Mouse ears" appearance. *(From Barkovich AJ.* Pediatric Neuroimaging, *4th ed, Philadelphia: Lippincott Williams & Wilkins; 2005:631.)*



**e-Figure 32.6. Aqueductal flow cerebrospinal fluid flow void.** Sagittal fluid-attenuated–inversion recovery (FLAIR) image demonstrates flow void in the aqueduct of Sylvius *(arrow)* with enlarging lateral ventricles *(not shown),* indicative of hydrocephalus.

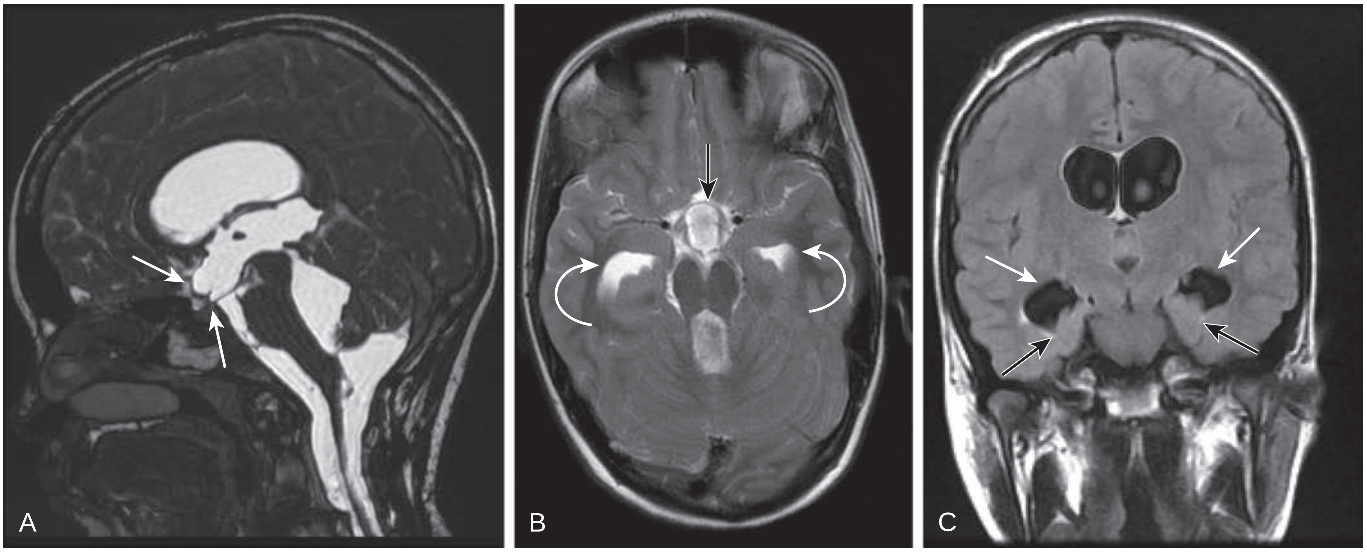


**Figure 32.2. MRI findings in hydrocephalus.** (A) Midsagittal T2-weighted MR image in a 10-year-old girl with tectal glioma demonstrates dilation of the chiasmatic and infundibular recesses *(arrows)*. (B) Axial T2-weighted MR image shows dilated anterior recess *(straight arrow)*. The temporal horns are also dilated *(curved arrows)*. (C) Coronal fluid-attenuated–inversion recovery (FLAIR) MR image shows the characteristic dilation of the temporal horns *(white arrows)* with enlargement of the choroidal fissure and inferomedial displacement of the hippocampi *(black arrows)* and with surrounding increase in signal suggesting increased transependymal cerebrospinal fluid resorption.

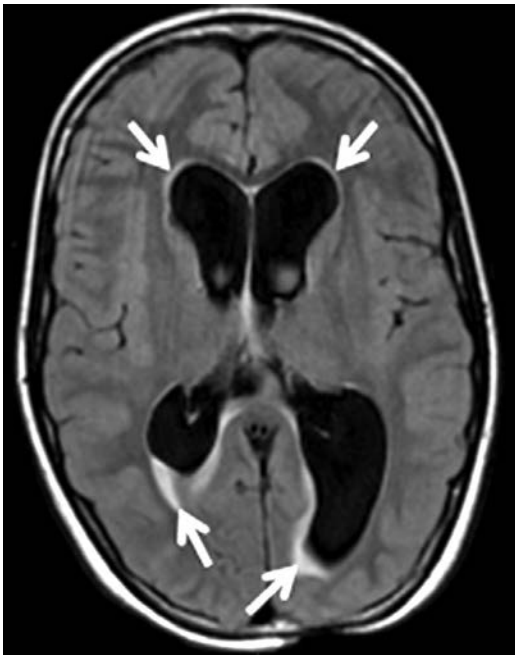

**Figure 32.5. Periventricular interstitial edema.** Axial fluid-attenuated–inversion recovery (FLAIR) MR image at the level of lateral ventricles demonstrates characteristically increased periventricular hyperintensities *(arrows)* indicating transependymal flow of cerebrospinal fluid.

Ventriculomegaly secondary to hydrocephalus causes mass effect and distortion of adjacent brain structures. There is stretching, upward displacement, and smooth, uniform thinning of the corpus callosum as a result of lateral ventricular enlargement. Corpus callosum thinning also occurs in atrophy. It is typically not elevated superiorly and may not be uniformly thin, as seen in hydrocephalus.

Marked hydrocephalus may lead to formation of atrial diverticula, which is herniation of the ventricular wall through the choroidal fissure of the ventricular trigone into the supracerebellar and quadrigeminal cisterns. The atrial diverticula may cause compression and distortion of the tectum. They may also mimic arachnoid cysts in the region of the quadrigeminal cistern.[8]

MRI in hydrocephalus frequently involves utilization of three-dimensional balanced steady-state free precession (SSFP). This sequence is particularly useful in demonstrating arachnoid membranes, intraventricular cysts, and aqueductal stenosis.

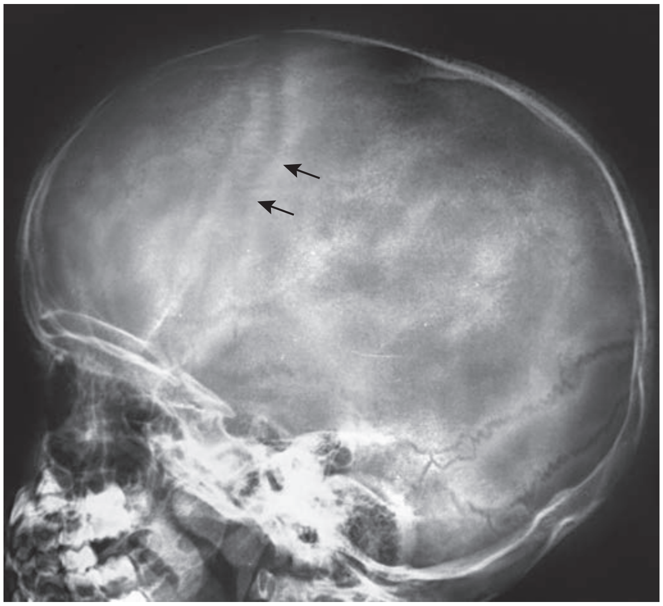
Qualitative and quantitative CSF analysis can be performed using phase contrast cine MRI. The technique is useful in demonstration of pulsatile flow at the craniocervical junction, aqueduct of Sylvius, and across a surgically created third ventriculostomy (Fig. 32.7).[9]

## Ultrasound

Head US is a useful initial examination for evaluation of macrocephaly in infants if the anterior fontanelle is open. Transcranial Doppler techniques may be helpful to identify infants with raised ICP, and they may help to determine the need for shunt placement. Under experimental conditions, with elevated ICP, arterial flow tends to be maximally affected during diastole, resulting in elevated pulsatility. Many researchers have demonstrated elevated resistive indices in infants with raised ICP and a subsequent decrease after ventricular tapping. These results, however, have not been uniformly reproducible.[10–12]

## Plain Radiographs

The changes related to elevated ICP on the plain radiograph of the skull depend on the age of the child. In children up to 8 or 10 years of age, sutural diastasis may occur within a few days of elevated pressures (e-Fig. 32.8). After 12 to 13 years of age, sutural diastasis is uncommon early, and the first sign of longstanding hydrocephalus may be erosion of the sellar cortex. The anterior part of the base of the dorsum is the earliest to be eroded. The



**e-Figure 32.8. Elevated intracranial pressure.** Lateral radiograph of the skull in an 18-month-old child with signs of elevated intracranial pressure, showing diastasis of the coronal sutures *(arrows)*. Magnetic resonance imaging performed subsequently demonstrated a supratentorial ependymoma.

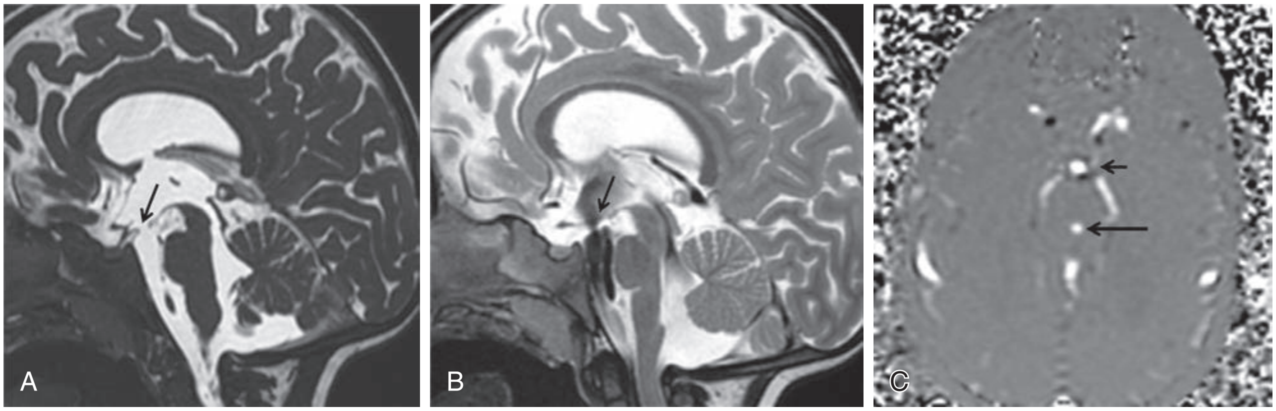


**Figure 32.7. Phase contrast cine MRI.** Images are acquired throughout the cardiac cycle and demonstrate pulsatile cerebrospinal fluid (CSF) motion. (A) Midsagittal steady-state free precession MR image shows patent third ventriculostomy *(arrow)*. (B) Sagittal T2-weighted MR image demonstrates flow void in third ventriculostomy *(arrow)*. (C) Axial phase contrast MR image demonstrates pulsatile CSF flow in third ventriculostomy *(short arrow)* and aqueduct of Sylvius *(long arrow)*.

**BOX 32.2** Hydrocephalus Without Known Extrinsic Causes[5]

**MYELOMENINGOCELE-ASSOCIATED HYDROCEPHALUS**

Proximal obstruction:

1. Aqueduct stenosis *L1CAM* mutation
2. Muscle-Eye-Brain syndrome

Distal obstruction: Posterior fossa crowding leading to Chiari 1

1. Crouzon syndrome
2. Pfeiffer syndrome
3. Carpenter syndrome
4. Achondroplasia
5. Thanatophoric dysplasia
6. Spondyloepiphyseal dysplasia
7. MPPH syndrome (megalencepahly, polydactyly, polymicrogyria, and hydrocephalus)

Hydrocephalus associated with cyst and cephaloceles:
  Oro-Facial-Digital syndrome
  Chudley-McCullough syndrome
  Aicardi syndrome

Communicating hydrocephalus:
  Cardio-facio-cutaneous with pulmonic stenosis
  Gorlin syndrome

Hydrocephalus with known extrinsic causes
Intraventricular hemorrhage
Infection
Trauma tumor vein of Galen malformation
Thrombosis of dural venous sinuses or other causes of obstruction to venous drainage

erosion may spread to involve the floor of the sella. The enlargement of the anterior recesses of the third ventricle is responsible for these changes.

## ETIOLOGY OF HYDROCEPHALUS

### In Newborns and Infants

The common etiologies for hydrocephalus in newborns and infants are listed in Box 32.2.

Infants with ventriculomegaly typically present with macrocephaly. It is critical and often difficult to differentiate between ventriculomegaly caused by communicating hydrocephalus, which requires shunting, and ventriculomegaly related to benign extraaxial fluid of infancy, which is a benign self-limiting condition and does not require intervention. These infants should be assessed clinically for other signs of elevated ICP, such as dilated scalp veins, bulging fontanelles, and sutural diastasis. They may have ocular signs and spasticity in the lower extremities secondary to disproportionate stretching of the corticospinal tracts arising from the leg area in the motor cortex by the enlarged ventricles. Infants with macrocephaly should be evaluated with imaging to assess for ventricular dilation. US is the most common initial modality for imaging infants with macrocrania. However, in patients with macrocephaly presenting with nonspecific symptoms, abusive head trauma should be included in the differential considerations. In these patients, CT or MRI could be obtained as a screening tool.[13]

### Benign ExtraAxial Collections of Infancy

The most common cause of macrocephaly in this age group is benign extraaxial collections of infancy. This condition has been variously called *benign enlargement of subarachnoid spaces in infancy*, *benign external hydrocephalus*, *benign macrocrania*, and *benign subdural collection of infancy*. It is a fairly common condition and rarely comes to clinical attention unless there is rapid increase in head size. These infants typically present between 2 and 6 months of age and have normal neurologic development with no clinical signs of raised ICP. The head circumference is above the 95th percentile and stabilizes along a curve parallel to the 95th percentile by 18 months of age. The subarachnoid spaces are mildly enlarged and return to normal size by 18 to 24 months of age. The CSF spaces are disproportionately larger, with the ventricles only mildly prominent. This condition likely represents transient communicating hydrocephalus from delay in maturation of the arachnoid villi.

Imaging demonstrates mild prominence of the subarachnoid spaces along the frontoparietal convexities, the cortical sulci, the Sylvian fissures, and the anterior interhemispheric fissures (Fig. 32.9). The ventricles are typically normal in size, but they may be mildly enlarged. The extraaxial fluid must be symmetric and have the same signal intensity as CSF, and it should not be associated with mass effect. If the fluid collection is of higher attenuation than CSF, is asymmetric, or exerts mass effect on adjacent structures, MRI may be performed to evaluate for blood or blood byproducts in a traumatic subdural hematoma. Both MRI and US can help differentiate between subarachnoid fluid and subdural hematoma. With enlarged subarachnoid spaces, the cortical veins course through the fluid and lie adjacent to the inner table of the calvarium.

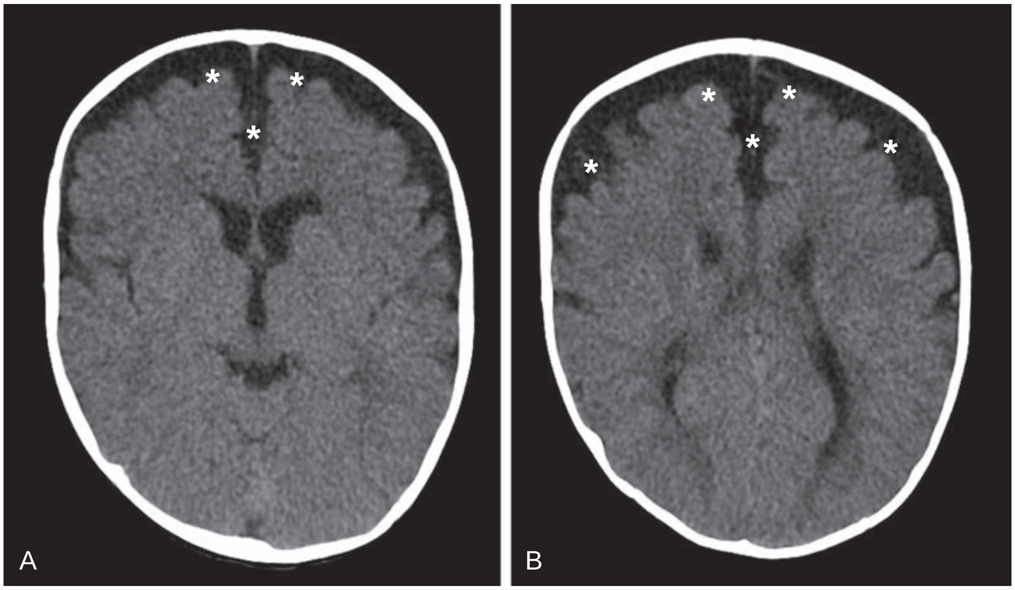

**Figure 32.9. Benign extraaxial collections of infancy.** (A and B) Axial computed tomography shows prominent subarachnoid extraaxial fluid spaces and interhemispheric fissure *(asterisks)*. The ventricles are also mildly prominent.

If the subdural space is enlarged, the cortical veins should be displaced away from the inner table toward the cerebral cortex. The signal intensity of chronic subdural hematoma also differs from that of CSF on MRI.[14] It has been questioned whether enlarged CSF spaces may make these patients more susceptible to subdural hemorrhage from minor trauma, as occurs in children with arachnoid cysts.

The diagnosis of benign extraaxial collection of infancy is a diagnosis of exclusion. Other causes of prominent CSF subarachnoid spaces include congenital anomalies, communicating hydrocephalus, infection, hypercortisolism, dehydration, cerebral atrophy, and drug induced (parenteral nutrition and chemotherapy).

In communicating hydrocephalus, the ventricles are typically disproportionately larger than the subarachnoid spaces (e-Fig. 32.10). At times, the two conditions cannot be differentiated on imaging. The imaging findings should always be interpreted in the context of the clinical history and serial head circumference measurements. Infants with communicating hydrocephalus usually have other signs of raised ICP and an abnormal neurologic examination. When the imaging findings and clinical examination are equivocal, a CSF cisternogram may help to differentiate between the two conditions. Rarely, the issue has to be resolved by invasive ICP monitoring.

### Older Children

Common causes of ventriculomegaly in older children are listed in Box 32.3. Because of the inability of their cranium to expand as quickly as in infants and young children, older children with hydrocephalus have a more acute presentation. They may have the classical triad of headache, vomiting, and lethargy. Children developing chronic hydrocephalus as a result of slowly expanding lesions typically present with persistent morning headaches and intermittent vomiting. Papilledema is often encountered. Focal neurologic deficits from the primary lesion may be present, and pyramidal tract signs, more marked in the lower extremities, are found. Hypothalamic-pituitary dysfunction may also develop as a result of compression of these structures by enlarging anterior recesses of the third ventricle.

**BOX 32.3** Causes of Ventriculomegaly in Older Children

Ventriculomegaly without elevated ICP
*Ex vacuo* dilation secondary to atrophy
Congenital anomalies
Ventriculomegaly with elevated intracranial pressure
Infection
Trauma
Superficial siderosis from prior hemorrhage (see e-Fig. 32.10)
Tumors: Direct pressure or leptomeningeal metastases
Delayed identification of congenital abnormality

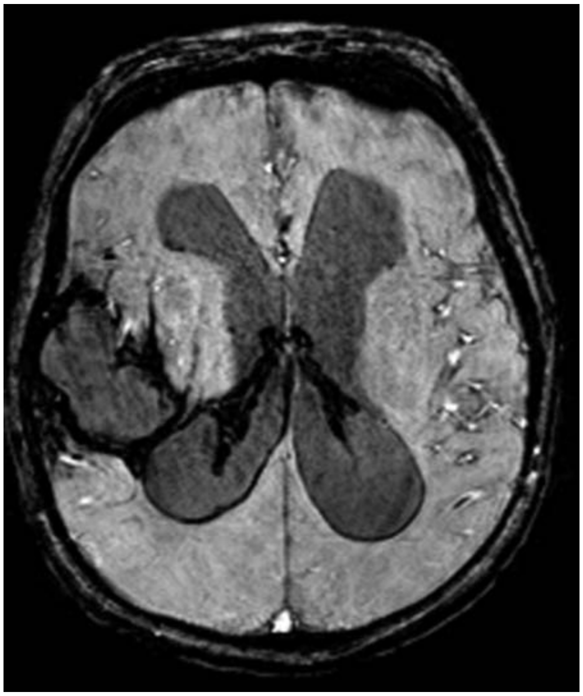
## NORMAL PRESSURE HYDROCEPHALUS

Intermittent high CSF pressures with consequent reduced cerebral blood flow may lead to brain damage and can lead to hydrocephalus if there is concomitant reduction in the compliance in the cranial cavity (Greitz model). This is the postulated pathogenesis for normal pressure hydrocephalus (NPH). The loss of compliance is felt to be due to damage to arachnoid membranes or loss of dural elasticity. NPH is mainly a disease of adults with pediatric cases seen in association with prior history of meningitis or intraventricular bleed. CSF volume is displaced at the craniovertebral junction during systole, and the venous stroke volume is decreased. Intracranial CSF pulse pressure is increased (though mean CSF pressure is normal) commensurate with reduced compliance in the meninges.

The CSF pressure assessed at lumbar puncture is normal. On imaging, fast flow or increased velocity flow at the aqueduct is seen on phase contrast cine MRI.

## GENETICS IN HYDROCEPHALUS

Genetic factors may play an important role in development of congenital hydrocephalus. Various animal models of congenital hydrocephalus have demonstrated abnormalities in cerebral



**e-Figure 32.10. Superficial siderosis leading to communicating hydrocephalus.** Axial GRE MR image in a patient with prior hemorrhage demonstrates low signal susceptibility changes in lateral ventricular wall leading to decreased absorption of cerebrospinal fluid. There is encephalomalacia with susceptibility changes in right temporal lobe from prior hemorrhage.

aqueduct or subarachnoid space.[15] There is a higher incidence of aqueduct stenosis in patients with ciliary dyskinesia suggesting abnormalities in ciliary processes in the ependyma may play a role.[15] In children with aqueduct stenosis, up to 14% have defined syndromes, and some patients have L1CAM mutations.[5] Children with congenital hydrocephalus and posterior fossa crowding had craniosynostosis or skeletal dysplasia and frequently demonstrated fibroblast growth factor receptor mutations.[5] Developmental communicating hydrocephalus is noted in children with family members having macrocephaly, with male children being more affected, suggesting X-linked inheritance.[5]

## ASSESSMENT OF CHILDREN WITH VENTRICULAR SHUNTS

### Methods of Shunting

Different methods have been used for CSF shunting, with the goal to decrease ICP by providing an alternative pathway for CSF absorption. The shunt catheters have a proximal intracranial segment connected in series to a valve and distal tubing. The proximal catheter may be inserted through the occipital, frontal, or posterior temporal approach. The placement of the ventriculostomy catheter is optimal if the tip and the side holes of the catheter are not in direct contact with the choroid plexus; this is most possible if the tip of the catheter lies in the frontal horn anterior to the foramen of Monro or in the atrium. This serves to minimize the chances of tissue ingrowth into the holes and occlusion of the proximal catheter. The distal catheter may be placed in various locations, including the peritoneal cavity, pleural cavity, central veins or right atrium, and gallbladder. The peritoneal cavity is the overwhelmingly favored location. The only relative contraindications to its use are active intraperitoneal infection, significant risk of future peritoneal infections, severe adhesions, and previous failure of peritoneal shunts as a result of inadequate absorption.

### Shunt Malfunction

One of the most common acute complications from insertion of the proximal catheter is hemorrhage, occurring in approximately 1% of patients (Box 32.4). It is even more common when an old catheter is removed. Neuronal injury may result in focal deficits such as hemiparesis if the catheter traverses the internal capsule. Seizures can occur and are more common with catheters placed through a frontal trajectory. With lumbar catheters, there is a 5% reported risk of radiculopathy and a 1% risk of myelopathy.

It is an axiom in pediatric medicine that, when a child with a ventricular shunt has a medical problem, the shunt is the cause of the problem until proven otherwise. The causes of shunt malfunction can be broadly divided into mechanical shunt failure involving the shunt apparatus[1] and shunt infection.[2] The most common time for the shunt to fail is in the first 6 months after insertion. Multiple studies indicate that patients younger than 6 months are at a higher risk of shunt malfunction. The overall 1-year failure rate is 40% for patients with a corrected median age of 55 days and 30% in older age groups.

#### Mechanical Failure of the Shunt

The leading cause of shunt malfunction is mechanical failure. Obstruction is most common at the proximal end and can result from occlusion by brain parenchyma, choroid plexus, protein plug, or tumor cells.[16] Disconnection may occur at any point in the shunt apparatus, but it is most frequent at the site of connection between the valve and the peritoneal catheter (e-Fig. 32.11) and at the site of increased mobility (i.e., the lateral neck). The shunt may migrate to a variety of sites.

**BOX 32.4** Complications of Catheter Insertion

Intracranial hemorrhage
Damage to neuronal tissue
Pneumocephalus; air lock in the shunt
Altered CSF flow dynamics: Loculated fourth ventricle
Slit ventricles
Subdural hematoma
Meningeal fibrosis
Craniosynostosis

*CSF*, Cerebrospinal fluid.

**BOX 32.5** Abdominal Complications of Distal Shunt Catheter

Acute abdomen
Ascites
Cerebrospinal fluid: Enteric fistula
Inflammatory pseudotumor of mesentery
Inguinal hernia
Intrahepatic abscess
Omental cyst
Perforation of bowel
Perforation of gallbladder
Pseudocyst
Small bowel obstruction
Umbilical fistula
Ureter obstruction
Volvulus

*From Martin AE, Gaskill SJ. Cerebrospinal fluid shunts: complication and results. In McLone DG, ed.* Pediatric Neurosurgery: Surgery of the Developing Nervous System, *4th ed, Philadelphia: WB Saunders; 2001:223.*

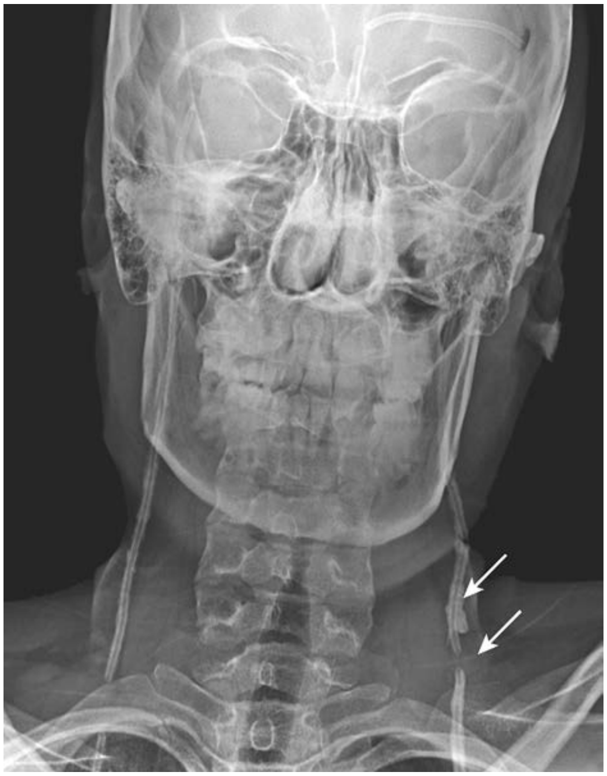
Preperitoneal displacement of the catheter may be evidenced by the sudden onset of shunt malfunction. This appears on a shunt survey as double-backing of the catheter through the peritoneal opening. The distal catheter has its own unique set of complications (Box 32.5), which are best evaluated with abdominal imaging. A pseudocyst may occur at the distal end, with or without infection, causing impairment of CSF absorption.

Chronic shunt placement may alter CSF flow dynamics, resulting in isolated ventricles. Isolated fourth ventricle may occur with shunting of noncommunicating hydrocephalus. On shunting, enlarged lateral ventricles collapse, resulting in obstruction of the aqueduct of Sylvius that over time becomes irreversible. The CSF being produced in the fourth ventricle cannot be drained from above because of obstruction at the aqueduct or below (because there is original outlet obstruction), causing progressive dilation of the fourth ventricle (e-Figs. 32.12 and 32.13).

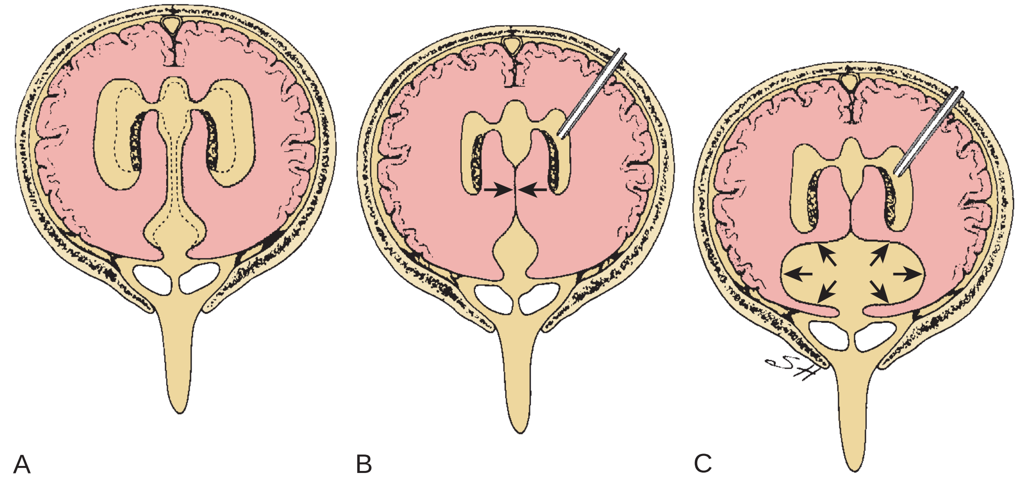
Other chronic complications include subdural hematomas, which occur because of rapid decompression of the ventricular system before the brain parenchyma can expand to fill the cranial vault. Meningeal fibrosis may rarely occur, possibly as a reaction to chronic subdural hematoma. The meninges show profuse enhancement on postcontrast images. Craniosynostosis is a rare complication occurring only in patients shunted before 6 months of age.

#### Shunt Infections

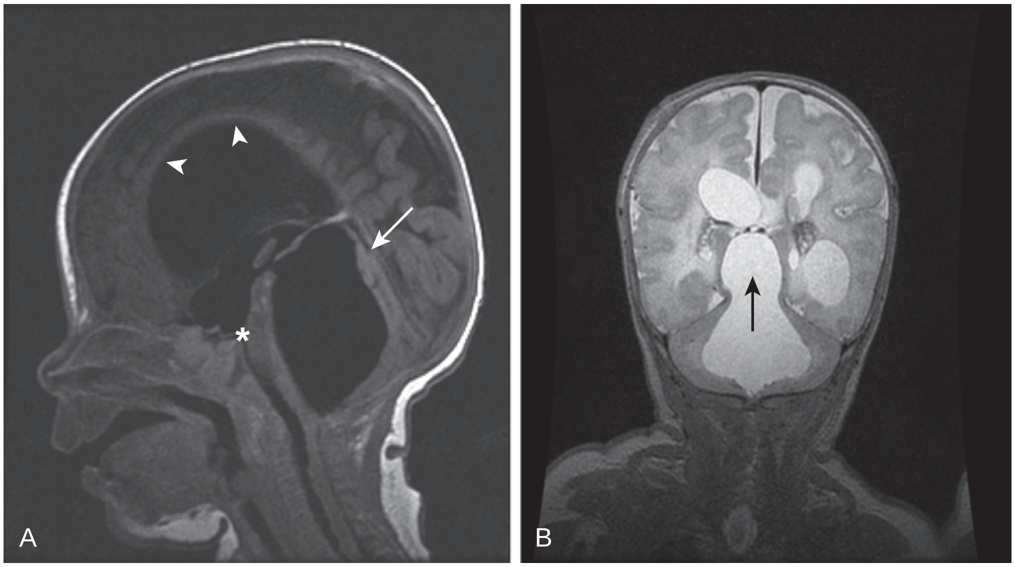
Shunt infections remain an important and distressing cause of shunt failure, with an overall infection rate of 5% to 10%. The



**e-Figure 32.11. Broken shunt.** Frontal radiograph of the neck in a patient with shunt malfunction new onset irritation and vomiting shows pericatheter calcification and break in the distal tubing *(arrows)*.



**e-Figure 32.12. Diagram of the pathophysiology of the isolated fourth ventricle.** (A) Panventricular hydrocephalus with dilation of the aqueduct of Sylvius and blockage of the basal cisterns. (B) The shunting of the lateral ventricles leads to collapse of the aqueduct of Sylvius *(arrows)* that, with time, becomes irreversible. (C) Because cerebrospinal fluid is still being produced in the fourth ventricle and cannot be drained from above or below, it causes progressive dilation of the fourth ventricle *(arrows)*. *(From Rekate HL. Treatment of hydrocephalus. In McLone DG, ed.* Pediatric Neurosurgery: Surgery of the Developing Nervous System, *4th ed, Philadelphia: WB Saunders; 2001:213.)*



**e-Figure 32.13. Trapped fourth ventricle.** (A) Midsagittal T1-weighted MR image in a 12-week-old infant with neonatal ventriculitis and intraventricular abscess shows marked dilatation and superior herniation of the enlarged fourth ventricle *(arrow)*. Note also the dilated anterior recess of third ventricle *(asterisk)* and thinning of corpus callosum *(arrowheads)*. (B) Coronal T2-weighted MR image shows fourth ventricular enlargement and supratentorial herniation *(arrow)* with cystic hydrocephalus as a result of resolving intraventricular infection.

rate of infection in infants is much higher (10%–20%). Most infections present within 2 months of surgery, indicating that they occur during the surgery. Shunt infection can also occur from other abdominal surgical procedures, such as bladder augmentation and gastrostomy tube placement.

## EVALUATION OF SHUNT MALFUNCTION

Diagnosis of shunt malfunction is based primarily on the clinical signs and symptoms with which the patient presents. The shunts may be evaluated by static or dynamic methods (Box 32.6).

Plain radiographs of the shunt and CT or MRI of the head are the primary radiologic investigations for evaluating shunt malfunction. The advantages of CT are that it is widely available and relatively inexpensive, and it allows quick examination and reproducible assessment of ventricular size and catheter position. However, children with hydrocephalus undergo many imaging procedures in their lifetime, so minimizing radiation exposure is especially important to reduce potential risks.

MRI is an alternative to CT for shunt evaluation, often performed with steady-state gradient recalled sequence and balanced SSFP sequences (Fig. 32.14). Fast MRI sequences such as single-shot or half-Fourier T2-weighted sequences and T1-weighted spoiled gradient sequences reduce the scan time dramatically, decreasing or eliminating the need for sedation. These sequences provide reliable visualization of the catheter, assessment of ventricular size, and anatomic detail without the need for sedation.[18]

**BOX 32.6** Evaluation of Shunt Malfunction

Static methods
Plain radiographs
Imaging: CT, MRI, US
Dynamic methods
Shunt injection studies (shuntogram)
Nuclear medicine studies
Others: Cine phase contrast MRI, Doppler

Plain radiographs of the entire shunt are obtained with frontal and lateral views of the skull, and with frontal views of the chest and abdomen. These assess for discontinuity or migration of the shunt. Calcification along the tubing is common in old shunts, which are prone to fracture (see e-Fig. 32.11). Abdominal complications such as mass effect from a pseudocyst, bowel perforation, and adhesions resulting in bowel obstruction are also evaluated on plain radiographs. If preperitoneal placement of distal tubing is suspected, with tight coiling of the peritoneal catheter, a lateral radiograph should be obtained.[17]

Imaging of the head is performed to assess changes in the shape and size of the ventricles as well as any other collections or loculated compartments. Imaging is usually obtained only when the patient is sick, so there is often no valid baseline comparison when the patient is well. The position and course of the catheter can be assessed. Dilation of ventricles compared with previous images is the clearest sign of shunt malfunction. However, some patients with shunt malfunction may demonstrate little if any enlargement, and some may have small ventricles. Therefore the ventricular size alone, especially in the absence of previous studies, may be misleading. Enlarged ventricles are seen in approximately 70% of patients with mechanical obstruction and 30% of those with shunt infection.

The subset of symptomatic patients with little or no change in ventricular size, or with small ventricles, may benefit from shunt tapping and, rarely, from a shuntogram. Tapping of the shunt is also helpful for CSF sampling if shunt infection is suspected. The shunt is tapped proximal to the reservoir with a 25-gauge butterfly needle after meticulous preparation of the site. Free flow of CSF may indicate adequate patency of the proximal catheter. Manometric measurements can also be performed. Contrast can be injected into the valve chamber at the time of shunt tapping and a shuntogram obtained with radiographs taken at 1 and 15 minutes. Shunt injection studies are more helpful in diagnosing distal malfunction, and peritoneal spill of contrast proves patency of the distal tubing. The results of the shuntogram may be inconclusive in patients with partially obstructed shunts, and there is a 25% to 40% rate of false-positive results in patients with proximal malfunction (i.e., failure of proximal CSF to pass through the distal tubing despite patent tubing). Similarly, radioisotope studies are occasionally used to assess shunt patency and obtain physiologic information about CSF flow through the shunt.

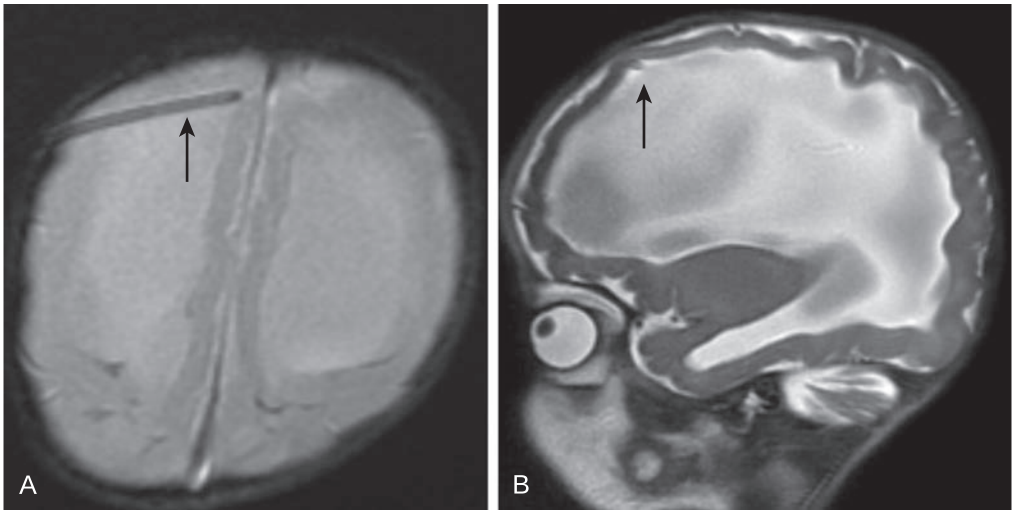


**Figure 32.14. Shunt evaluation.** (A) Axial steady-state gradient sequence demonstrates the course of the catheter in the right lateral ventricle *(arrow)*. (B) Sagittal balanced steady-state free precession (SSFP) sequence demonstrates the tip of the catheter within an enlarged lateral ventricle *(arrow)*.

## Slit Ventricle Syndrome

In general, small ventricles in a child with a shunt are good, and large ventricles are bad. A small subset of 1% to 5% of patients with very small, or slit, ventricles becomes symptomatic with acute or chronic headaches, nausea, vomiting, and lethargy. These patients have been lumped together under the term slit ventricle syndrome (Fig. 32.15). This terminology is confusing as it has been used for multiple clinical entities.[19] At one end of the spectrum is a child with small ventricles who is very sick as a result of intracranial hypertension. At the other end of the spectrum is an asymptomatic child with a harmless and inconsequential CT finding.

## ENDOSCOPIC THIRD VENTRICULOSTOMY

There is increasing interest in treating hydrocephalus with endoscopic procedures (Box 32.7). The major attraction is to give these children freedom from lifelong dependency on shunts and their numerous inherent complications. Endoscopic third ventriculostomy (ETV) is most often used for obstructive hydrocephalus, where the success rate is reportedly 60% to 70%. The technique involves using an endoscope to perforate the floor of the third ventricle just anterior to the mammillary bodies, thereby establishing communication between the ventricles and cisterns. Endoscopic fourth ventricular aqueductoplasty, with or without stent placement, has recently been described as an alternative method when ETV is not feasible.[20] This is especially useful in patients with a trapped fourth ventricle. In patients who have an intrathird ventricular tumor causing obstruction of the foramen of Monro or of the mouth of the aqueduct, direct endoscopic removal of the tumor may effectively relieve the obstruction. Large intrathird ventricular arachnoid cysts can be endoscopically fenestrated and fulgurated to reconstruct the floor of the third ventricle and restore the CSF pathways.

On postoperative imaging, there is a gradual decrease in the size of the ventricles over months to years. This is contrary to postshunting imaging, when there is rapid reduction in size of the ventricles. The third ventricle responds early and decreases in size over 3 months, while the lateral ventricles decrease over 2 years. It is therefore difficult to assess for third ventriculostomy patency on the basis of ventricular size.[21]

Fast spin echo T2-weighted sequences are sensitive in assessing patency of the third ventriculostomy. Midline sagittal images show hypointensity in the region of the ventriculostomy as a result of CSF-related flow-void if the ventriculostomy is patent (Fig. 32.16). Balanced SSFP images can also demonstrate closure of the ventriculostomy by the absence of a defect. Please note that the flow void may not be detected using balanced SSFP images.

Phase contrast cine MRI is helpful to assess ventriculostomy patency.[9] Using cardiac gating, phase contrast images can demonstrate pulsatile CSF flow through the ventriculostomy and determine flow velocity. Velocity ratios between the flow in prepontine cistern from the ventriculostomy and posterior cervical spine have been used for assessing the patency of the third ventriculostomy. A caveat of phase contrast cine MRI is the presence of turbulent or pulsatile flow secondary to third ventricular floor motion (e-Fig. 32.17). Third ventriculostomy may fail if the liliquist membrane is not perforated (e-Fig. 32.18).

**BOX 32.7** Common Indications for Third Ventriculostomy

Delayed-onset aqueductal obstruction CSF shunt obstruction in patients with obstructive hydrocephalus
Older patients with spina bifida and blocked shunts
Obstructive hydrocephalus caused by pineal and posterior fossa tumors

KEY POINTS

- Hydrocephalus is one of the most common sequelae of any insult to a child's CNS.
- The most common cause of macrocephaly in infants is benign extraaxial collections of infancy.
- US of the head is a useful initial examination if the anterior fontanelle is open. After fontanelle closure, CT or MRI is required for evaluation of the ventricular system and shunts.
- The most reliable sign of hydrocephalus is enlargement of the anterior and posterior recesses of the third ventricle.

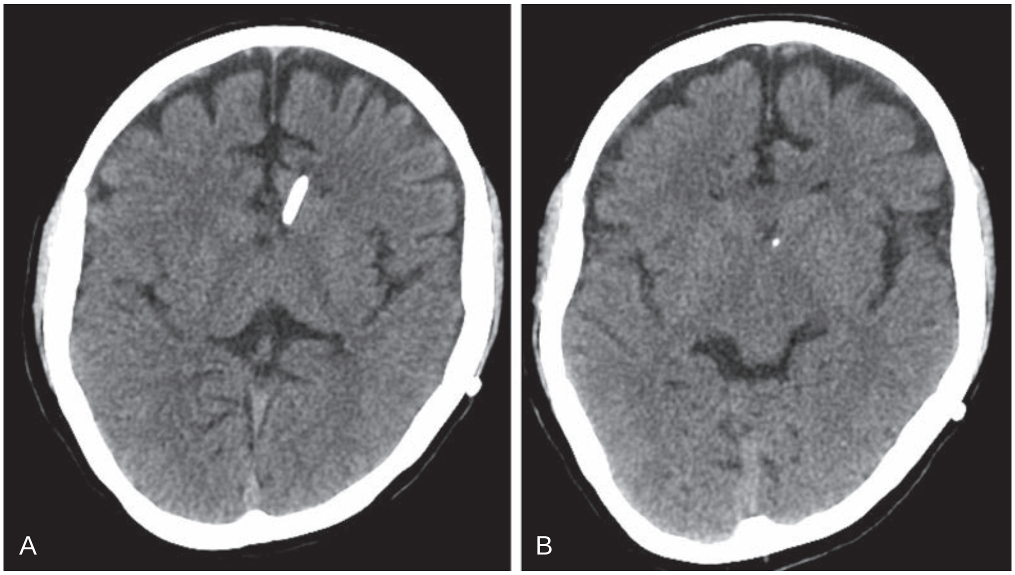

**Figure 32.15. Slit ventricle syndrome.** CT images in a 13-year-old with shunted hydrocephalus with the tip of VP shunt in left frontal horn (A) resulting in slit-like ventricles (B).

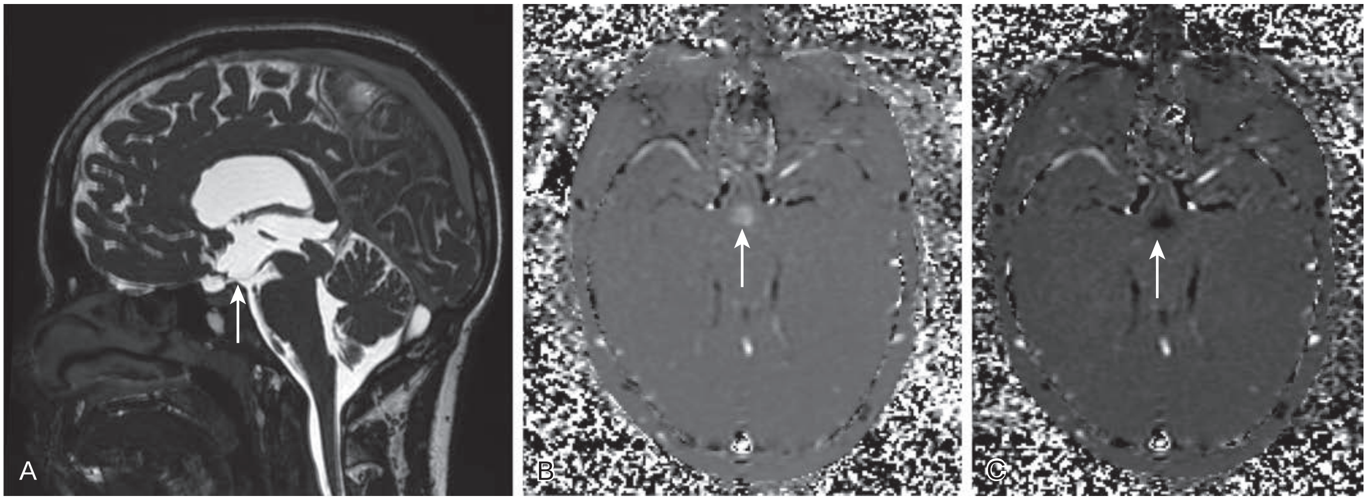
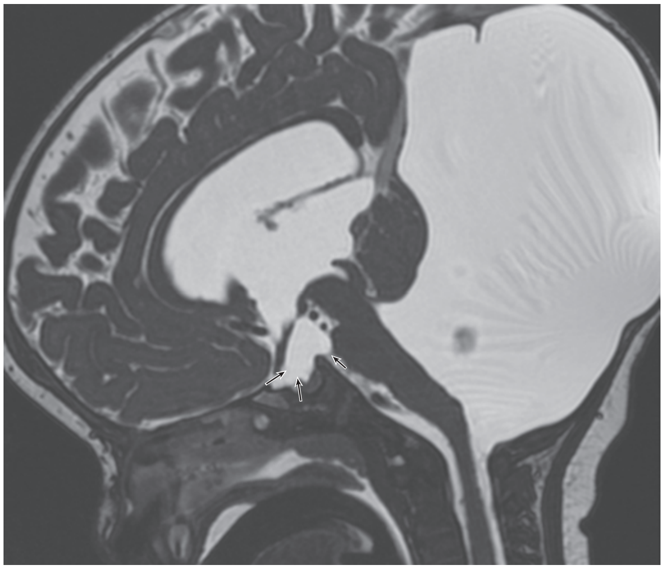


**e-Figure 32.17. Failed third ventriculostomy.** (A) Midsagittal T2-weighted MR image through the third ventricle floor demonstrates absence of the third ventriculostomy defect. (B and C) Axial phase contrast image may be deceiving as the signal noted is secondary to the on-off motion of the floor of third ventricle and not flow of cerebrospinal fluid through the third ventricle floor.



**e-Figure 32.18. Failed third ventriculostomy.** Sagittal steady-state free precession MR image in a patient with Dandy-Walker malformation and failed third ventriculostomy demonstrates failure to perforate the liliquist membrane *(arrows)*.

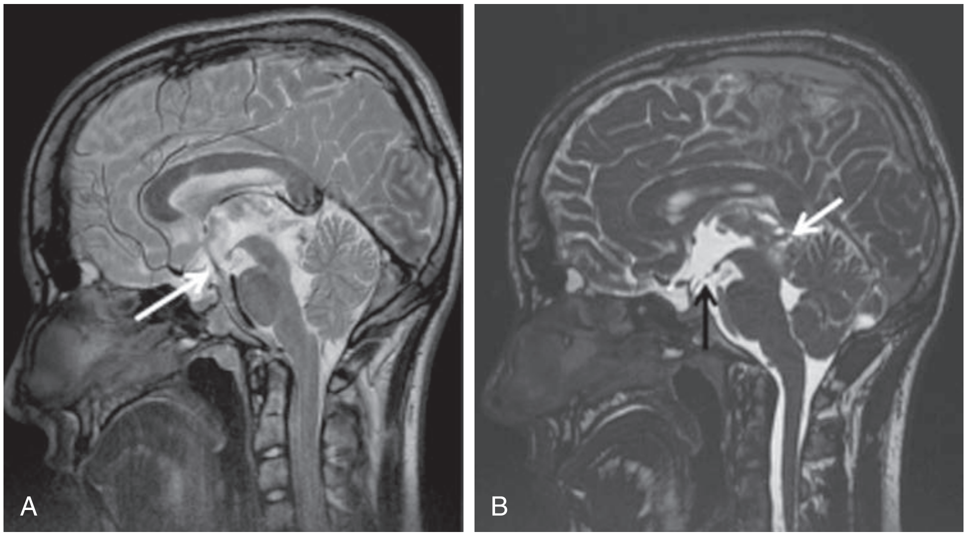


**Figure 32.16. Third ventriculostomy.** (A) Midsagittal T2-weighted image through the third ventricle at 2-mm section thickness and 512 × 512 matrix demonstrates the flow void through the ventriculostomy in a patient affected by tectal tumor. (B) Midsagittal balanced steady-state free precession image shows the ventriculostomy defect *(dark arrow)* and the tectal tumor *(white arrow)*.

# Inherited Metabolic and Neurodegenerative Disorders

Giulio Zuccoli and Kim M. Cecil

## INHERITED METABOLIC BRAIN DISORDERS

Inherited metabolic brain disorders produce changes in brain metabolism and structure as a result of genetic mutations. Clinically, children with metabolic brain disorders often present with nonspecific symptoms, such as hypotonia, seizures, and developmental delay, which often makes diagnosis difficult. A combination of neurologic symptoms with and without visceral manifestation and age at onset of symptoms often are important factors indicating an underlying inherited metabolic brain disorder. The diagnosis traditionally has been accomplished by laboratory analyses of biologic specimens (urine or blood) and tissue (muscle or fibroblast) biopsy. However, the increased availability of imaging studies incorporating advanced techniques, specifically magnetic resonance imaging (MRI) with diffusion-weighted imaging (DWI) and MR spectroscopy (MRS), offers more diagnostic features, thereby improving the ability to recognize disease patterns and classify patients for metabolic and genetic investigations with candidate diseases prioritized from imaging and clinical features. Although the number of metabolic brain disorders is significant, neuroradiologists should be able to recognize the features of the key disorders outlined in this chapter.

Because these disorders generally are progressive, the classification of neurodegenerative features also is used appropriately as imaging findings worsen—for example, cortical volume loss, gliosis, and hypomyelination. The generic term "hypomyelination" is used to describe abnormal myelination, whether it is improperly formed or altered after formation, because distinguishing demyelination from dysmyelination is a pathologic diagnosis not distinguished objectively by imaging alone. Because these diseases frequently or primarily involve the white matter, they often are put into a general category of leukodystrophy. The known leukodystrophies are genetic diseases involving defects in oligodendroglia function and myelinogenesis. The term "leukodystrophy" describes a chronic, progressive, destructive process of the white matter within the central nervous system (CNS) characterized by a metabolic disorder of myelin sheath formation and maintenance, often with a slow but progressive loss of nervous system structures. The clinical course is progressive and typically includes mental retardation with signs of long tract dysfunction, such as pyramidal and cerebellar disturbances, with abnormal conduction of visual auditory and somatic sensory input as measured by evoked potentials.

In young children, more heavily T2-weighted sequences with a repetition time of 2,500 to 3,000 msec and time to echo (TE) of 100 to 200 msec should be obtained. It is difficult to evaluate the degree of myelination in children younger than 2 years because the normal myelination process does not begin until the fifth month of fetal gestation and proceeds rapidly during the first 2 years of life. Fluid-attenuated inversion recovery (FLAIR) imaging may be misleading before 18 months of age because it sharpens the difference between myelinated and even physiologically unmyelinated white matter. By 2 years of age, 90% of all the white matter fiber tracts have become myelinated, but myelination is incomplete, and some variability exists in the meeting of various milestones. In children younger than 2 years, destructive processes may not be adequately demonstrated on T2-weighted images. However, by 2 years of age and older, destructive processes resulting in white matter fiber abnormal T2 hyperintensity is demonstrated in the leukodystrophies. In recent reports, contrast enhancement has been helpful because many of the newly recognized leukodystrophies have disruption of the blood-brain barrier. The end-stage appearance of all the leukodystrophies on computed tomography (CT) or MRI is marked generalized volume loss. Most leukodystrophies involve the central white matter in a symmetric fashion; Canavan disease is the exception. Patients with delayed myelination or symmetrically abnormal myelination from an earlier insult may have an imaging appearance similar to an early leukodystrophy, making radiologic diagnosis less accurate. Symptoms in these children may be similar to those in children with a leukodystrophy.

DWI provides information about the gross mobility of water (see also Chapter 26). Cytotoxic and myelinic edema can produce a hyperintense signal of diffusion-weighted images. To distinguish this signal from a hyperintense signal arising from T2 weighting, an apparent diffusion coefficient (ADC) map can be generated. On an ADC map, cytotoxic and myelinic edema generates a hypointense signal, indicating a restriction of water diffusion. Diffusion tensor imaging holds the promise of providing white matter microstructural details by revealing the magnitude and direction of water movement along the axons. As myelination is detected, water molecules demonstrate reduced diffusivity and increased diffusion anisotropy. Abnormal myelin can be quantitated from changes in these properties using measures such as mean diffusivity and fractional anisotropy.

MRS is useful in the evaluation of metabolic diseases in children because many laboratory studies that test for systemic metabolic diseases often do not reveal abnormalities, especially when the metabolic derangements are within localized regions of the brain. When CNS involvement is demonstrated on anatomic MR images, the MRS spectrum is usually abnormal. In some metabolic disorders, abnormalities are observed in the MRS spectrum in the absence of anatomic MR abnormalities (e.g., creatine deficiency syndromes).

In the evaluation of a possible metabolic disorder, acquiring both short- and long-echo spectra offers the most diagnostic utility. The use of a short echo time allows for the detection of metabolites with faster T2 decay, especially glutamine/glutamate and myo-inositol (mI). The long-echo spectra have a flatter baseline, which is important for the detection of lactate, a double resonance at 1.3 ppm. Identification of lactate within cerebral tissue typically reflects mitochondrial impairment and should raise suspicion of mitochondrial disease, with confirmation by a muscle biopsy and possibly laboratory analyses of serum or cerebrospinal fluid (CSF). Mitochondrial enzyme systems are involved in many key cell metabolic pathways—oxidative phosphorylation, oxidation of fatty acids and amino acids, and processes involved in the Krebs cycle and part of the urea cycle. Abnormal lactate accumulation detected in patients with mitochondrial disorders can reflect the following mechanisms: (1) a high degree of nonoxidative glycolysis resulting from impaired oxidative energy metabolism, (2) the use of anaerobic metabolism by infiltrating macrophages, and (3) damage to or loss of viable neuroaxonal tissue.

## Abstract:

Inherited metabolic brain disorders cause changes in brain metabolism and structure due to genetic mutations involving enzymatic function, protein, and mitochondrial expression. In inherited metabolic brain disorders, the presentation symptoms are often non-specific. In lysosomal storage disorders, mechanical disruption of the cell results from storage of nondegradable material leading to cellular dysfunction. Lysosomal disorders primarily targeting the gray matter include the gangliosidoses, mucopolysaccharidoses, and neuronal ceroid lipofuscinoses (NCLs). Metachromatic leukodystrophy (MLD) and Krabbe disease also known as Globoid Cell Leukodystrophy, demonstrate abnormalities in the white matter, cranial nerves and cauda equina roots. Mitochondrial disorders usually refer to disorders of the mitochondrial respiratory chain resulting in impaired respiratory chain function and reduced adenosine triphosphate production. Imaging findings of mitochondrial disorders include bilateral symmetrical signal intensity alterations involving the brainstem and the basal ganglia with restricted diffusion on DWI (Leigh Syndrome, Subacute Necrotizing Encephalomyelopathy). Brain MRIs of patients suffering from mitochondrial encephalomyopathy, lactic acidosis, and stroke-like symptoms (MELAS) are characterized by abnormal signal involving the brain cortex in a non-territorial distribution mimicking cortical infarcts on DWI. Magnetic Resonance Spectroscopy (MRS) can be very useful during the early phases of a mitochondrial disorder since it may reveal metabolic anomalies in an otherwise normal appearing brain parenchyma. In patients affected by neurodegeneration with brain iron accumulation (NBIA), Susceptibility Weighted Imaging discloses iron accumulation within the basal ganglia and cerebellar atrophy.

## Keywords:

Mitochondrial Diseases
Leigh Syndrome
Lysosomal storage disease
Magnetic Resonance Spectroscopy
Magnetic Resonance Imaging
Glutaric Aciduria
Menkes Disease

This chapter includes as a reference a large listing of metabolic brain diseases encountered in imaging (Tables 33.1 to 33.10). For convenience, the recognized metabolic or genetic defect and the patterns of inheritance are summarized. However, because of space limitations, the following discussion will address only the most commonly encountered of these rare disorders.

## LYSOSOMAL STORAGE DISEASES

Many neurodegenerative diseases are characterized by the accumulation of nondegradable molecules in cells or at extracellular sites in the brain. Lysosomes are intracellular organelles responsible for degrading lipids, proteins, and complex carbohydrates. In most lysosomal disorders, the genetic mutation resulting in the absence or deficiency of an enzyme or protein is known and functionally understood. In most, the substrate for the defective enzyme builds up, leading to intralysosomal storage. Although the diseases are complex, storage of nondegradable material primarily leads to neuronal dysfunction rather than neuronal loss. Exceptions are the differential loss of Purkinje cells that characterize several storage diseases (including Niemann-Pick disease type C) and the massive cell loss that occurs in the neuronal ceroid lipofuscinoses (NCLs). It is not known whether the storage material affects cellular function only when it begins to accumulate in extralysosomal sites or if problems in cell homeostasis are triggered while the material is still confined to the lysosome.

Lysosomal disorders typically are inherited as autosomal-recessive traits, usually afflict infants and young children, and are untreatable. The collective frequency of lysosomal storage diseases is estimated to be approximately 1 in 8,000 live births, with some occurring at higher frequency in select populations.

**TABLE 33.1** Summary of Metabolic Disorders Encountered in the Pediatric Neuroimaging Setting: Adrenoleukodystrophy—Argininosuccinate Lyase Deficiency

| Disorder | Gene Name; Abbreviation (Locus) | OMIM | Mode of Inheritance | Primary Classification | Primary Defect |
|---|---|---|---|---|---|
| Neonatal adrenoleukodystrophy | *PTS1* and Peroxin genes | 202370 | Autosomal recessive | Peroxisomal | Deficiency in oxidizing VLCFA |
| X-linked adrenoleukodystrophy | Adrenoleukodystrophy; *ALD/ABCD1* (Xq28) | 300100 | X-linked | Peroxisomal | Inability to oxidize VLCFA into shorter chain fatty acids |
| Alexander disease | Glial fibrillary acidic protein; *GFAP* (17q21.31) | 203450 | Autosomal dominant | Leukodystrophy | Presence of Rosenthal fibers, glial fibrillary acid proteins in astrocytes |
| Alpers disease | Nuclear encoded mitochondrial DNA polymerase-gamma; *POLG* (15q26.1) | 203700 | Autosomal recessive | Mitochondrial | Respiratory chain abnormalities |
| Argininemia (arginase deficiency) | Arginase; *ARG1* (6q23.2) | 207800 | Autosomal recessive | Urea cycle | Defect encoding enzyme *ARG1* |
| Argininosuccinate lyase deficiency | Argininosuccinate lyase; *ASL* (7q11.21) | 207900 | Autosomal recessive | Urea cycle | Defect encoding enzyme *ASL* |

**TABLE 33.2** Summary of Metabolic Disorders Encountered in the Pediatric Neuroimaging Setting: Biotinidase Deficiency—Citrullinemia

| Disorder | Gene Name; Abbreviation (Locus) | OMIM | Mode of Inheritance | Primary Classification | Primary Defect |
|---|---|---|---|---|---|
| Biotinidase deficiency | Biotinidase gene; *BTD* (3p25.1) | 253260 | Autosomal recessive | Organic or amino acid | Biotinidase deficiency with elevated lactate, β-hydroxyisovalerate |
| Canavan disease | Aspartoacylase; *ASPA* (17p13.2) | 271900 | Autosomal recessive | Leukodystrophy | Enzyme deficiency; aspartoacylase deficiency; inability to metabolize NAA into aspartate and acetate |
| Carbamoyl phosphate synthetase I deficiency | Carbamoyl phosphate synthetase I; *CPS1* (2q34) | 237300 | Autosomal recessive | Urea cycle | Defect encoding enzyme; *CPS1* enzyme deficiency; catalyzes first committed step in the urea cycle |
| Cerebrotendinous xanthomatosis | 27-sterol hydroxylase: *CYP27* (2q35) | 213700 | Autosomal recessive | Lysosomal | Enzyme deficiency—sterol 27-hydroxylase |
| Childhood ataxia with diffuse CNS hypomyelination (vanishing white matter) | *EIF2B1-5* (12q24.31, 14q24.3, 1p34.1, 2p23.3, 3q27) | 603896 | Autosomal recessive | Leukodystrophy | Gene defect in eukaryotic translation initiation factor (mRNA translated into proteins) |
| Citrullinemia, classic (argininosuccinate synthetase deficiency) | Argininosuccinate synthetase; *ASS* (9q34.11) | 215700 | Autosomal recessive | Urea cycle | Gene defect encoding enzyme argininosuccinate synthetase |

**TABLE 33.3** Summary of Metabolic Disorders Encountered in the Pediatric Neuroimaging Setting: Cockayne Disease—Creatine Deficiency

| Disorder | Gene Name; Abbreviation (Locus) | OMIM | Mode of Inheritance | Primary Classification | Primary Defect |
|---|---|---|---|---|---|
| Cockayne disease | Excision-repair cross-complementing group 8 gene; *ERCC8* (5q12.1) | 216400 | Autosomal recessive | Miscellaneous | Defective DNA repair |
| Congenital muscular dystrophies | Fukuyama: fukutin; *FCMD* (9q31.2) | 253800 | Autosomal recessive | Congenital muscular dystrophy | Defect in dystrophin-associated proteins |
|  | Merosin-deficient: laminin alpha-2-gene; *LAMA2* (6q22.33) | 607855 | Autosomal recessive | Congenital muscular dystrophy | Absence of merosin in muscle |
|  | Duchenne: dystrophin *DMD* (Xp21.2–p21.1) | 310200 | X-linked recessive | Congenital muscular dystrophy | Absence of dystrophin in muscle |
| Creatine deficiency—creatine transporter defect | *SLC6A8* (Xq28) | 300352 | X-linked | Miscellaneous | Creatine transport impaired to the brain |
| Creatine deficiency—arginine:glycine amidinotransferase deficiency | *GATM* (15q21.1) | 612718 | Autosomal recessive | Miscellaneous | Creatine synthesis impaired |
| Creatine deficiency—guanidinoacetate methyltransferase deficiency | *GAMT* (19p13.3) | 612736 | Autosomal recessive | Miscellaneous | Creatine synthesis impaired |

**TABLE 33.4** Summary of Metabolic Disorders Encountered in the Pediatric Neuroimaging Setting: Ethylmalonic Aciduria—Hydroxyglutaric Aciduria

| Disorder | Gene Name; Abbreviation (Locus) | OMIM | Mode of Inheritance | Primary Classification | Primary Defect |
|---|---|---|---|---|---|
| Ethylmalonic aciduria | *ETHE1* (19q13.31) | 602473 | Autosomal recessive | Organic or amino acid | Ethylmalonic aciduria with cytochrome c oxidase deficiency in skeletal muscle; lactic acidemia |
| Galactosemia | galactose-1-phophate uridylyltransferase; *GALT* (9p13.3) | 230400 | Autosomal recessive | Miscellaneous | Defect encoding galactose-1-phosphate uridyltransferase |
| Globoid cell leukodystrophy (Krabbe disease) | Galactocerebrosidase; *GALC* (14q31.3) | 245200 | Autosomal recessive | Lysosomal | Enzyme deficiency—galactocerebroside beta-galactosidase deficiency |
| Glutaric aciduria | Type I glutaryl-CoA-dehydrogenase; *GCDH* (19p13.13) | 231670 | Autosomal recessive | Organic or amino acid | Enzyme deficiency altering metabolism of lysine, hydroxylysine, tryptophan |
| Glutaric aciduria | Type II multiple acyl CoA-dehydrogenase genes (19q13.41, 15q24.2–q24.3, 4q32.1) | 231680 | Autosomal recessive | Organic or amino acid | Disorder of fatty acid, amino acid, and choline metabolism |
| Homocystinuria | Cystathionine β-synthase; *CBS* (21q22.3) | 236200 | Autosomal recessive | Organic or amino acid | Increased urinary homocystine and methionine |
| L-Hydroxyglutaric aciduria | *L2HGDH* 14q21.3 | 236792 | Autosomal recessive | Organic or amino acid | Increase of L-2-hydroxy glutaric acid in urine |

Lysosomal disorders primarily affecting gray matter include the gangliosidoses, mucopolysaccharidoses, and NCLs. Two of the more common lysosomal disorders, metachromatic leukodystrophy (MLD) and Krabbe disease, demonstrate abnormalities in white matter. However, broader involvement of gray and white matter often occurs in later stages of lysosomal disease progression.

## Gangliosidoses

The gangliosidoses are divided into two groups, referred to as GM1 and GM2. In the GM1 group, the primary enzyme deficiency is in β-galactosidase, and in the GM2 group there is a hexosaminidase deficiency.

**TABLE 33.5** Summary of Metabolic Disorders Encountered in the Pediatric Neuroimaging Setting: Isovaleric Acidemia—Ketothiolase Deficiency

| Disorder | Gene Name; Abbreviation (Locus) | OMIM | Mode of Inheritance | Primary Classification | Primary Defect |
|---|---|---|---|---|---|
| Isovaleric acidemia | Isovaleryl CoA dehydrogenase; *IVD* (15q15.1) | 243500 | Autosomal recessive | Organic or amino acid | Accumulation of isovaleric acid |
| Juvenile Huntington disease | Huntington; *HTT* (4p16.3) | 143100 | Autosomal dominant | Miscellaneous | Neural cell death from production of quinolinic acid |
| Kearns-Sayre syndrome | Various mitochondrial deletions | 530000 | Mitochondrial | Mitochondrial | Lactic acidosis, decreased Co-Q |
| Kernicterus | Uridine diphosphate-glucuronosyltransferase; *UGT1A1* (2q37.1) | 237900 | Autosomal recessive | Miscellaneous | Hyperbilirubinemia |
| b-Ketothiolase deficiency | Acetyl-Co-A-acetyltransferase 1; *ACAT1* (11q22.3) | 203750 | Autosomal recessive | Organic or amino acid | Increased urinary 2-methyl-3-hydroxybutyric acid |
| Leigh syndrome | Nuclear and mitochondrial-encoded genes involved in energy metabolism | 256000 | Autosomal recessive, mitochondrial | Mitochondrial | Lactic acidosis |
| Leukoencephalopathy with brainstem and spinal cord involvement with elevated lactate | *DARS2* (1q25.1), mitochondrial aspartyl-tRNA synthetase | 611105 | Autosomal recessive | Leukodystrophy | Lactic acidosis |
| Lowe disease | Phosphatidylinositol polyphosphate 5-phosphatase; *OCRL* (Xq26.1) | 309000 | X-linked recessive | Organic or amino acid | Increased phosphatidylinositol-4,5-biphosphate |

*OMIM,* Online Mendelian Inheritance in Man Database.

**TABLE 33.6** Summary of Metabolic Disorders Encountered in the Pediatric Neuroimaging Setting: Maple Syrup Urine Disease—Molybdenum Cofactor Deficiency

| Disorder | Gene Name; Abbreviation (Locus) | OMIM | Mode of Inheritance | Primary Classification | Primary Defect |
|---|---|---|---|---|---|
| Maple syrup urine disease | Mutations in the catalytic subunit genes of the branched chain alpha ketoacid dehydrogenase complex; *BCKD, DBT, DLD* (19q13.2, 6q14.1, 1p21.2) | 248600 | Autosomal recessive | Organic or amino acid | Defect in the genes of the branched chain alpha ketoacid dehydrogenase blocking oxidative decarboxylation |
| MELAS | Multiple mitochondrial genes | 540000 | Mitochondrial | Mitochondrial | Lactic acidosis |
| Menkes disease | Cu(2+) transporting ATPase, alpha polypeptide; *ATP7A* (Xq21.1) | 309400 | X-linked recessive | Mitochondrial | Low copper |
| Metachromatic leukodystrophy | Arylsulfatase A; *ASA/ARSA* (22q13.33) | 250100 | Autosomal recessive | Lysosomal | Decreased arylsulfatase A, *ARSA* activity |
| Methylmalonic aciduria | Methylmalonyl-CoA mutase; *MUT* (6p12.3) | 251000 | Autosomal recessive | Organic or amino acid | Defect in methylmalonyl-CoA mutase; disorder of methylmalonate and cobalamin metabolism |
| Molybdenum cofactor deficiency | Molybdenum cofactors; *MOCS1* (6p21.3); *MOCS2* (5q11.2); gephyrin *GPHN* (14q23.3) | 252150 | Autosomal recessive | Miscellaneous | Increased urinary sulfite, taurine, and xanthine |

*ATPase,* Adenosine triphosphatase; *MELAS,* mitochondrial encephalomyopathy, lactic acidosis, and strokelike symptoms; *OMIM,* online Mendelian Inheritance in Man Database.

## GM1 Gangliosidosis

Three types of GM1 gangliosidosis exist: type I (infantile), type II (late infantile/juvenile), and type III (adult). An intermediate form between infantile and juvenile has been reported.[1] The clinical presentation of GM1 gangliosidosis typically occurs in infancy; its features include seizures, decerebrate posturing, pitting edema of the face, hypotonia, developmental delay, hepatosplenomegaly, macrocephaly, and cherry-red spots involving the macula of the retina. Additional features include broad digits, kyphoscoliosis, skeletal dysplasia with widening of the metaphyses, and dermal pigmentary lesions.[2] The course is progressive, with death common by 2 years of age. The juvenile form presents during the second year of life with progressive ataxia, but without many features of the infantile variety.

The underlying deficiency of β-galactosidase results in accumulation of GM1 ganglioside in both gray and white matter of the cerebrum, brainstem, cerebellum, and spinal cord. Results of cerebral MRI initially are normal, with subsequent loss of cortical gray matter. Secondary changes to the white matter manifest later and typically exhibit an abnormal, nonspecific, patchy, hyperintense T2 signal within the centrum semiovale. Hypointensity of the thalami on T2-weighted images also has been reported.[3]

## GM2 Gangliosidosis

The most common forms of GM2 gangliosidoses include Tay-Sachs disease and Sandhoff disease. Tay-Sachs disease arises with β-*N*-acetylhexosaminidase-A isoenzyme deficiency in Jewish children

**TABLE 33.9** Summary of Metabolic Disorders Encountered in the Pediatric Neuroimaging Setting: Propionic Aciduria—Sandhoff Disease

| Disorder | Gene Name; Abbreviation (Locus) | OMIM | Mode of Inheritance | Primary Classification | Primary Defect |
|---|---|---|---|---|---|
| Propionic aciduria | Propionic-CoA carboxylase; *PCCB* (3q22.3) and *PCCA* (13q32.3) | 232050 | Autosomal recessive | Organic or amino acid | Defect in propionic-CoA carboxylase |
| Pyruvate decarboxylase deficiency | E1-alpha polypeptide of pyruvate dehydrogenase; *PDHA1* (Xp22.12) | 312170 | X-linked | Mitochondrial | Defect in first of 3 enzymes in PDH-glycolysis and TCA cycle |
| Pyruvate dehydrogenase deficiency | Multiple genes of the pyruvate dehydrogenase complex | Multiple | Multiple | Mitochondrial | Defect in enzymes coupling glycolysis and TCA cycle for conversion of pyruvate to acetyl-CoA |
| Refsum disease | Infant: *PEX1* 7q21.2, *PXMP3* 8q21.11, *PEX26* 22q11.21 Adult: *PHYH* 10p13, *PEX7* 6q23 | 266510, 266500 | Autosomal recessive | Peroxisomal | Phytanic acid oxidase deficiency |
| Ribose 5-phosphate isomerase deficiency | Ribose 5-phosphate isomerase deficiency; *RPIA* 2p11.2 | 608611 | Autosomal recessive | Leukodystrophy | Deficiency in ribose 5-phosphate isomerase |
| Salla disease | *SLC17A5* (6q13) | 604369 | Autosomal recessive | Lysosomal | Defect in sialic acid transport at the lysosomal membrane |
| Sandhoff disease | Hexosaminidase; *HEXB* 5q13.3 | 268800 | Autosomal recessive | Lysosomal | Defect in beta subunit of hexosaminidase A and B isoenzymes |

**TABLE 33.10** Summary of Metabolic Disorders Encountered in the Pediatric Neuroimaging Setting: Sjögren-Larsson Syndrome—Zellweger Syndrome

| Disorder | Gene Name; Abbreviation (Locus) | OMIM | Mode of Inheritance | Primary Classification | Primary Defect |
|---|---|---|---|---|---|
| Sjögren-Larsson syndrome | Fatty aldehyde dehydrogenase; ALDH3A2 (17p11.2) (17p11.2) | 270200 | Autosomal recessive | Lysosomal | Fatty alcohol oxidation failure |
| Succinate semialdehyde dehydrogenase deficiency | Succinic semialdehyde dehydrogenase; *ALDH5A1* (6p22.3) | 271980 | Autosomal recessive | Organic or amino acid | Succinic semialdehyde dehydrogenase deficiency with 4-hydroxybutyricaciduria |
| Tay-Sachs disease | Hexosaminidase A; *HEXA* 15q23 | 272800 | Autosomal recessive | Lysosomal | Defect in alpha subunit of hexosaminidase A |
| Vacuolating megalencephalic leukoencephalopathy (with subcortical cysts, MLC) | *MLC1* (22q13.33) | 604004 | Autosomal recessive | Leukodystrophy | Defect in MLC1 |
| Walker-Warburg syndrome | protein O-mannosyltransferase-1; *POMT1* (9q34.13) | 236670 | Autosomal recessive | Congenital muscular dystrophy | Elevated creatine kinase; defective glycosylation of alpha-dystroglycan |
| Wilson disease | *ATP7B* (13q14.3) | 277900 | Autosomal recessive | Miscellaneous | Defect in copper transport |
| Zellweger syndrome | Several genes involved in peroxisome biogenesis, *PEX1* (7q21.2) | 214100 | Autosomal-recessive | Peroxisomal | Decreased dihydroxyacetone phosphate acyltransferase (DHAP-AT) activity |

*OMIM,* Online Mendelian Inheritance in Man Database.

Data from The Johns Hopkins University, Online Mendelian Inheritance in Man (OMIM), McKusick-Nathans Institute for Genetic Medicine, Johns Hopkins University (Baltimore, MD) and the National Center for Biotechnology Information, National Library of Medicine (Bethesda, MD), 2000. Available at http://www.ncbi.nlm.nih.gov/omim/.*

of eastern European descent. Onset is usually before the age of 1 year with irritability, hypotonia, seizures, blindness, and cherry-red spots on the macula in 90% of patients. Death usually results by 2 to 3 years of age. Sandhoff disease is attributed to a deficiency of A and B isoenzymes of hexosaminidase. The clinical course is similar to that of Tay-Sachs disease. There is visceral involvement, including hepatomegaly and cardiac and renal tubular abnormalities. Brain MRI in the early stages demonstrates increased T2 signal in the basal ganglia, particularly with enlarged caudate nuclei. Later, cortical and deep gray matter volume loss occurs with patchy increases in T2 signal in the white matter. Thalamic involvement is more reflective of Sandhoff disease. In adult-onset Sandhoff disease, lower motor neuron involvement has been reported. Cerebellar atrophy is variable and does not correlate with clinical severity.[4] In persons with Tay-Sachs disease, the thalami may be hypointense on T2-weighted images and hyperintense on T1-weighted images because of calcium deposition. T2-weighted hyperintensity in cerebral matter may indicate abnormal myelin production and active demyelination.[5] Elevated levels of cytokines have been reported, possibly indicating inflammation as a contributing factor to the progression of gangliosidosis.[6] In the B1 variant of GM2 gangliosidosis, the thalami may appear hyperdense/hyperintense on CT and T1-weighted MRI and show T2-hypointense signal in the ventral thalami and a hyperintense signal in the posteromedial thalami. Other findings in this variant include involvement of the medullary lamellae, bilateral T2 hyperintense/swollen basal ganglia, diffuse white matter hyperintensity on T2-weighted images, and brain atrophy in later stages.[7]

## Mucopolysaccharidoses

The mucopolysaccharidoses are the best known of the lysosomal abnormalities affecting predominately gray matter. The primary metabolic defect is a failure to break down sulfates (dermatan, heparan, and keratan); mucopolysaccharides fill and overburden the lysosomes within histiocytes of the brain, bone, skin, and other organs. Glycosaminoglycans accumulate with target organs such as the bone, liver, and brain. Eight subtypes have been defined; however, six distinct forms are now recognized within this classification scheme, based on which metabolite is involved. The six are referred to as Hurler (IH), Hunter (II), Sanfilippo (III), Morquio (IV), Maroteaux-Lamy (VI), and Sly (VII), with the classic prototypical disease being Hurler syndrome. All of these diseases are autosomal recessive except Hunter (type II), which is an X-linked recessive condition. Coarse facial features and complex skeletal manifestations are well-known clinical characteristics for all of these disorders. Without treatment, death usually comes within the first decade of life.

MRI demonstrates two major abnormalities (Fig. 33.1): (1) diffuse patches of hyperintensity on T2-weighted images resulting from accumulation of mucopolysaccharide in neurons and astrocytes and degenerative effects on myelin, and (2) prominent cystic or perivascular spaces resulting from metabolite accumulation within histiocytes located in perivascular areas, which is the most characteristic imaging feature; reversal of these changes after bone marrow transplantation has been reported. Hydrocephalus is common, probably as a result of plugging of the pacchionian granulations. Spinal stenosis is especially common in Morquio and Maroteaux-Lamy variants but may be demonstrated in other variants. Bullet-shaped vertebral bodies are characteristic.

For the mucopolysaccharidoses, proton MRS reveals a broad resonance at 3.7 ppm, which is attributed to a composite of mucopolysaccharide molecules. After bone marrow transplantation, the resonance at 3.7 ppm decreases in the brain of some patients, which may aid in determining the efficacy of the therapy. N-acetylaspartate (NAA) levels may improve in response to treatment.

## Neuronal Ceroid Lipofuscinoses

NCL is a group of disorders characterized by striking volume loss of brain parenchyma. NCL, which can be divided into six subtypes based on age at onset, is one of the most common neurodegenerative syndromes, with an incidence of 1 per 25,000 live births. The various subtypes are associated with different mutations in the *CLN* genes and have similar clinical manifestations occurring at different ages. These manifestations include seizures and abnormal eye movements with subsequent vision loss, dementia, hypotonia, and speech and motor deficits. CSF neurotransmitter abnormalities have been reported.[8] At pathology, these disorders are characterized by distinctive granular inclusions in neuronal lysosomes (granular osmiophilic deposits). Imaging findings lag the clinical presentation in all but the infantile form of NCL and are dominated by progressive cerebral and cerebellar volume loss. Later disease stages are characterized by the development of a band of hyperintense signal in the periventricular white matter on T2-weighted images. In palmitoyl protein thioesterase-1 related NCL, isolated, symmetric dentate nucleus T2 hyperintensities have been reported in early stages.[9] Proton MRS has shown progressive decreases in NAA and relative increases in mI in persons with NCL.

## Metachromatic Leukodystrophy

The primary metabolic defect in MLD is a deficiency in the enzyme arylsulfatase A, resulting in lysosomal accumulation of cerebroside sulfate. MLD has four subtypes: congenital, late infantile, juvenile, and adult. The late infantile subtype is the most common and presents from around 14 months to 4 years of age. The early presentations are an unsteady gait that progresses to severe ataxia and flaccid paralysis, dysarthria, mental retardation, and decerebrate posturing. Gallbladder involvement has been reported, possibly appearing before the onset of neurologic symptoms. Intestinal involvement also has been reported, specifically polypoid masses in one patient.[10]

Histologic analysis of the abnormal nervous tissue demonstrates a complete loss of myelin (demyelination) followed by axonal degeneration. Metachromatic granules are reported within engorged lysosomes in white matter and neurons, and on peripheral nerve biopsies. Oligodendrocytes are reduced in number, and areas of demyelination predominate throughout the deep white matter region. An inflammatory response typically is absent, which accounts for a lack of enhancement, but eventually even myelinated white matter is replaced by astrogliosis and scarring. The corpus callosum is involved early, whereas subcortical arcuate white matter fibers ("U" fibers) remains unaffected until the disease has progressed; atrophy is a late sign. Demyelination also can be seen in the posterior limbs of the internal capsule, descending pyramidal tracts, and the cerebellar white matter.[11] Thalamic changes may be common in primary MLD, and isolated cerebellar atrophy may be seen in some atypical later-onset variants. On T2-weighted images, there is marked hyperintensity of the white matter fiber tracts involving the cerebral hemispheres that may extend to the cerebellum, brainstem, and spinal cord. The findings initially are focal and patchy, but later, a diffuse, hyperintense T2 signal of the centrum semiovale develops. Two distinct white matter appearances have been noted that mimic what was previously considered to be pathognomonic of Pelizaeus-Merzbacher disease (PMD) and globoid cell leukodystrophy (Krabbe disease). Punctate areas of hypointensity ("leopard skin" appearance) and radiating patterns of linear tubular structures of T2 hypointensity ("tigroid" appearance) are seen, with areas of relatively normal-appearing white matter within the areas of demyelination. On T1-weighted images, the white matter fibers may be isointense with, or hypointense to, gray matter (Fig. 33.2).

Proton MRS studies have demonstrated reduced NAA, which is expected with neuroaxonal loss, but they also have revealed disturbances in glial cell metabolism associated with elevated mI and choline. The levels of NAA in white matter have been found to correlate with motor function in children with MLD.[12]

## Globoid Cell Leukodystrophy (Krabbe Disease)

Globoid cell leukodystrophy (Krabbe disease) arises from a deficiency in the enzyme β-galactocerebrosidase, leading to the accumulation of cerebroside and galactosylsphingosine, which induces apoptosis in oligodendrocyte cell lines. It is an autosomal-recessive disorder with a frequency of 2 in 100,000. Onset of symptoms usually begins between 3 and 5 months after birth with irritability. Disease progression leads to symptoms mimicking encephalitis with motor deterioration and atypical seizures. At the

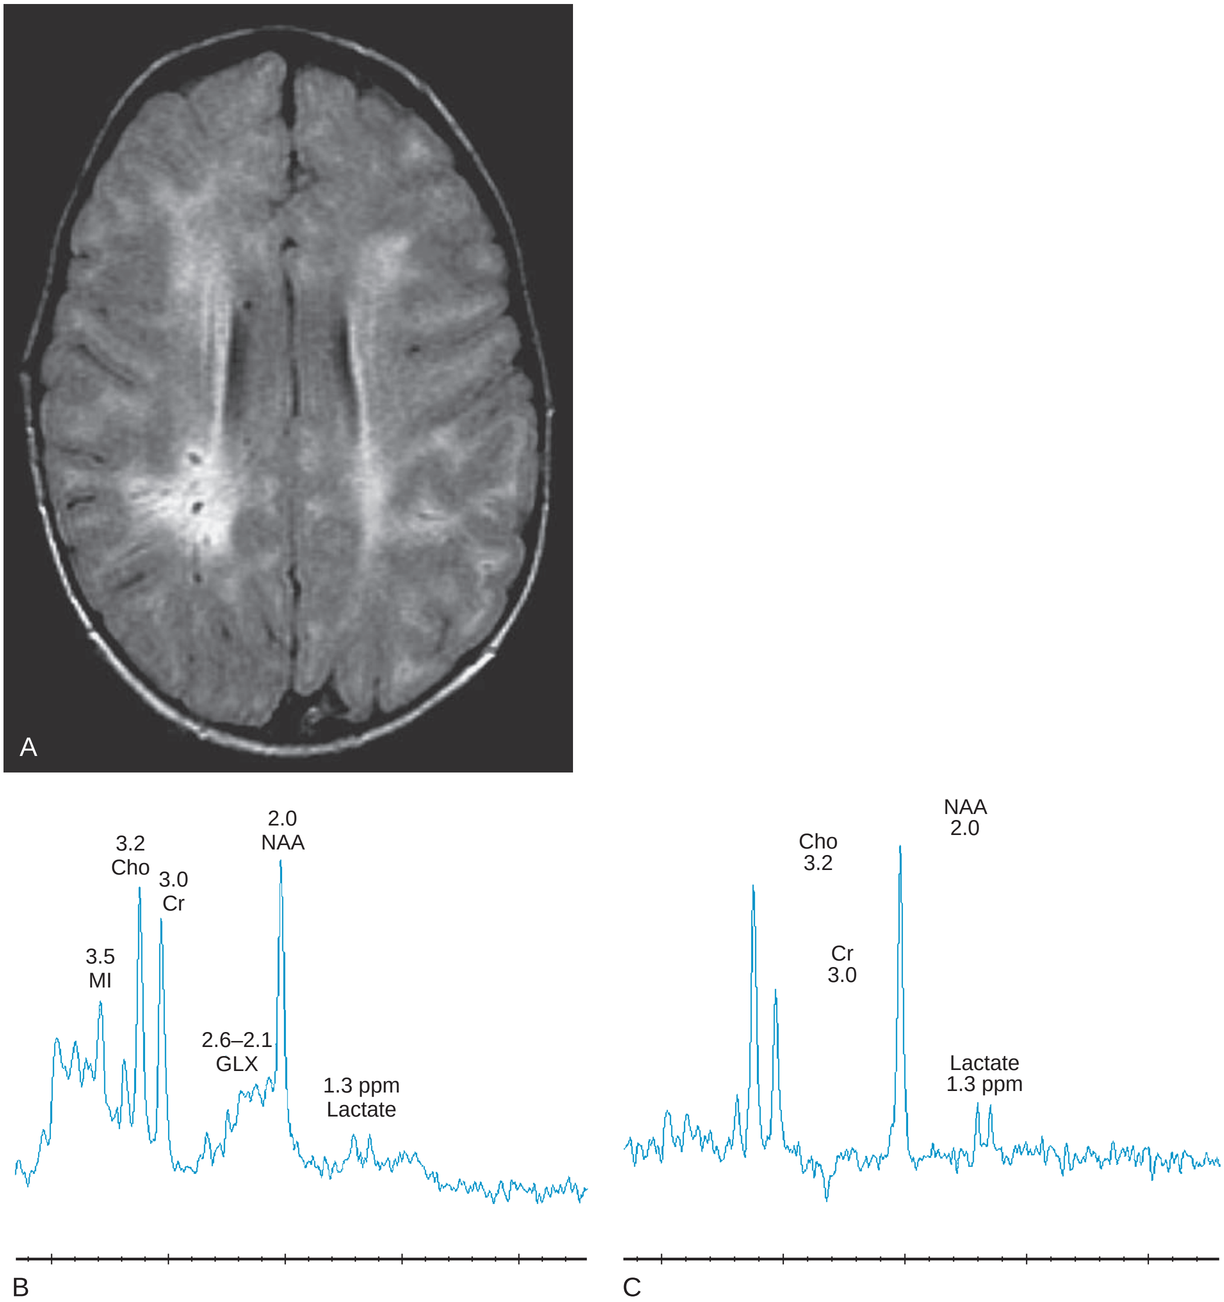

**Figure 33.1. Hunter syndrome, mucopolysaccharidoses type II, in a 2-year-old boy.** Axial fluid-attenuated inversion recovery (A), short echo (time to echo [TE] 35 milliseconds [msec]) magnetic resonance spectroscopy (MRS) (B), and long echo (TE 288 msec) MRS (C) images are shown. The patient underwent scanning within months of a stem cell transplant. Prominent perivascular spaces are demonstrated with a diffuse, abnormal, hyperintense signal throughout the periventricular and subcortical white matter. The spectra demonstrate diminished N-acetylaspartate levels with elevated lactate, which may reflect histiocytic cell infiltration of the perivascular spaces and brain parenchyma. PPM, parts per million. *(From Cecil KM. MR spectroscopy of metabolic disorders.* Neuroimaging Clin N Am*. 2006;16:87–116; used with permission.)*

end stage of the disease, the child is in a vegetative state with decerebrate posturing. Elevated CSF protein has been reported, more so in adult phenotypes than in phenotypes affecting younger people.[13] In nerve conduction studies, the severity of abnormalities appears to correlate with the severity of clinical symptoms.[14,15]

The disease predominantly involves the white matter of the cerebral hemispheres, cerebellum, and spinal cord. Pathologic changes include a marked toxic reduction in the number of oligodendrocytes. Globoid multinucleated cells and reactive macrophages are scattered throughout the white matter. Hypomyelination may be extensive and eventually leads to white matter gliosis and scarring. Gray matter involvement in the basal ganglia region also can be found with punctate calcification.

In infantile Krabbe disease, MRI findings may be normal or show delayed myelination, but as the disease progresses, classic Krabbe features emerge.[16] The appearance of Krabbe disease on MRI is featured as one of either two patterns. The first is a patchy hyperintense periventricular signal on T2-weighted

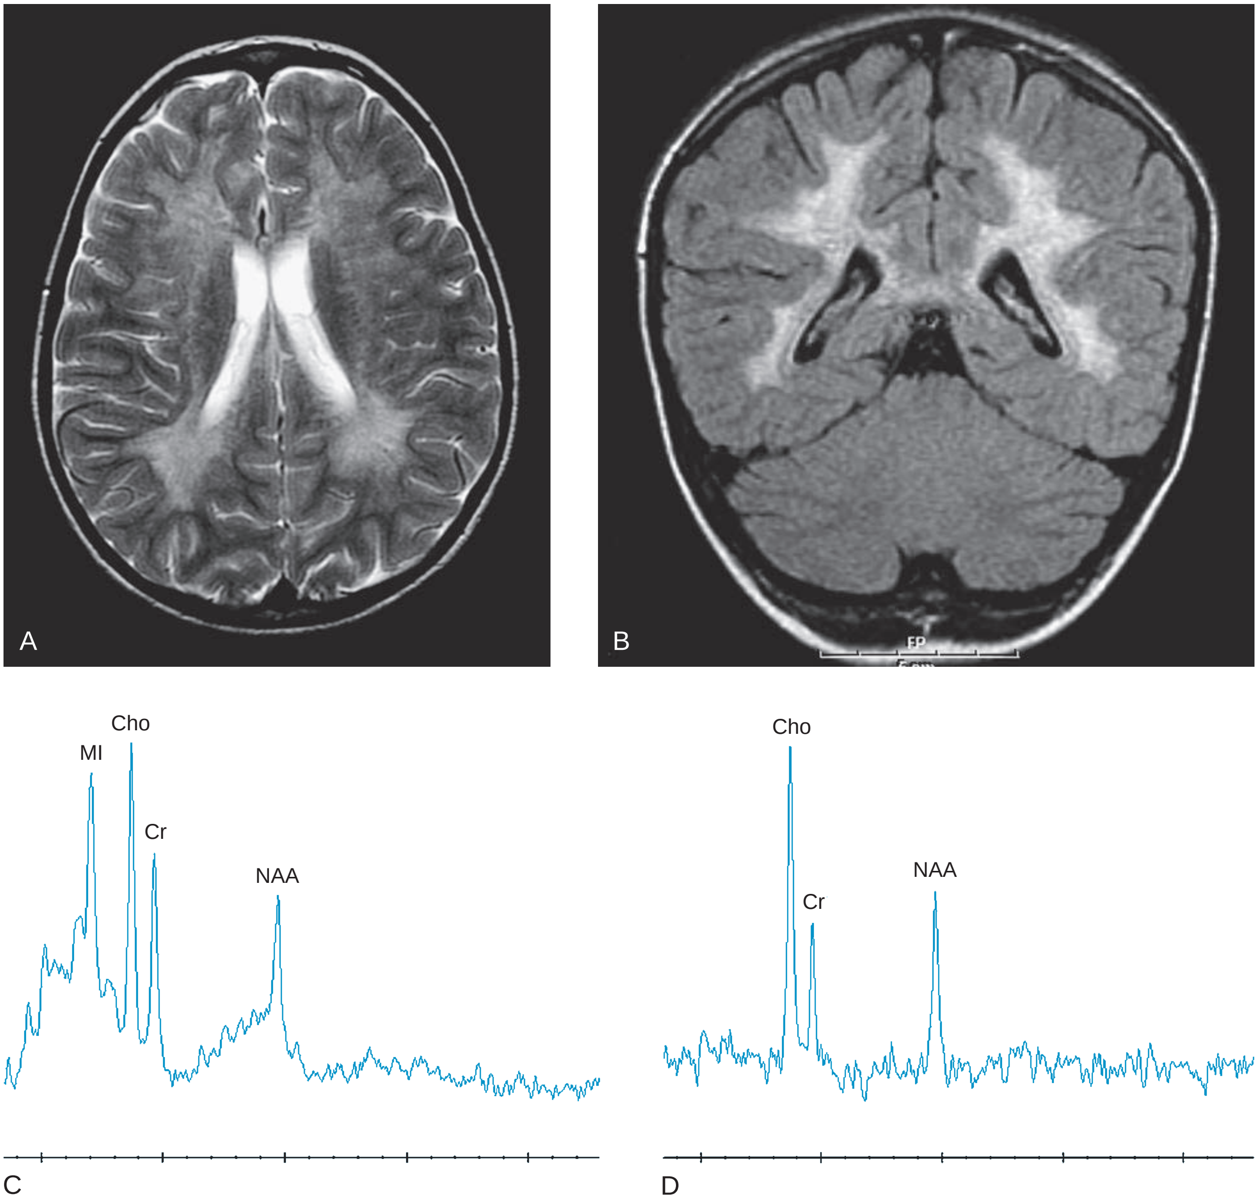

**Figure 33.2. Metachromatic leukodystrophy in a 7-year-old boy.** Axial T2-weighted (A), coronal fluid-attenuated inversion recovery (B) with left parietal white matter short echo magnetic resonance spectroscopy (MRS) (C) and long echo MRS (D) images reveal an abnormal hyperintense signal in the periventricular white matter throughout the cerebrum, sparing the subcortical U fibers. The signal has a "tigroid" appearance on T2-weighted images. The spectra demonstrate significant elevations of choline and myo-inositol with diminished N-acetylaspartate reflecting neuroaxonal loss, demyelination, and glial activation. *(From Cecil KM. MR spectroscopy of metabolic disorders.* Neuroimaging Clin N Am*. 2006;16:87–116; used with permission.)*

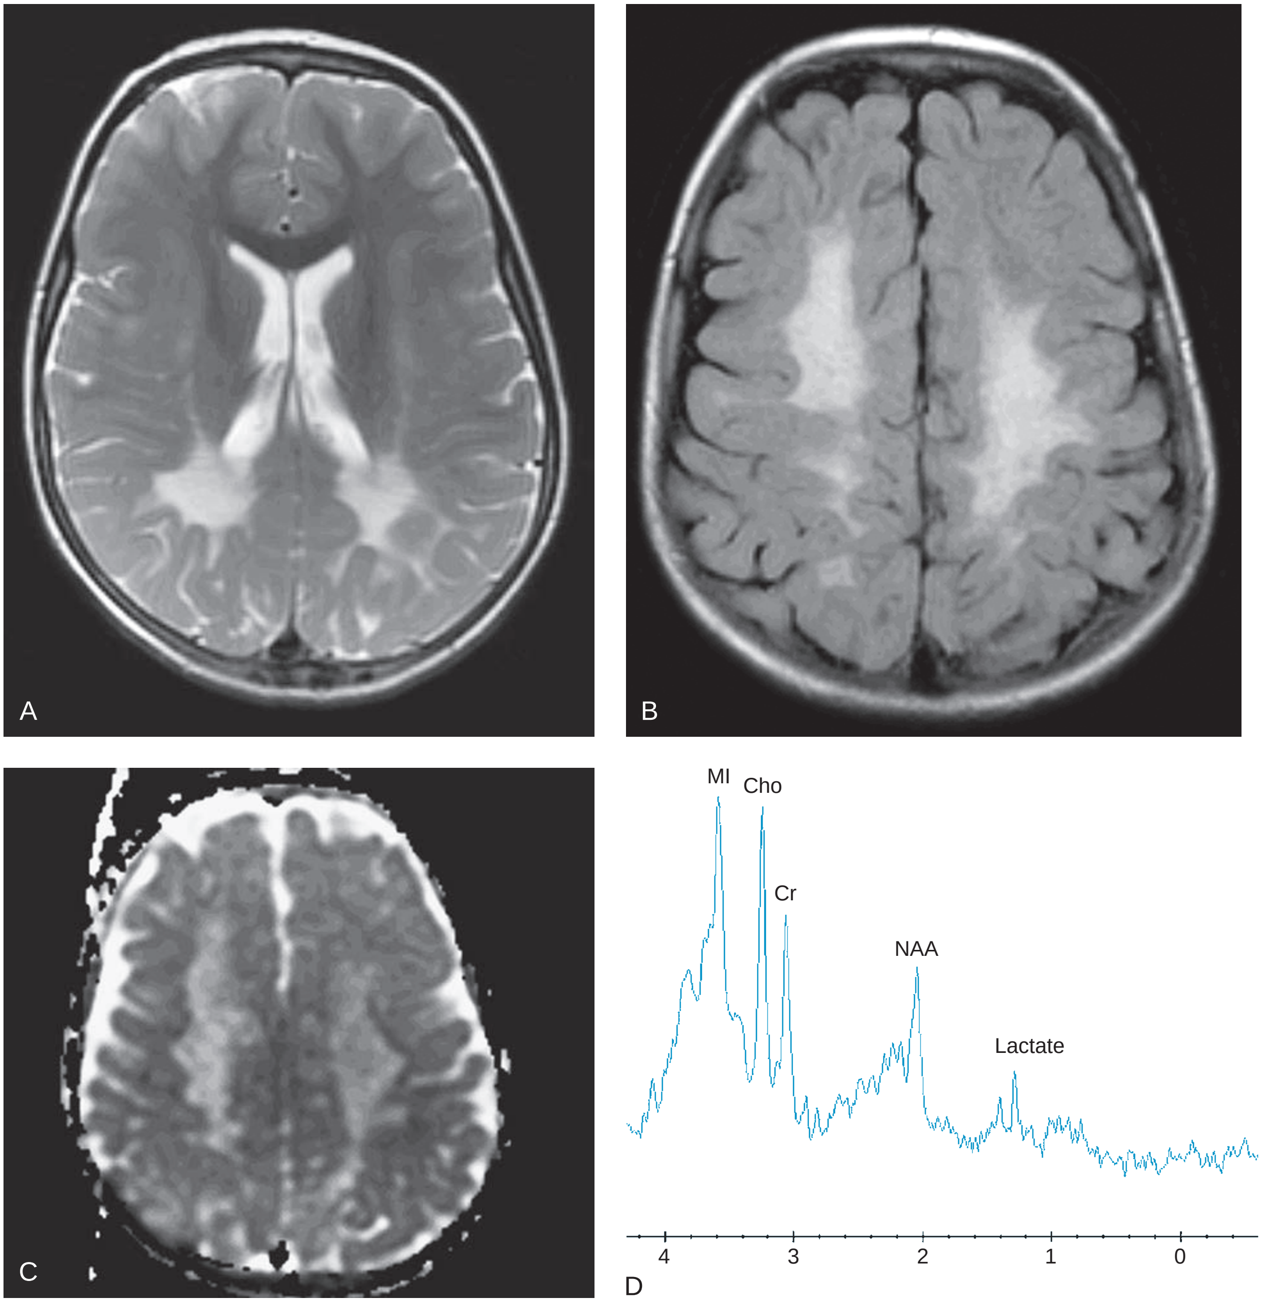
images, consistent with hypomyelination, which eventually may become more diffuse; involvement of the thalami is often present as well. The second pattern is a patchy low signal on T2-weighted images in a similar distribution to the hyperdense regions seen on CT, which is suspected to represent a paramagnetic effect from calcium deposition in the region. Additional early changes include increased density in the distribution of the thalami, cerebellum, caudate heads, and brainstem that may precede the abnormally low attenuation of white matter in the centrum semiovale. Symmetric enlargement of the optic nerves also has been described. The distal optic nerves are primarily involved; however, a case has been described with proximal prechiasmatic enlargement of the nerves.[17] T2 hyperintensity within the cerebellar white matter has been reported. The findings within the spinal cord are visualized as atrophic changes. Diffuse volume loss and periventricular white matter abnormalities predominate in the latter stages of this disease (Fig. 33.3). Midbrain morphology on midsagittal MR images reflects the extent of neurodegeneration in Krabbe disease. The morphology of the midbrain (i.e., convex, flat, concave) appears to be a reliable tool in assessing the clinical progression of the disease.[18] On MRI of the spine, abnormal thickening of the cauda equina roots is observed in Krabbe disease.[19]

Proton MRS demonstrates the reduced NAA expected with neuroaxonal loss but also has revealed disturbances in glial cell metabolism associated with hypomyelination. Elevated levels of choline and mI also have been reported, which is consistent with the general neurodegenerative pattern seen on proton spectroscopy. DWI also has been applied in a limited number of patients with



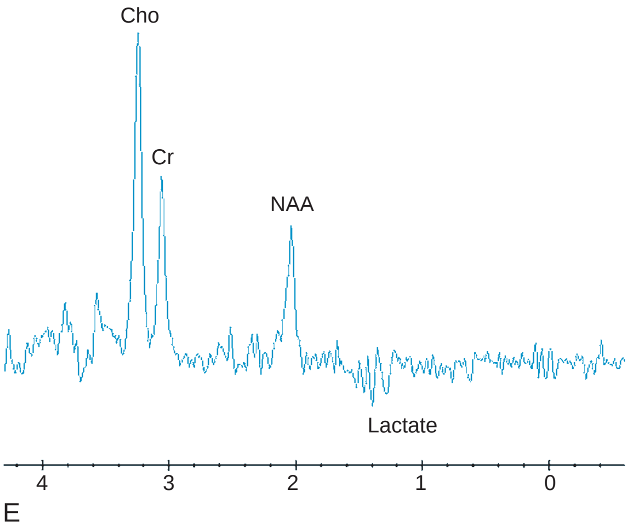


**Figure 33.3. Krabbe disease in a 4-year-old girl.** Axial T2-weighted fast spin echo (A), axial fluid attenuated inversion recovery (FLAIR) (B), axial apparent diffusion coefficient (ADC) map (C), short echo magnetic resonance spectroscopy (MRS) (D), and intermediate (time to echo 144 milliseconds [msec]) echo MRS (E) images are shown. Abnormal hyperintense T2 and FLAIR signals are noted within the centrum semiovale with sparing of the subcortical U fibers and posterior limbs of the internal capsules. Relatively increased diffusion is seen in the periatrial and parietal white matter. The spectra demonstrate significant elevations of lactate, choline, and myo-inositol, with diminished N-acetylaspartate reflecting neuroaxonal loss, demyelination, and glial activation.

Krabbe disease; loss of diffusion relative anisotropy preceded changes in T2 hyperintensity.

## PEROXISOMAL DISORDERS

Peroxisomes are organelles within a cell that contain enzymes responsible for critical cellular processes, including biosynthesis of membrane phospholipids, cholesterol, and bile acids; conversion of amino acids into glucose; oxidation of fatty acids; reduction of hydrogen peroxide by catalases; and prevention of excess oxalate synthesis. Peroxisomal disorders are subdivided into two major categories: (1) peroxisomal biogenesis disorders (PBDs) that arise from a failure to form viable peroxisomes, resulting in multiple metabolic abnormalities, and (2) disorders resulting from the deficiency of a single peroxisomal enzyme. Four different disorders constitute the genetically heterogeneous PBD group: Zellweger syndrome (ZS), infantile Refsum disease, neonatal adrenoleukodystrophy (ALD), and rhizomelic chondrodysplasia punctata.

### Zellweger Syndrome (Cerebrohepatorenal Syndrome)

ZS is an autosomal-recessive disease characterized by defective peroxisomal functions. Infants are symptomatic early, with hypotonia, seizures, hepatomegaly, and limb and facial anomalies that are easily recognizable at birth. MRI shows a diffuse lack of myelination throughout the white matter, combined with cortical dysplasia. The gyri are broad, with shallow intervening sulci found mainly in the anterior frontal and temporal lobes but also over the convexities in the perirolandic area (e-Fig. 33.4). The presence of a germinolytic cyst in the caudothalamic groove is common and may have hemorrhage.[20] In one case, signal abnormality suggestive of demyelination was identified almost solely in the brainstem corticospinal tracts.[21] Clinical overlap may occur with other conditions, including neonatal ALD, infantile Refsum disease, and hyperpipecolic acidemia. Death usually comes with many of these conditions within the first 2 years of life.

MRS in older patients with ZS and Refsum disease reveals similar features, with dramatic lipid and choline elevations, minor mI elevations, and reduced NAA levels in sampled white matter. For rhizomelic chondrodysplasia punctata, two studies report elevations of mobile lipids, mI-glycine, and acetate and reduced choline. In contrast to ZS, infantile Refsum disease, and neonatal ALD, rhizomelic chondrodysplasia punctata does not feature liver disease, which is significant to account for the mI differences. To detect mI levels, a short echo technique (i.e., TE ≤35 msec) must be used to recognize a resonance appearing at 3.5 ppm. For MRS performed at 1.5 T, the mI resonance normally is distinct, with four of the molecule's six methine protons magnetically indistinguishable, thereby coresonating at the same location (3.5 ppm). However, increased spectral dispersion inherent at higher field strengths (3 T) produces two distinct resonances (3.5 and 3.6 ppm) for the four protons, effectively reducing the signal by half. Although some reports have found improved detection of mI at high field strength arising from increased signal/noise ratio, it may be problematic depending on the acquisition conditions.

### Neonatal Adrenoleukodystrophy

Neonatal ALD is characterized by the presence of multiple recognizable enzyme deficiencies with grossly normal but deficient numbers of peroxisomes. Specific conditions include pipecolic and phytanic acidemia, and a deficiency of plasmalogen synthetase. This condition presents with hypotonia in the first months of life but without many of the facial features of ZS. Cortical dysplasia can be found, as well as hypomyelination, in cerebral white matter (Fig. 33.5).

### Adrenoleukodystrophy

X-linked ALD is the prototypical peroxisomal disorder in which organelle morphology is normal on electron microscopy but a single enzyme defect, acyl-CoA synthetase, along with a failure of incorporation into cholesterol esters for myelin synthesis, leads to the accumulation of very-long-chain fatty acids and progressive CNS deterioration in the form of a chronic progressive encephalopathy. This "classic" form of ALD is an X-linked disorder with a clinical onset between the ages of 5 to 7 years, followed by a rapidly progressive decline in neurologic function and death within the ensuing 5- to 8-year period. The first indication of this condition may include mental status changes or a decline in school performance, progressing to subtle alterations in neurocognitive function, and ultimately resulting in severe spasticity and visual deficits, leading finally to a vegetative state and death. Childhood cerebral ALD, although rare, can present with raised intracranial pressure (ICP) and an elevated level of CSF protein.[22]

CT and MRI findings in X-linked ALD show predominately posterior involvement that, over time, progresses anteriorly into the frontal lobes and from the deep white matter to the peripheral subcortical white matter. On CT, the involvement appears as symmetrical low attenuation in a butterfly distribution across the splenium of the corpus callosum, surrounded on its periphery by an enhancing zone (inflammatory intermediate zone). Three zones are readily distinguished on MR: an inner zone of astrogliosis and scarring corresponds to the low density zone seen on CT that appears hypointense on T1-weighted images and hyperintense on T2-weighted sequences; an intermediate zone of active inflammation that appears isointense on T1-weighted images and isointense or hypointense on T2-weighted images; and an outer zone of active demyelination that appears minimally hypointense on T1-weighted images and hyperintense on T2-weighted scans. Enhancement after administration of gadolinium is demonstrated within the intermediate zone of active inflammation and may disappear as the first change after bone marrow transplantation (Fig. 33.6).

Proton MRS demonstrates abnormal spectra within regions of abnormal signal, as well as white matter that appears normal. The spectral profile for normal-appearing white matter of neurologically asymptomatic patients is characterized by slightly elevated concentrations of composite choline compounds, with an increase of both choline and mI reflecting the onset of demyelination. Markedly elevated concentrations of choline, mI, and glutamine in affected white matter suggest active demyelination and glial proliferation. A simultaneous reduction of the concentrations of NAA and glutamate is consistent with neuronal loss and injury. An elevated lactate level is consistent with inflammation and/or macrophage infiltration. The more severe metabolic disturbances in persons with ALD correspond to progressive demyelination, neuroaxonal loss, and gliosis leading to clinical deterioration and death. The detection of MRS abnormalities before the onset of neurologic symptoms may help in the selection of patients for bone marrow transplantation and stem cell transplantation, and monitoring after treatment. Stabilization and partial reversal of metabolic abnormalities is demonstrated in some patients.

## MITOCHONDRIAL DISEASES

Mitochondrial diseases generally refer to disorders of the mitochondrial respiratory chain, the only cellular metabolic pathway under control by both the mitochondrial genome (mtDNA) and the nuclear genome (nDNA). Mitochondrial diseases demonstrate impaired respiratory chain function and reduced adenosine triphosphate production. The mtDNA mutations can be divided into two categories: those that impair mitochondrial protein synthesis *in toto* and those that affect respiratory chain subunits. Disorders

**e-Figure 33.4. Zellweger syndrome (A and B) and Refsum disease (C, D, and E).** Axial fluid attenuated inversion recovery (FLAIR) (A) and short echo magnetic resonance spectroscopy (MRS) (B) images were acquired in the left frontal lobe of a 3-year-old boy with Zellweger syndrome. Imaging demonstrates mildly enlarged ventricles and extraaxial spaces consistent with parenchymal volume loss with abnormal hyperintense signal throughout the white matter. Axial FLAIR (C), short echo MRS (D), and long echo MRS (E) images were acquired in the periventricular white matter of a 6-year-old boy with Refsum disease. An abnormal hyperintense signal is demonstrated in the periventricular white matter and is noted along the course of the corticospinal tracts. Spectra from both patients demonstrate an elevated lipid peak, representing stored fatty acids. Reduced N-acetylaspartate with elevated choline and myo-inositol levels also are demonstrated in the spectra. *(From Cecil KM. MR spectroscopy of metabolic disorders.* Neuroimaging Clin N Am. *2006;16:87–116; used with permission.)*

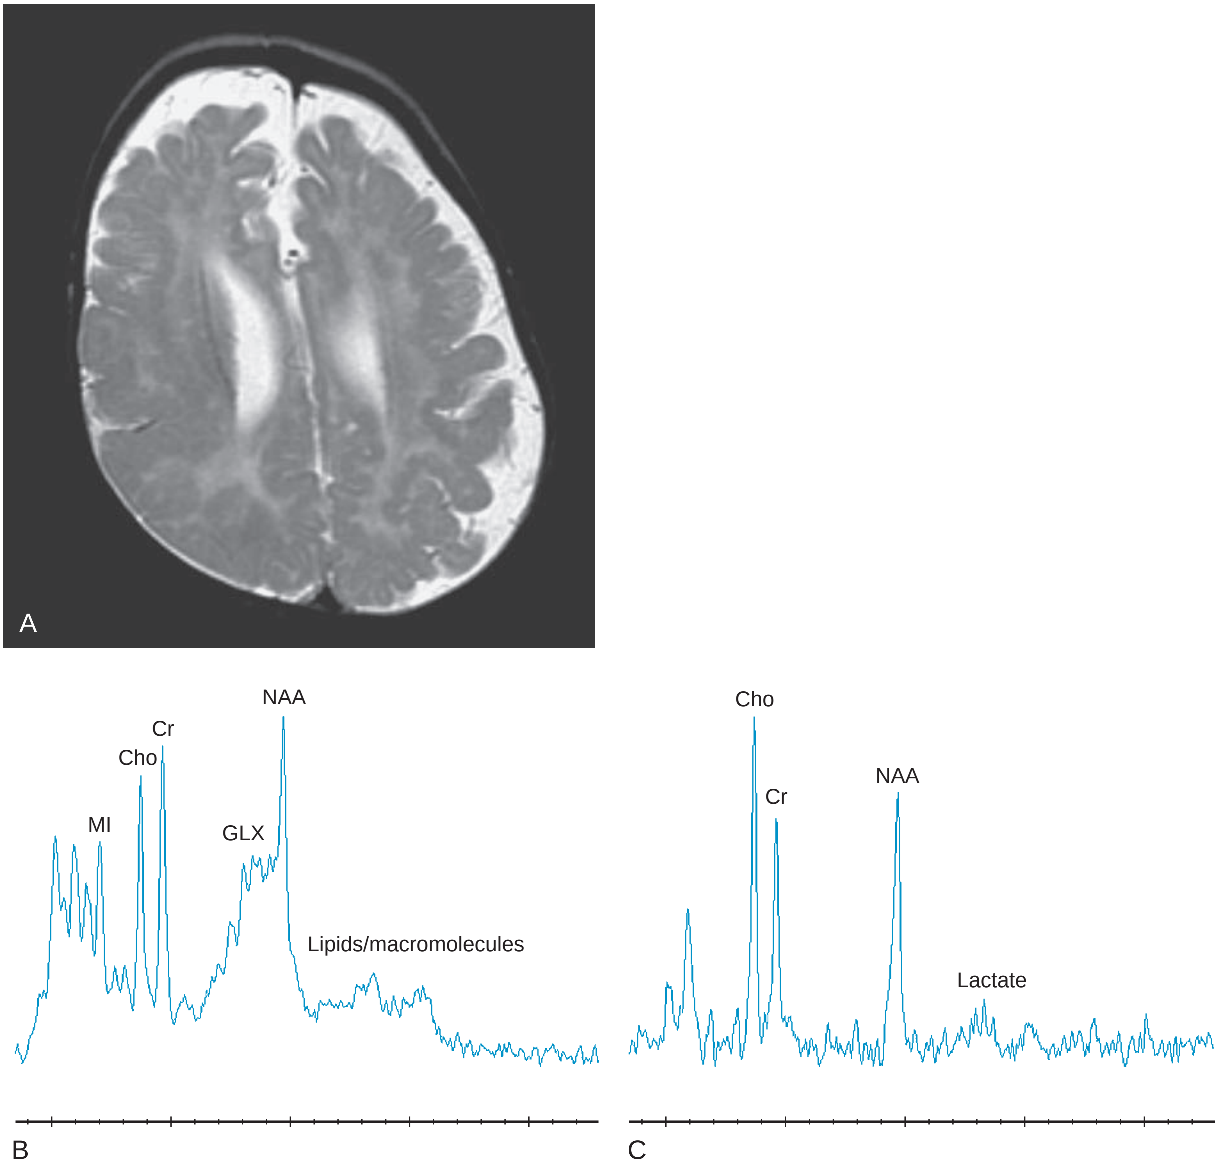

**Figure 33.5. Neonatal adrenoleukodystrophy in a 12-month-old boy.** Axial T2-weighted (A), short echo magnetic resonance spectroscopy (MRS) (B), and long echo MRS (C) images are shown. The imaging reveals an abnormal hyperintense signal within the central white matter and an abnormal cerebral gyral pattern consistent with polymicrogyria. The lateral ventricles and extraaxial spaces are prominent in size with a thin corpus callosum. The spectroscopy performed in the left parietal cortex and white matter reveals elevated glutamate and glutamine with a slightly elevated lactate signal and reduced N-acetylaspartate levels. *(From Cecil KM. MR spectroscopy of metabolic disorders.* Neuroimaging Clin N Am. *2006;16:87–116; used with permission.)*

attributed to mtDNA mutations follow lax rules of mitochondrial genetics. However, disorders arising from nDNA mutations are governed by Mendelian genetics. The disorders attributed to mutations in nDNA are more abundant because most respiratory chain subunits are nucleus-encoded and the correct assembly and functioning of the entire respiratory chain require numerous steps. The clinical phenotypes of nDNA-related mitochondrial disorders tend to be uniform, whereas both the spectrum and severity of clinical manifestations associated with mtDNA-related disorders are extremely variable. Marked genotype-phenotype variability is characteristic of mtDNA-related disorders. The clinical diversity observed in patients with mtDNA-related disorders can be partially explained by heteroplasmy, the coexistence of mutant and wild-type mtDNA within a cell. Only when the proportion of mutant genomes exceeds a particular level is the disease expressed.

## Kearns-Sayre Syndrome

A group of clinical syndromes arising from mtDNA rearrangements, either deletions or duplications, includes Kearns-Sayre syndrome, Pearson syndrome, and progressive external ophthalmoplegia.

Kearns-Sayre syndrome is characterized by external ophthalmoplegia, retinal pigmentary degeneration, and conductive hearing block. Ragged red fibers indicative of a defect in the respiratory chain of mitochondria are demonstrated on muscle biopsy, in common with mitochondrial encephalomyopathy, lactic acidosis,

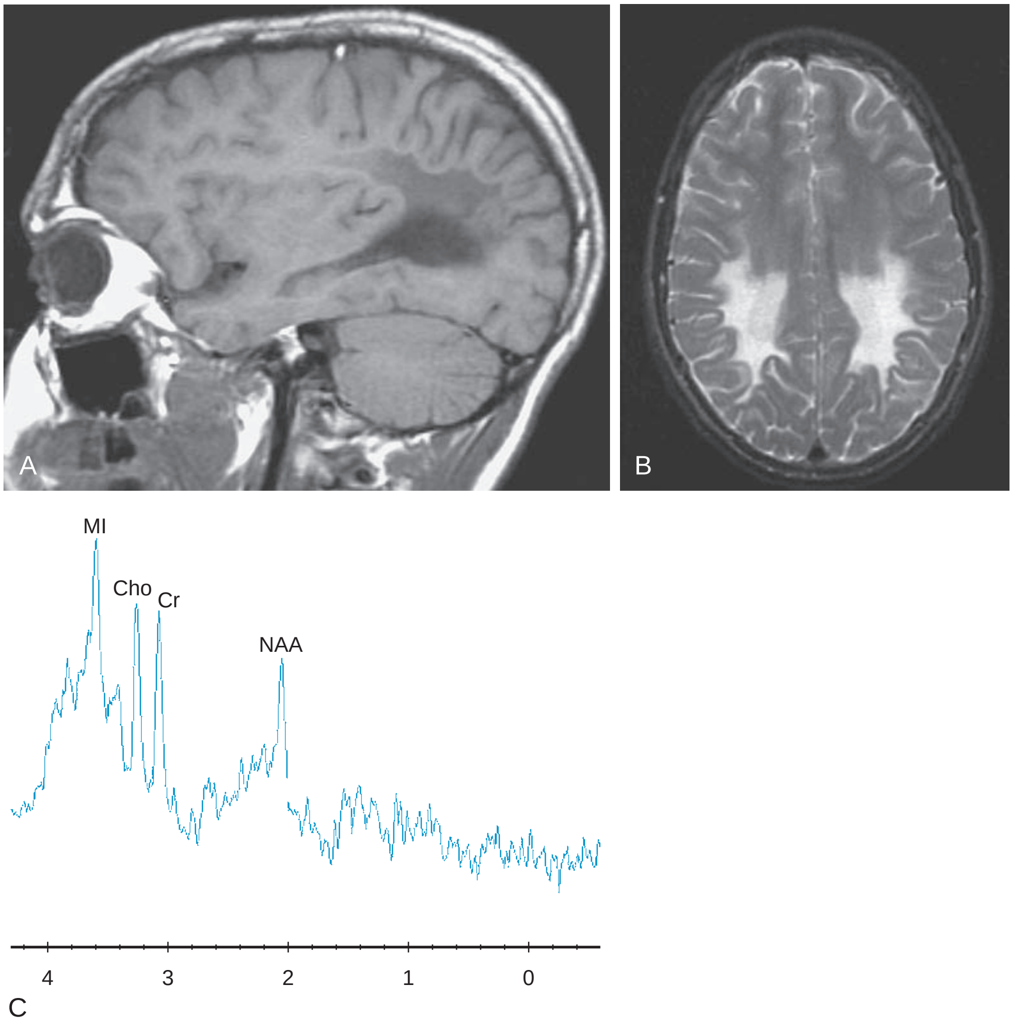

**Figure 33.6. X-linked adrenoleukodystrophy in a 16-year-old boy, 8 months after a bone marrow transplant.** Sagittal T1-weighted (A), axial T2-weighted (B), and short echo magnetic resonance spectroscopy (MRS) (C) images are shown. The imaging demonstrates an abnormal signal in the posterior portion of the cerebrum. The spectra sampled in the right posterior parietal white matter reveals a diminished N-acetylaspartate level with an elevated myo-inositol level. Imaging and spectroscopy reflected disease stability for this patient.

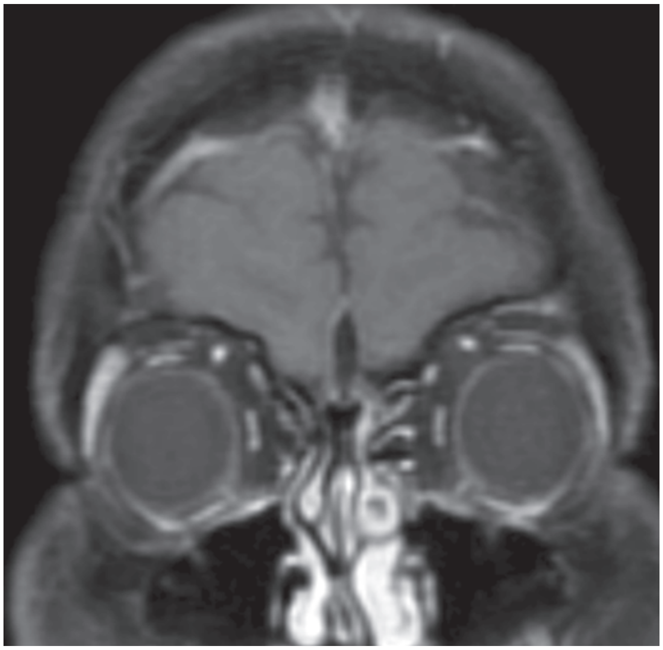
and strokelike symptoms (MELAS) and myoclonic epilepsy with ragged red fibers (MERRF) syndromes. The heart is often affected, causing conduction defects, which progress to heart block and heart failure.[23] Choroid plexus failure also has been reported.[24] Cerebral MRI demonstrates diffuse, patchy areas of hyperintensity on T2-weighted images. In the presence of calcification, both the basal ganglia and dentate nuclei may show hyperintense T1-weighted signal. On T2-weighted and FLAIR images, bilateral involvement of the thalamus, basal ganglia, and brainstem are observed. Cerebral and, more frequently, cerebellar atrophy often are observed.[25] Ocular myopathy characterizes some patients affected by Kearns-Sayre syndrome (e-Fig. 33.7).

## MELAS Syndrome

There are several clinical syndromes arising from point mutations in mtDNA, the most notable being MELAS syndrome, MERRF syndrome, neurogenic weakness and ataxia with retinitis pigmentosa syndrome, and Leber hereditary optic neuropathy. MELAS syndrome often is caused by an A3243G point mutation in $\text{tRNA-leu}^{\text{UUR}}$ or the *MTTL1* gene (80% of cases). Other phenotypes can result in the A3243G point mutation (e.g., maternally inherited deafness and diabetes). The clinical presentation of MELAS syndrome resembles that of cerebral infarction; however, the “infarcts” lack the usual arterial stroke distribution. Age of onset is usually between 2 and 11 years. The basal ganglia and parietal, temporal, and occipital lobes are most commonly involved. MRI demonstrates areas of T2 hyperintensity with volume loss a late development.

Proton MRS has been used to aid diagnosis of mitochondrial disorders, with the assumption that elevation of lactic acid is a primary feature. However, positive lactate at spectroscopy does not necessarily equal the presence of a mitochondrial disorder, and the absence of lactate on MRS does not rule out a defect in mitochondrial function. Proton MRS in patients with MELAS syndrome can demonstrate variable results as strokelike lesions emerge and evolve. Proton MRS details energy failure with increased lactate and decreased creatine. Elevation of lactate in the acute and subacute stages typically is observed, with subsequent declines in NAA and creatine, consistent with neuroaxonal injury that may or may not be reversible. It has been reported that increase of lactate peaks in MRS and hyperperfusion with arterial spin label imaging both indicate active lesions.[26] MELAS syndrome shows a gradual spread of the core of edematous lesions, a



**e-Figure 33.7. Kearns-Sayre syndrome.** Coronal contrast-enhanced T1-weighted fat-saturated MR image shows atrophic extraocular muscles.

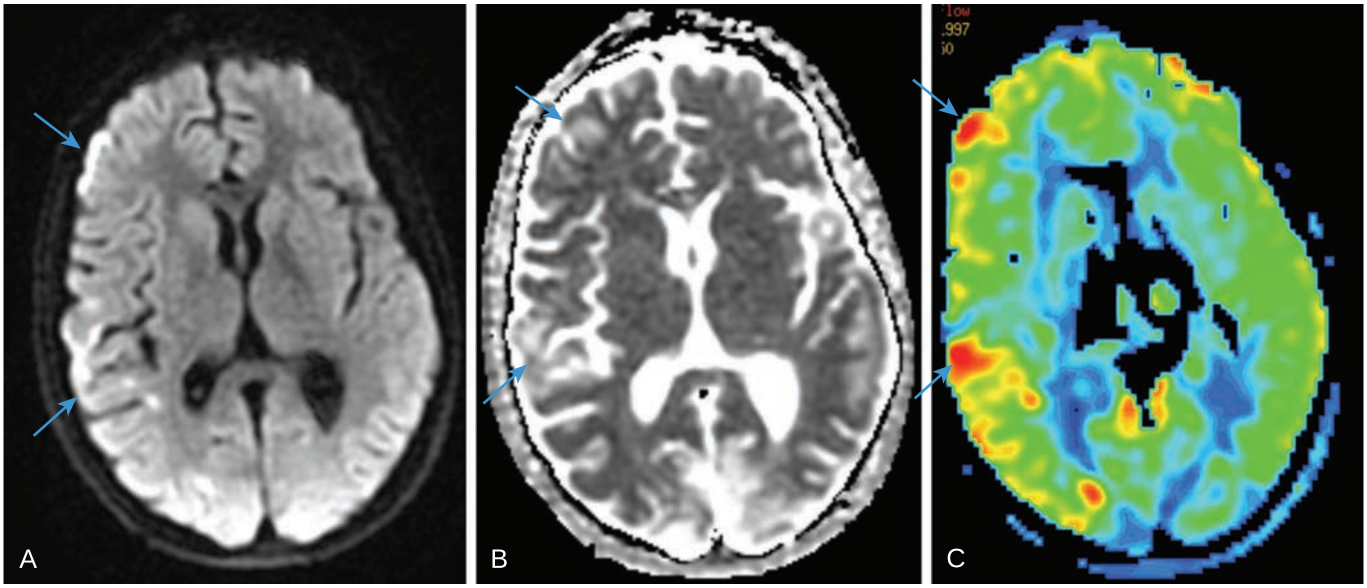


**Figure 33.8. Mitochondrial encephalomyopathy, lactic acidosis, and strokelike symptoms (MELAS) in a 13-year-old boy.** Axial diffusion-weighted imaging (A), axial apparent diffusion coefficient (ADC) map (B), and an axial arterial spin labeling color map (C) are shown. Scattered foci of vasogenic edema denoted by *arrows* corresponding to increased perfusion are identified in the acute phase of the disease in the right cerebral hemisphere.

contributing factor to the prolonged ADC decline, which helps differentiate it from ischemic stroke[27] (Fig. 33.8).

## Leigh Syndrome (Subacute Necrotizing Encephalomyelopathy)

Disorders arising from defects in nDNA are numerous, but the most commonly encountered is Leigh syndrome. The genetic defect of Leigh syndrome can arise from several sources, including pyruvate dehydrogenase complex deficiency, complex I deficiency, complex V deficiency with adenosine triphosphatase 6 mutation, and cytochrome oxidase deficiency with *SURF1* mutation. This group of disorders characteristically presents at 3 months to 2 years of age but may begin with symptoms of hypotonia in the newborn period or even in adulthood. Clinical signs include ophthalmoplegia, cerebellar signs, and spasticity, which are slowly progressive. Other features include psychomotor regression, extrapyramidal signs, blindness, nystagmus, respiratory compromise, or cranial nerve palsies. Onset of symptoms within the first years of life typically portends a rapid downhill course. A later onset of symptoms is generally associated with slower progression.

Pathologically, this syndrome involves both gray and white matter of the brain and spinal cord. Common sites of anatomic involvement include the basal ganglia, specifically the globus pallidus and putamina, and the thalami, midbrain, pons, cerebellum, and medulla. Pathologic changes include spongiform degeneration, demyelination, and vascular compromise and proliferation.

Abnormal low signal on T1-weighted images or a high signal on T2-weighted images in the basal ganglia, periaqueductal gray matter, and brainstem/cerebellum are characteristic of this group of disorders. Bilateral symmetric lesions in the basal ganglia (globus pallidus and putamen) characterized by hypointensity on T1-weighted images and hyperintensity on T2-weighted images is highly suggestive of this condition and should prompt further clinical investigation for signs of lactic acid in the serum or CSF. Late involvement may manifest as regions of an abnormal hyperintense signal on T2-weighted images in the centrum semiovale (Fig. 33.9 and e-Fig. 33.10).

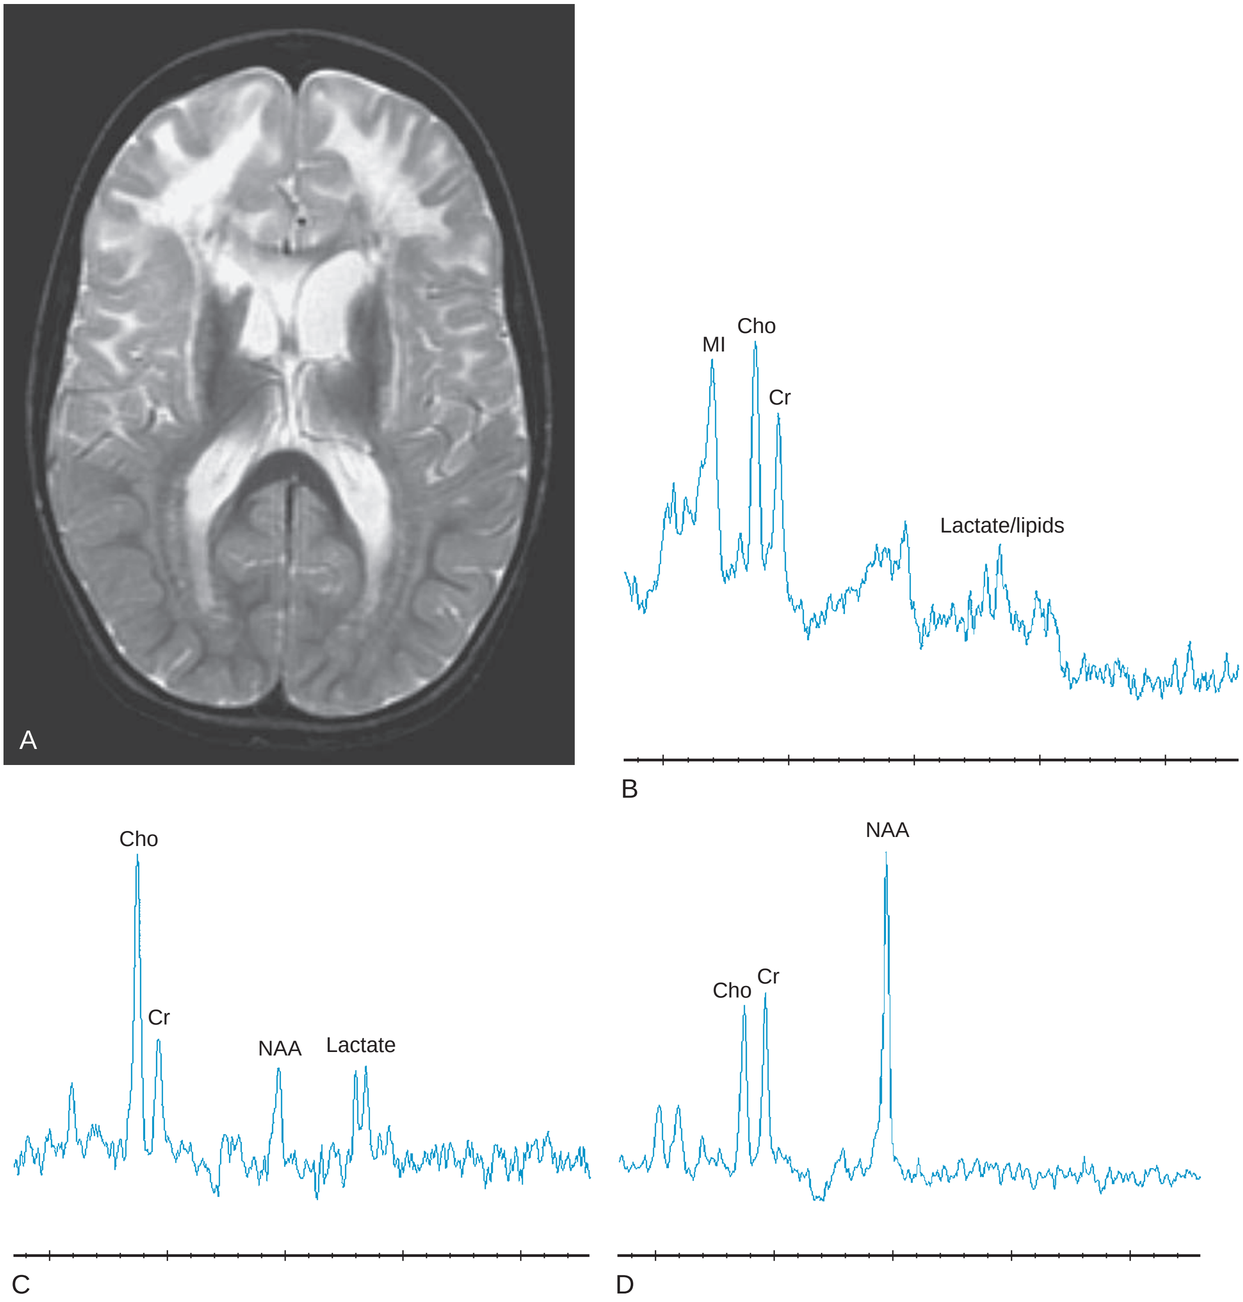
Proton MRS images obtained from the basal ganglia, occipital cortex, and brainstem show elevations in lactate, which are most pronounced in regions where abnormalities are seen with routine T2-weighted MRI. Proton MRS images in regions of abnormal MRI signal also reveal a decrease in the NAA/creatine ratio and an increase in the choline/creatine ratio, representing neuronal loss and breakdown of membrane phospholipids. Some evidence indicates that a reduction of lactate levels may correlate with response to therapy, such as with dichloroacetate and coenzyme Q10.

## Pantothenate Kinase-Associated Neurodegeneration

Pantothenate kinase-associated neurodegeneration, also called neurodegeneration with brain iron accumulation (NBIA), is caused by mutations in the gene that encodes pantothenate kinase 2 *(PANK2)*. *PANK2* is necessary for the production of coenzyme A in mitochondria. Other similar mutations result in atypical presentations of the same syndrome. "Classic" NBIA has an early onset of disease in infancy, with rapid progression of gait impairment, development of choreoathetoid movements, rigidity, dysarthria, and cognitive decline. Dystonia is a prominent feature of this disorder. All of these clinical manifestations reflect the impact of the disease upon the basal ganglia and striatum. Atrophy of the cerebellum and iron accumulation in the basal ganglia on susceptibility weighted images (SWI) are prominent imaging features of these disorders. Atypical NBIA has a later presentation with slower progression (Fig. 33.11).

## Menkes Disease

Menkes disease (also known as trichopoliodystrophy or kinky-hair syndrome) is an X-linked recessive mitochondrial cytopathy. The disease may commence in utero and has been recognized at birth. It appears in males with the clinical features of hypotonia, seizures, spastic quadriplegia, and profound retardation with sparse, fragile hair that is easily broken. Growth failure and microcephaly are common. Absorption of copper from the gastrointestinal tract is



**e-Figure 33.10. Complex I deficiency acquired in a 4-year-old girl.** Note the dramatic differences in the imaging and spectroscopy compared with Fig. 33.9. Axial T2-weighted image (A), a short echo magnetic resonance spectroscopy (MRS) image in the frontal white matter (B), a long echo MRS image in the frontal white matter (C), and a long echo MRS image in the posterior cortex parasagittally (D) are shown. The imaging reveals an abnormal hyperintense signal within the white matter of frontal lobe, including the U fibers but sparing the internal capsule with enlarged ventricles, suggesting volume loss of the caudates. Within the frontal lobe, decreased N-acetylaspartate with lactate, choline, and myo-inositol elevations are seen, representing mitochondrial dysfunction, demyelination, axonal loss, and astrocytosis. The sampled spectrum within the posterior cortex is unremarkable. *(From Cecil KM. MR spectroscopy of metabolic disorders.* Neuroimaging Clin N Am. *2006;16:87–116; used with permission.)*

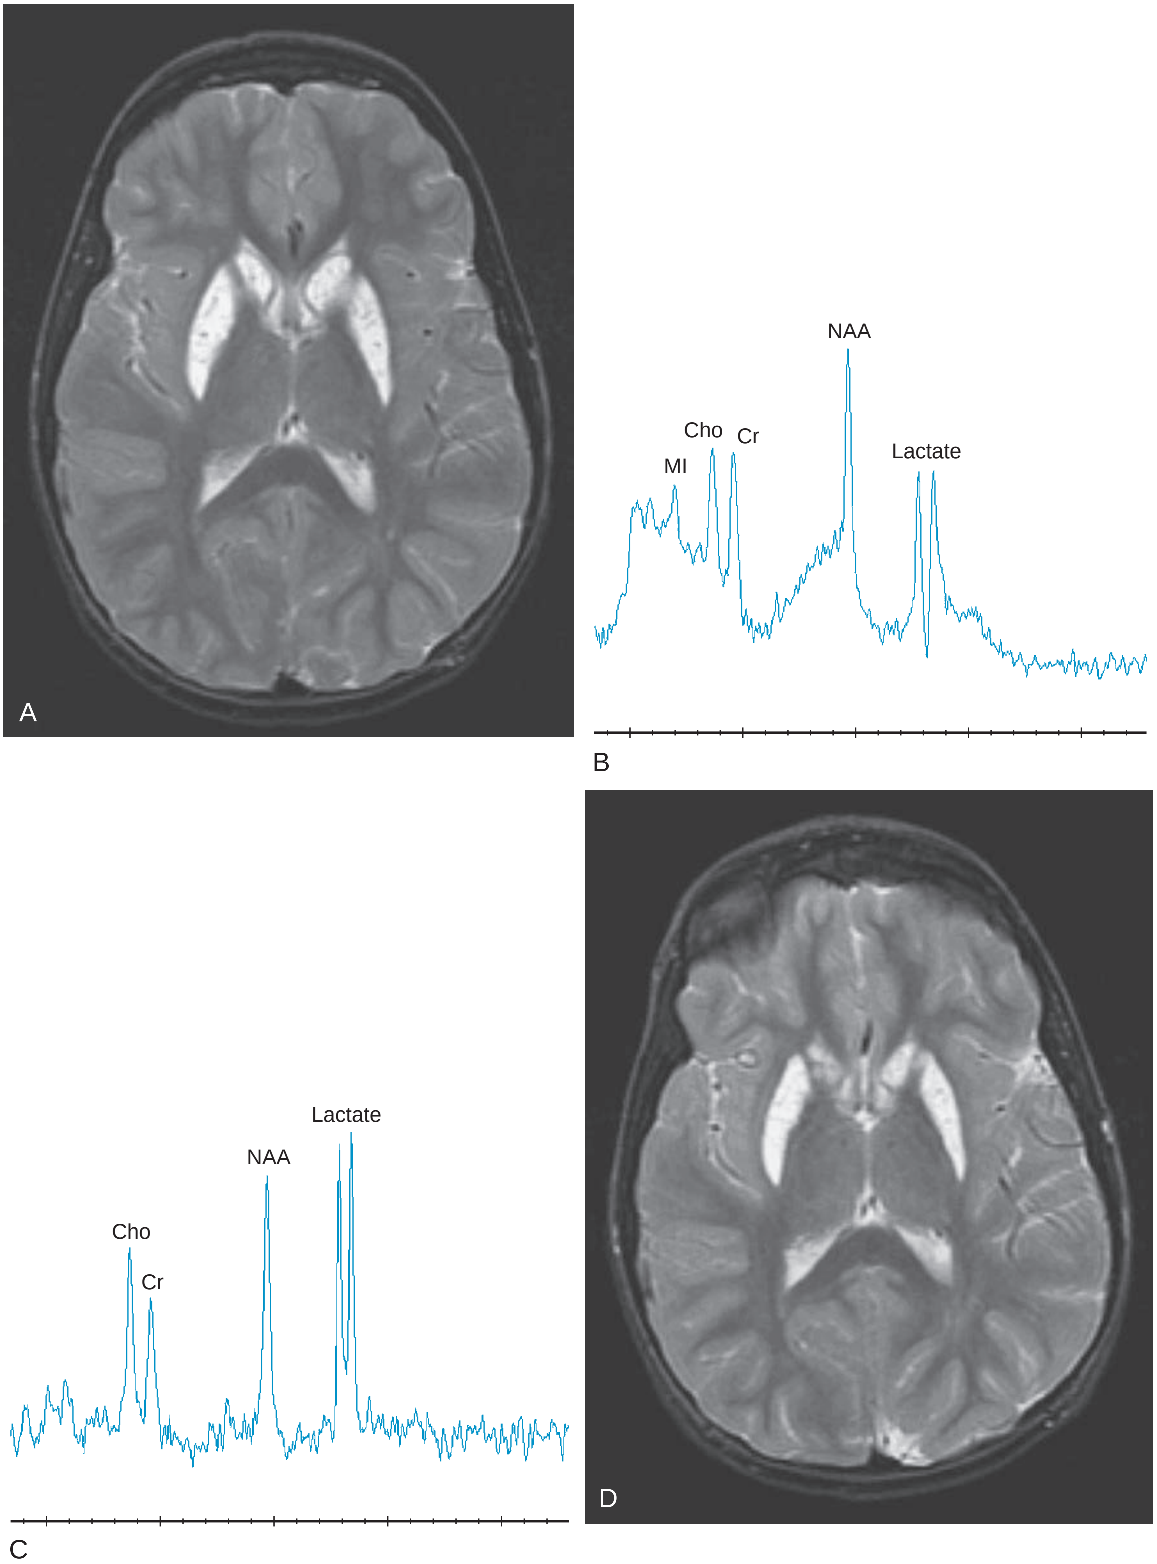


**Figure 33.9. Complex I deficiency in an 8-year-old girl with magnetic resonance examinations acquired approximately 3 months apart.** Axial T2-weighted (A), short echo magnetic resonance spectroscopy (MRS) (B), and long echo MRS (C) images were obtained. The imaging reveals a pattern characteristic of "Leigh syndrome" with an abnormal hyperintense signal bilaterally within the caudate and globus pallidus. The MRS image acquired in the left basal ganglia at a period of clinical exacerbation caused by febrile illness demonstrates a dramatic elevation of lactate compared with her routinely observed levels as shown in axial T2-weighted (D), short echo MRS (E), and long echo MRS (F) images. The spectra acquired 3 months later demonstrates a significant reduction in lactate. A comparison of the imaging data is unremarkable between the examinations. The dramatic elevation of lactate revealed on MRS in (B) and (C) corresponds to worsening clinical symptoms (seizures and leg stiffening). The lactate levels observed in (E) and (F) are typical and consistent with this mitochondrial defect. *(From Cecil KM. MR spectroscopy of metabolic disorders.* Neuroimaging Clin N Am. *2006;16:87–116; used with permission.)*

*Continued*

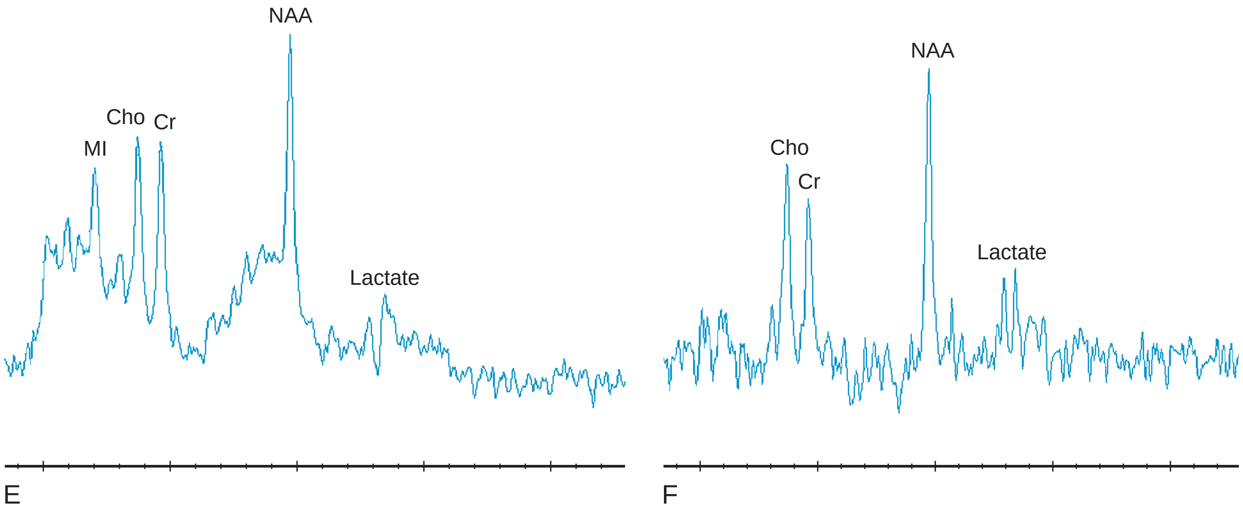

**Figure 33.9, cont'd.**

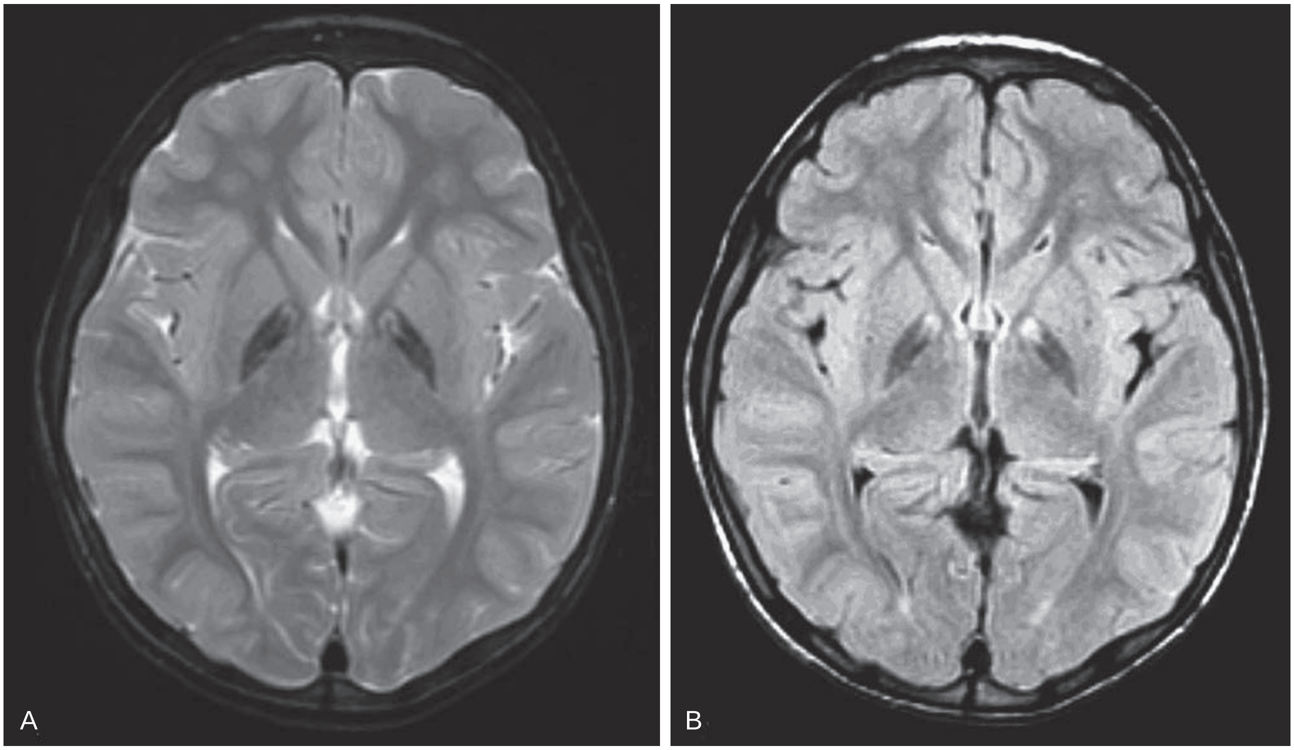

**Figure 33.11. Pantothenate kinase-associated neurodegeneration or neurodegeneration with brain iron accumulation, traditionally referred to as Hallervorden-Spatz syndrome in a 6-year-old girl.** Axial T2-weighted (A) and axial fluid attenuated inversion recovery (FLAIR) (B) MR images are shown. An abnormal hypointense signal is demonstrated bilaterally in the globus pallidus.

decreased. The defective intracellular binding and membrane transport of copper are related to an abnormal metallothionein, a copper-binding protein. Decreased activity of copper-dependent enzymes is found in the liver, brain, and white cells.

Radiographs may demonstrate wormian bones in the skull, rib fractures, and metaphyseal infarctions in long bones. Neuroimaging findings include cerebral volume loss and subdural collections, and cerebral angiography shows dilated and tortuous vessels within the circle of Willis. Basal ganglia lesions have been reported in advanced stages; however, reports of basal ganglia involvement in the early stages of Menkes disease exist.[28] Hyperintense white matter T2 signal indicates a lack of myelination but may also be related to a relative lack of blood flow as a result of the vascular involvement (Fig. 33.12). The combination of extracerebral collections and metaphyseal infarctions may simulate battered child syndrome.

## ORGANIC AND AMINO ACID DISORDERS

Many disorders of organic acid metabolism affect mitochondrial function, and as such they demonstrate imaging features similar to those of mitochondrial disorders. Two key disorders are glutaric aciduria and methylmalonic acidemia. Myelin formation is dependent on amino acids. Defects in amino acid metabolism lead

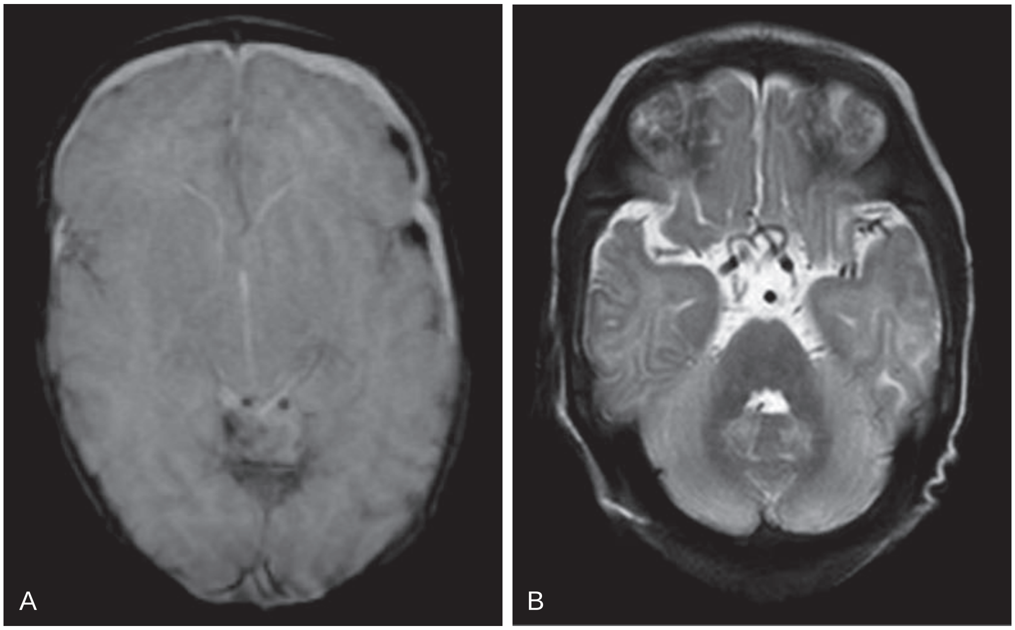

**Figure 33.12. Menkes disease in a male patient.** (A) Axial multiple planar gradient recalled MR image reveals bilateral subdural collections with evidence of hemorrhage at 6 weeks. (B) Axial T2-weighted MR image at the cerebellum at 4 months.

to failure of formation and maintenance of normal myelin. Disorders primarily of amino acid metabolism include phenylketonuria, maple syrup urine disease (MSUD), homocystinuria/hyperhomocysteinemia, and nonketotic hyperglycinemia.

## Glutaric Aciduria

Glutaric aciduria type I is an autosomal recessive organic aciduria resulting from deficiency of the enzyme glutaryl-CoA dehydrogenase, which is involved in the metabolism of hydroxylysine, lysine, and tryptophan. Presentation may be acute with encephalopathy or chronic with multiple neurologic abnormalities, including hypotonia, ataxia, dysmetria, and delayed achievement of milestones.

MRI demonstrates T2 hyperintensity in the basal ganglia, especially the putamen, but also in the caudate nucleus and globus pallidus. Myelination is delayed. Bilateral temporal arachnoid cysts and enlarged frontotemporal spaces with subdural hematomas may be found. As a consequence, this rare disorder is sometimes considered as a differential diagnosis in children with abusive head trauma. The development of T2 prolongation in the basal ganglia and periventricular white matter would support the diagnosis of glutaric aciduria type I in such cases. The enlargement of extraaxial spaces makes glutaric aciduria type I one of the metabolic diseases associated with macrocrania. Unlike in Alexander disease and Canavan disease, the macrocrania does not reflect megalencephaly. Enlargement of the Sylvian fissure has been correlated with severity of the enzyme deficiency. Acute striatal necrosis is the main cause of death during infancy; it can be visualized as usually symmetric, strokelike signal hyperintensity on T2-weighted and diffusion-weighted MRI, bilateral striatal lucency on CT, or a sharp decline of fluorodeoxyglucose uptake on positron emission tomography.[29] Prenatal MRI has been shown to be useful in identifying GA1, revealing focal reduction of the anterior pole of both temporal lobes with widening of CSF spaces[30] (Fig. 33.13).

## Methylmalonic and Proprionic Acidemias

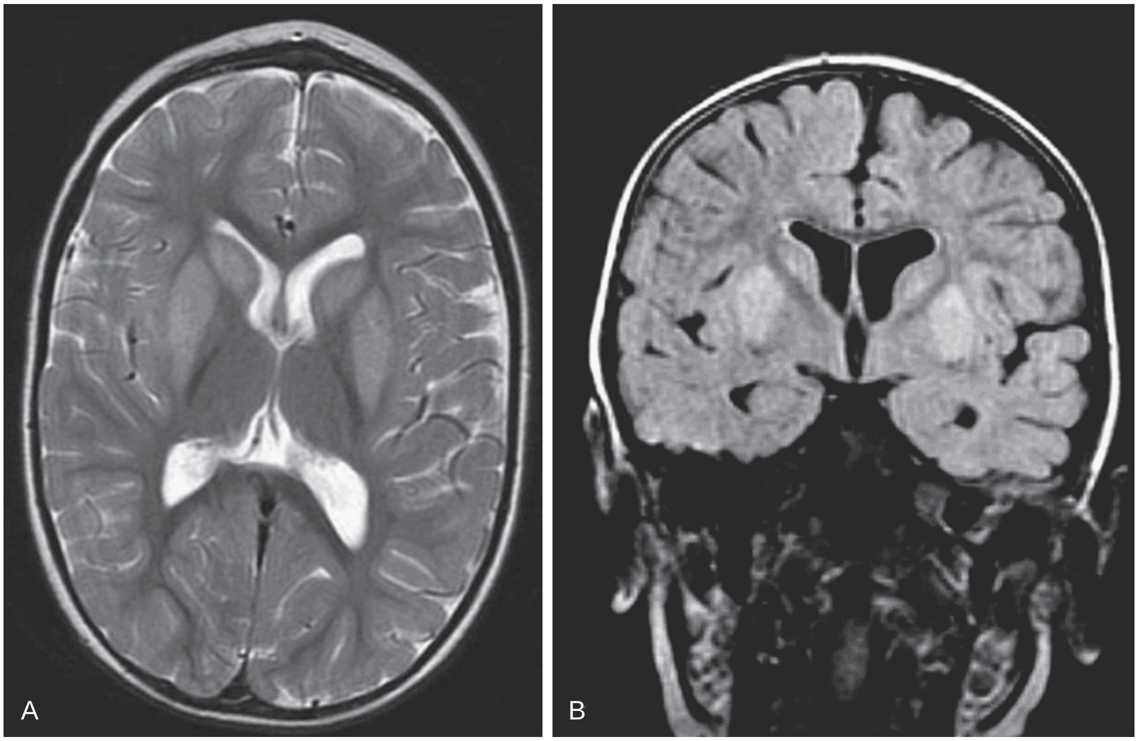
Methylmalonic acidemia results from a deficiency in methylmalonyl CoA mutase, an enzyme required for the conversion of methylmalonic CoA to succinyl CoA, which is necessary for the proper metabolism of the amino acids methionine, threonine, isoleucine, and valine. The high levels of methylmalonic acid resulting from the enzyme deficiency inhibit succinate dehydrogenase, which disrupts aerobic metabolism in the mitochondria. A relatively milder form of the disease is caused by deficiency of the cobalamin coenzyme. Propionic aciduria is a result of a deficiency in propionyl-CoA carboxylase and presents in a similar fashion.

Epilepsy is common in patients with methylmalonic acidemia, and cardiac involvement, including cardiomyopathy, arrhythmias, carnitine deficiency, and structural heart disease, have been reported.[31,32] Hyperglycemia also has been reported.[33] On imaging, parenchymal volume often is decreased, with delays in myelination. Optic neuropathy also has been reported.[34] Like other mitochondrial-based syndromes, the organic acidemias have a strong tendency to cause lesions in the basal ganglia, most particularly the globus pallidus. Lesions in the globus pallidus are striking in their stereotypical appearance from patient to patient. Affected areas will appear low in attenuation on CT and hyperintense on T2-weighted MRI (e-Fig. 33.14). Strokelike episodes similar to MELAS occasionally may be encountered. DWI will show restricted diffusion in affected regions. Proton MRS has shown decreases in NAA and elevation of lactate levels. Lactate elevation also can be found in the CSF, which is important for narrowing the differential diagnosis.

## Phenylketonuria

Phenylketonuria is an autosomal-recessive disorder resulting from enzyme deficiencies (phenylalanine hydroxylase, dihydrobiopterin reductase, and dihydrobiopterin biosynthesis) that impair the ability to convert phenylalanine to tyrosine, thereby producing the accumulation of neurotoxic acids. Its frequency is on the order of 1:14,000 live births.

MRI initially demonstrates symmetric hyperintense areas on T2-weighted images in the periatrial white matter. Extension occurs into the optic radiations and periventricular frontal white matter with more severe involvement and contrast enhancement. In untreated patients, it has been reported that diffuse white matter



**e-Figure 33.14. Propionic aciduria in a 2-year-old boy.** Axial T2-weighted fast spin echo (A) and coronal fluid attenuated inversion recovery (FLAIR) MR images (B) reveal an abnormal hyperintense signal bilaterally within the putamen without evidence of volume loss.

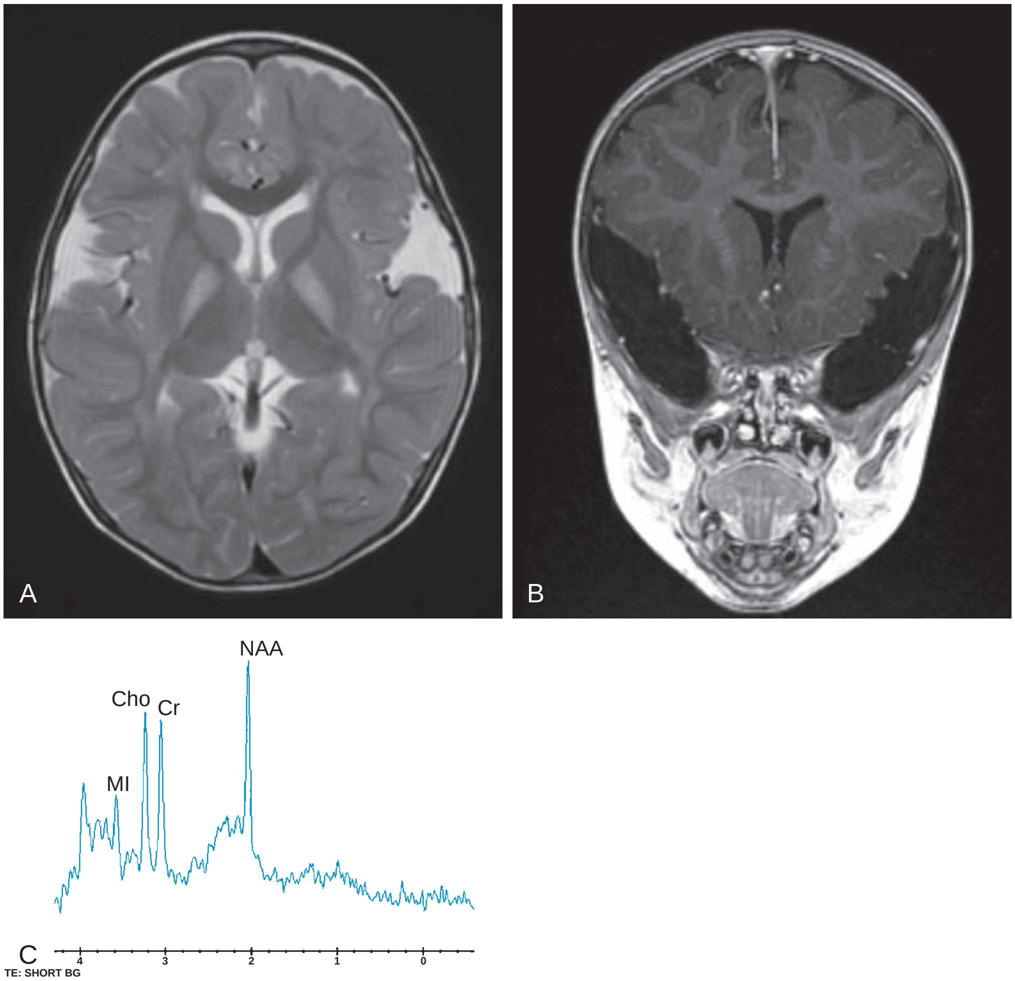


**Figure 33.13. Glutaric aciduria I in a 22-month-old boy.** (A) Axial fast spin echo T2-weighted MR image demonstrates a hyperintense signal bilaterally within the globus pallidus. (B) Coronal spoiled gradient echo MR image features the prominent symmetric, bilateral widening of the Sylvian fissures with frontotemporal hypoplasia. (C) A short echo (time to echo 35 milliseconds [msec]) magnetic resonance spectroscopy (MRS) image acquired within the basal ganglia demonstrates an elevation of choline.

pathology is evidence of hypomyelination; however, white matter abnormalities in patients who are treated early are indicative of intramyelinic edema.[35] Hyperintensity in multiple areas on T1-weighted images has been reported, corresponding to subcortical parenchymal calcification.

MRI white matter alterations in patients with phenylketonuria correlated to blood phenylalanine concentrations and to brain phenylalanine concentrations measured by proton MRS. MRS may demonstrate an abnormal peak at 7.30 ppm resulting from elevated phenylalanine. Interindividual variations of blood-brain barrier phenylalanine transport constants and variations of the individual brain phenylalanine consumption rate are responsible for the patient differences.

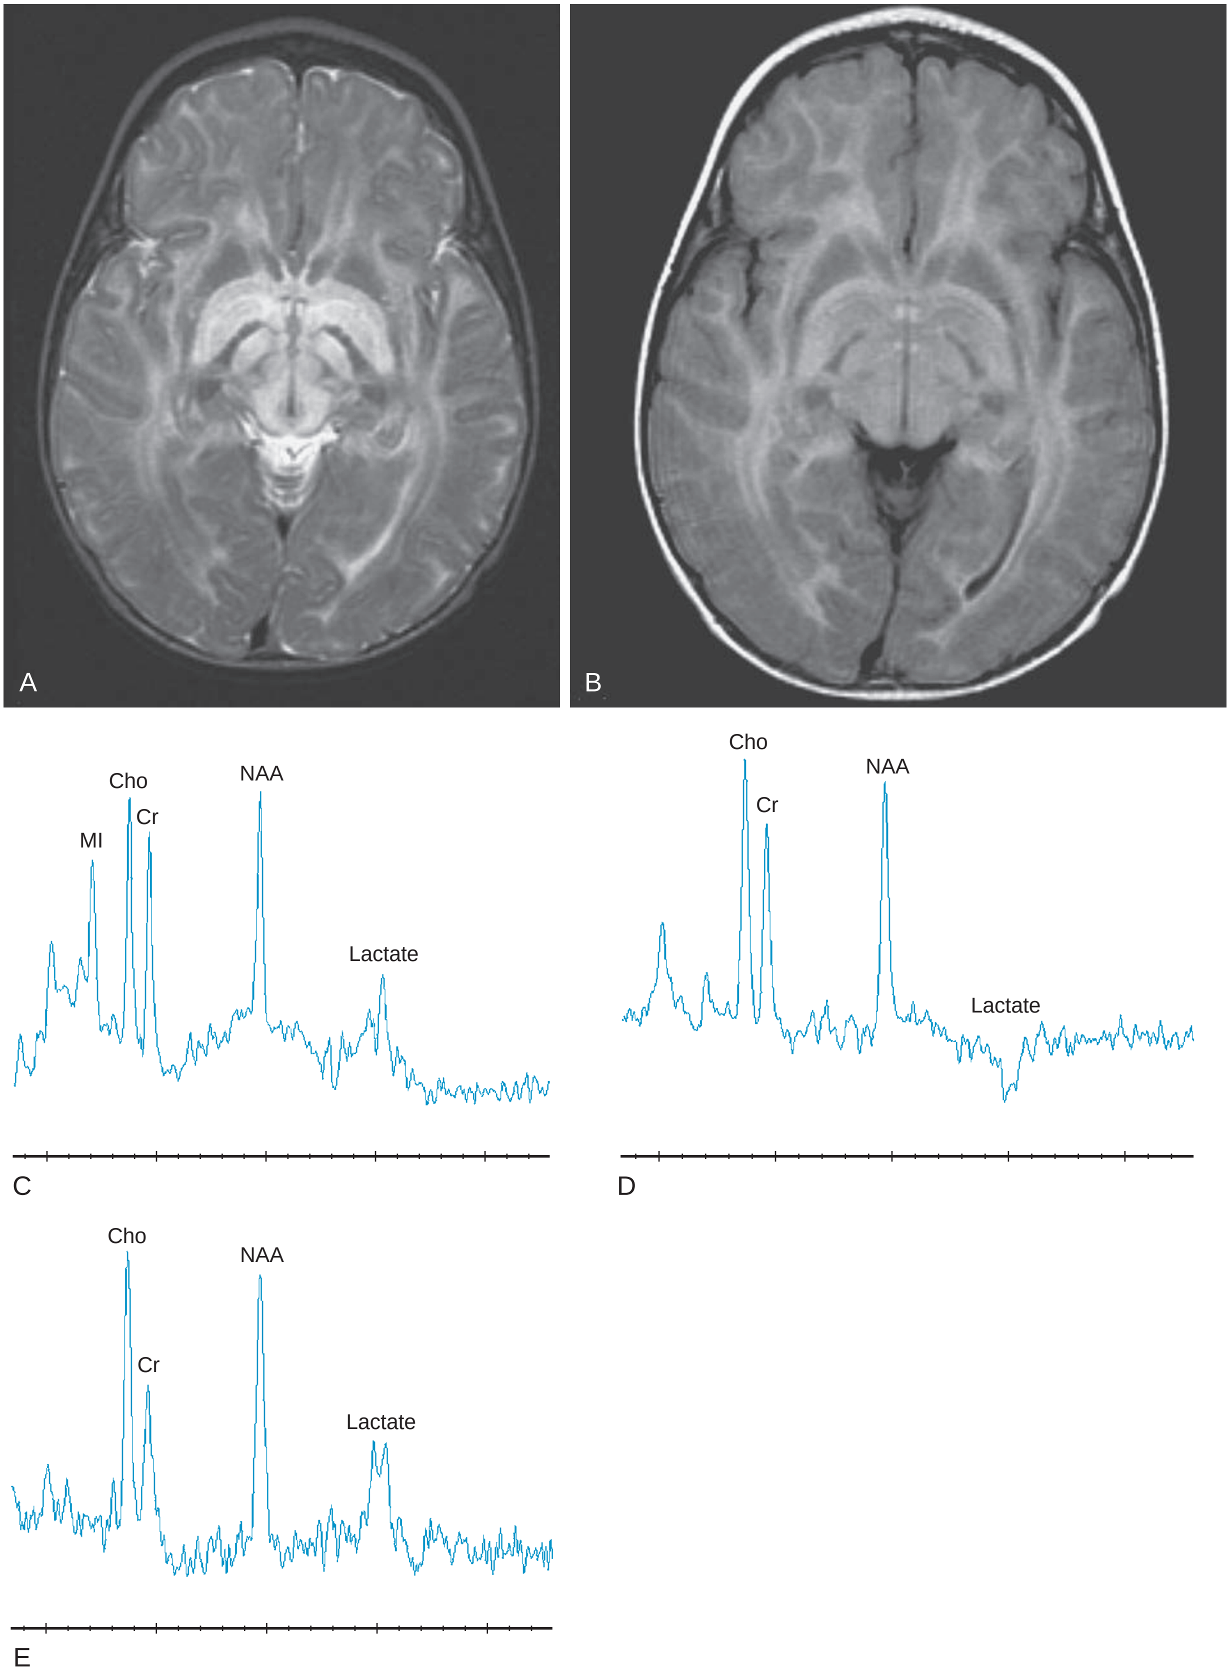
## Maple Syrup Urine Disease

MSUD is a rare autosomal-recessive disorder caused by defective oxidative decarboxylation of three branched-chain amino acids: valine, isoleucine, and leucine. The accumulation of metabolites in the urine leads to the characteristic odor, which resembles that of maple syrup. Although cerebral imaging findings initially may be unremarkable, diffuse cerebral edema develops with subsequent residual areas of hyperintensity in the dorsal brainstem and pons. Proton MRS of the brain appears to be useful for examining patients who have MSUD in different metabolic states. The accumulation of abnormal branched-chain amino acids and branched-chain alpha-ketoacids appear as a broad peak at 0.9 ppm accompanied by an elevated lactate level. The presence of cytotoxic or intramyelinic edema as evidenced by restricted water diffusion on DWI, with the presence of lactate on spectroscopy, could imply cell death. However, in the context of metabolic decompensation in MSUD, it appears that changes in cell osmolarity and metabolism can reverse completely after metabolic correction. Classification of MSUD includes a form responsive to thiamine (e-Fig. 33.15).

## Nonketotic Hyperglycinemia

Nonketotic hyperglycinemia occurs when a metabolic defect impairs the conversion of glycine to serine, resulting in CNS accumulation of glycine. The toxic effects of an elevated glycine level present in the neonatal period as lethargy, hypotonia, myoclonus, and seizures that may lead to an unresponsive state with apnea. Prognosis is poor, with few patients surviving beyond the neonatal period.

Pathology in nonketotic hyperglycinemia is characterized by vacuolation, astrocytosis, and demyelination, also called vacuolating



**e-Figure 33.15. Maple syrup urine disease in an infant.** Axial T2-weighted (A), axial fluid attenuated inversion recovery (FLAIR) (B), short echo magnetic resonance spectroscopy (MRS) (C), intermediate echo MRS (D), and long echo MRS (E) images reveal an abnormal signal within the brainstem, internal capsule, and globus pallidus. On short echo MRS, a composite of branched chain amino acids (0.9 parts per million [ppm]) with lactate (1.35 ppm) is inverted on intermediate echo and upright on long echo MRS. Notice the reduced signal intensity associated with the inversion at time to echo (TE) 144 milliseconds (msec) with partial restoration of the signal intensity at TE 288 msec. *(From Cecil KM. MR spectroscopy of metabolic disorders.* Neuroimaging Clin N Am. *2006;16:87–116; used with permission.)*

myelinopathy. Because these changes only occur in myelinated white matter, in the neonate they are restricted to the dorsal limbs of the internal capsule, dorsal brainstem, pyramidal tracts in the coronal radiata, and lateral thalamus. A long tractlike lesion involving the spinal cord has been reported in persons with late-onset disease.[36] On MR, these areas will show a hyperintense signal on T2-weighted images and restricted diffusion on DWI. Volume loss ensues and may be present at birth as a result of the toxic effects of glycine in utero. Proton MRS can detect the accumulated glycine itself, as a distinct resonance at 3.55 ppm. In patients with nonketotic hyperglycinemia, elevated cerebral glycine can be measured with proton MRS. Using long echo times, such as 288 ms, MRS reveals glycine at 3.5 ppm. With use of short echo times, the resonance at 3.5 is a composite of mI and glycine. Select metabolite ratios (NAA, mI, and glycine) appear to correlate with the patient's course (Fig. 33.16).

## PRIMARY DISORDERS OF WHITE MATTER (LEUKODYSTROPHIES)

The term "leukodystrophy" generally is reserved for conditions that are both progressive and genetically determined. Although

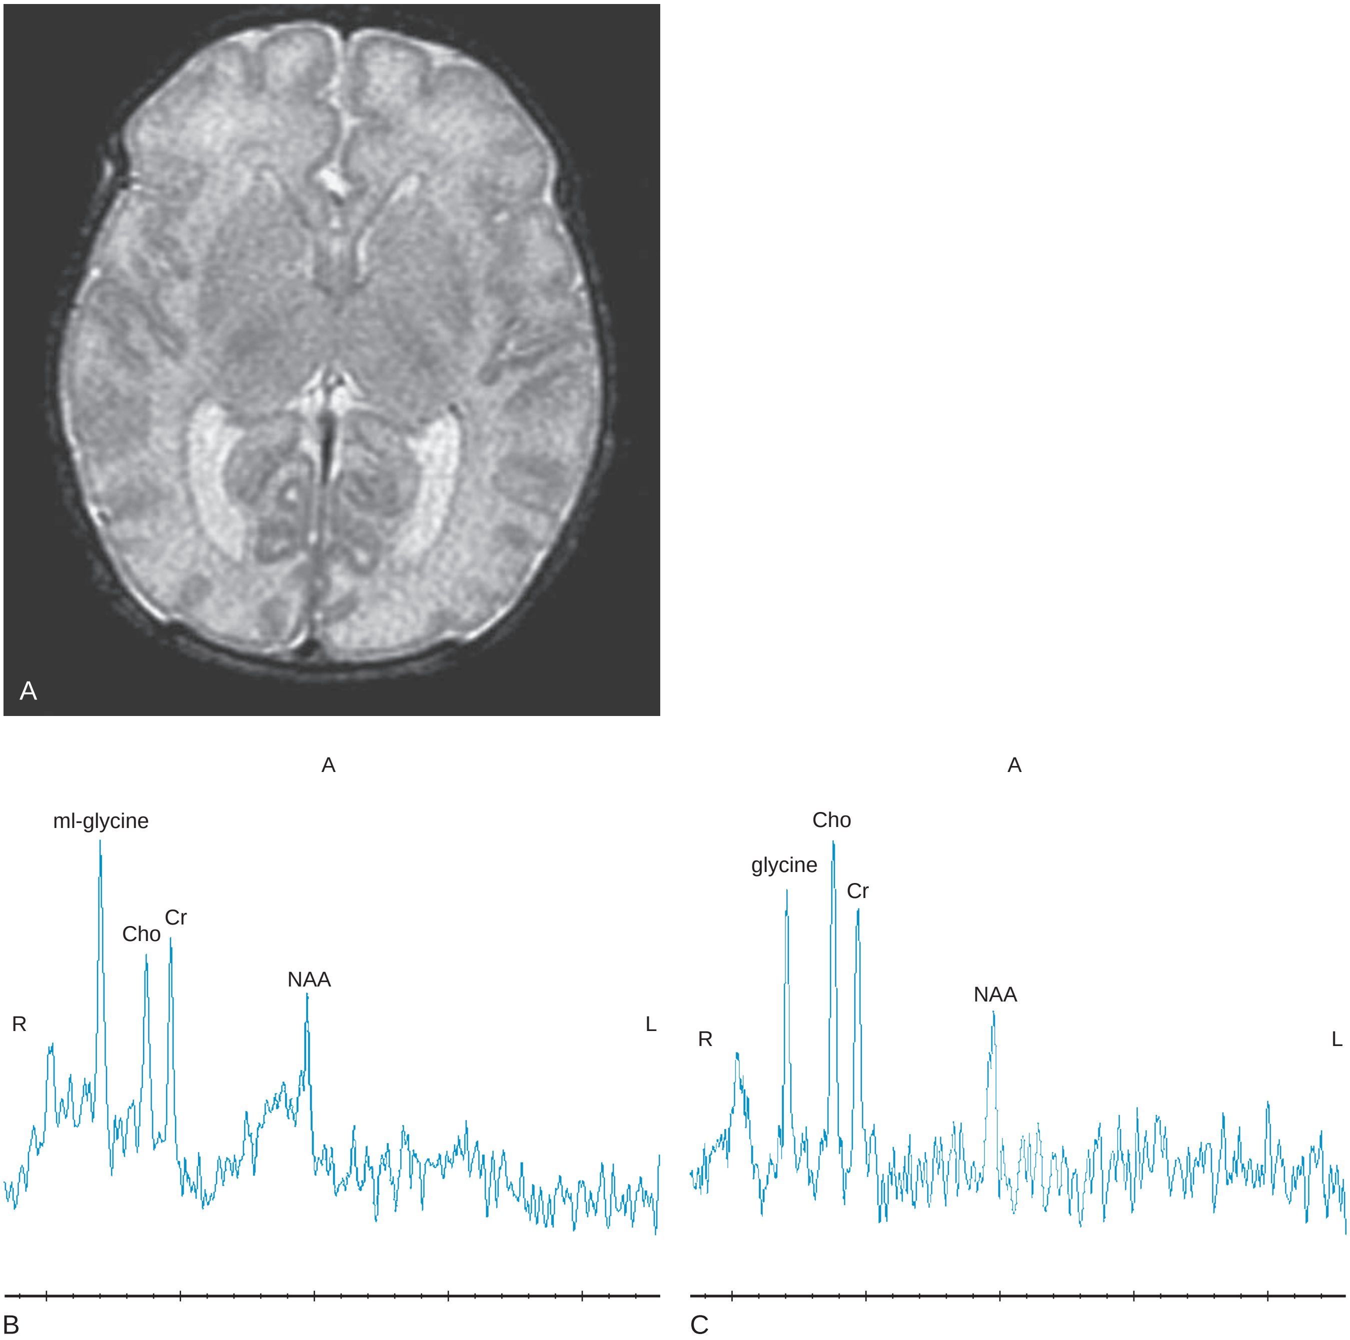


**Figure 33.16. Nonketotic hyperglycinemia in a neonate.** Axial T2-weighted (A), short echo magnetic resonance spectroscopy (MRS) (B), and intermediate (144 milliseconds [msec]) MRS (C) images are shown. The short echo spectrum demonstrates a composite myo-inositol and glycine resonance at 3.5 parts per million (ppm). The intermediate echo demonstrates glycine. *(From Cecil KM. MR spectroscopy of metabolic disorders.* Neuroimaging Clin N Am. *2006;16:87–116; used with permission.)*

these conditions eventually may involve and alter gray matter, the primary features affect the white matter.

## Canavan Disease

Canavan disease is an autosomal-recessive disorder arising from a deficiency of the enzyme aspartoacylase, which results in the accumulation of NAA in the brain. Three clinical subtypes—infantile, juvenile, and adult—are recognized. The most common is the infantile type, which usually presents within the first 6 months of life with hypotonia, irritability, and enlarging head size, leading to spasticity, blindness, choreoathetoid movement, and myoclonic seizures.

The diagnosis is made by demonstrating increased amounts of NAA in the urine and plasma. On histologic examination, the disease is seen to begin in a peripheral location, involving the U fibers of the subcortical white matter of the cerebral hemispheres. Later, the abnormality involves the deep white matter structures of both cerebral hemispheres, and eventually it extends to the cerebellum and spinal cord. The involvement of the U fibers of the white matter is diffuse, with evidence of vacuoles within the subcortical white matter and extending into the adjacent cortex.

The MRI findings are related to the myelin degeneration of the white matter tracts. The first change detected is hyperintensity on T2-weighted images of the subcortical U fibers. Eventually, there is diffuse involvement of all the white matter fiber tracts in both cerebral hemispheres. In the later stages of the disease, volume loss of the cerebral hemispheres occurs. Enlarged perivascular spaces, likely reflecting spongiform degeneration of the white matter, has been described.[37] MRS demonstrates marked elevation of the NAA peak, which is diagnostic for Canavan disease (Fig. 33.17).

## Alexander Disease

Missense mutations in the gene encoding for glial fibrillary acidic protein (GFAP) are found in all three clinical variants (infantile, juvenile, and adult) of Alexander disease. In brain biopsy specimens, Rosenthal fibers label extensively for GFAP upon immunocytochemistry. The mutations in Alexander disease are heterozygous and dominant, and accordingly most cases are sporadic. The most commonly encountered variant of Alexander disease is the infantile form, which presents in the first 2 years of life with megalencephaly and developmental delay, frequently with seizures. Children with the infantile form of the disease rarely survive to the second decade. The juvenile form presents after 4 years of age with speech and swallowing difficulties, ataxia, and spasticity. Progression is slower, with a more prolonged survival. Adult-onset disease has a more variable clinical presentation and occasionally is diagnosed incidentally at autopsy.

The diagnosis traditionally has been performed via a brain biopsy. The predominant histologic feature is a considerable amount of Rosenthal fibers within the white matter. Most commonly, the disease begins in the periventricular white matter, usually involving the frontal lobes and then extending into the parietotemporal and then the occipital regions. Eventually, involvement of the cerebellar white matter and spinal cord occurs. CSF oligoclonal bands have been reported in the adult-onset variant.[38]

The MRI findings demonstrate macrocephaly with hyperintensity on T2-weighted images involving the white matter areas, which commonly is seen in the frontal areas with progression posteriorly to involve other parts of the cerebral hemispheres (Fig. 33.18). Five MRI characteristics can be applied to suspected cases of Alexander disease to make a presumptive diagnosis: (1) extensive cerebral white matter changes with frontal predominance, (2) a periventricular rim with a high signal on T1-weighted images and a low signal on T2-weighted images, (3) signal abnormalities with swelling or volume loss in the basal ganglia and thalami, (4) brainstem signal abnormalities, and (5) contrast enhancement of one or more of the following structures: ventricular lining, periventricular rim, white matter of the frontal lobes, optic chiasm, fornix, basal ganglia, thalamus, dentate nucleus, or brainstem structures. Although many of these abnormalities may be seen in other leukodystrophies, the association of four or more appears to be relatively specific for Alexander disease (see Fig. 33.18).[39,40] The extent and pattern of contrast enhancement and the distinctive periventricular rim of abnormal signal are not encountered in many other processes, making contrast administration useful in this specific diagnosis.

Proton MRS has shown elevated concentrations of mI in conjunction with normal or increased choline compounds in gray and white matter, basal ganglia, and cerebellum, that indicate astrocytosis and demyelination.[41] Neuroaxonal degeneration, as reflected by a reduction of NAA, was most pronounced in cerebral and cerebellar white matter.

## Megalencephalic Leukoencephalopathy With Subcortical Cysts

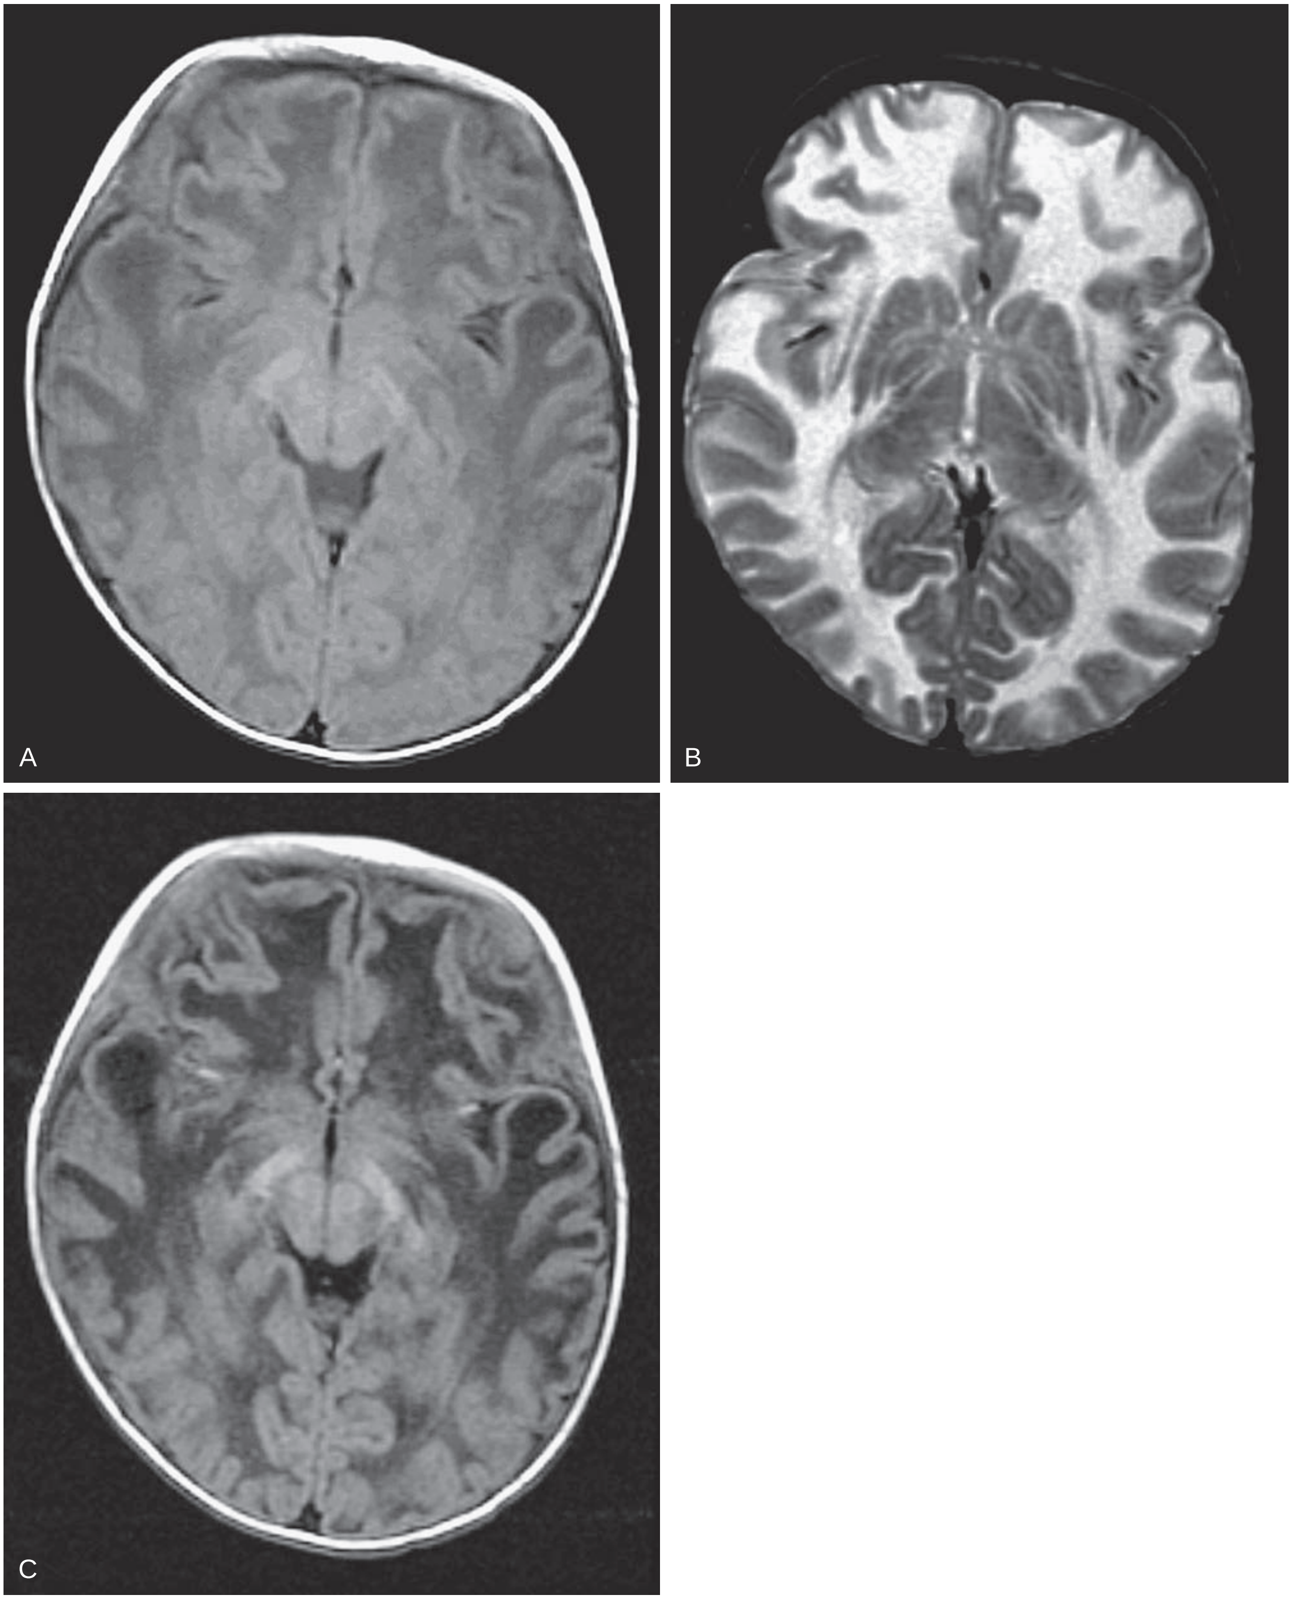
Megalencephalic leukoencephalopathy with subcortical cysts typically presents in infancy or childhood with macrocrania, developmental delay, seizures, and motor disability. MRI demonstrates widespread signal abnormalities throughout the white matter, with sparing of deep structures. Cysts typically are identified in the subcortical temporal lobes and less frequently in the frontal, parietal, or occipital lobes. Despite the extensive abnormalities on imaging, many affected patients achieve a high level of normal function. The genetic source of the condition has been traced to the *MLC1* gene on the long arm of chromosome 22 (22q13.33). The disease is inherited in an autosomal-recessive pattern, and because of the variable phenotype, identification of a single case should prompt further investigation and genetic counseling (e-Fig. 33.19).

## Leukoencephalopathy With Brainstem and Spinal Cord Involvement and Elevated White Matter Lactate

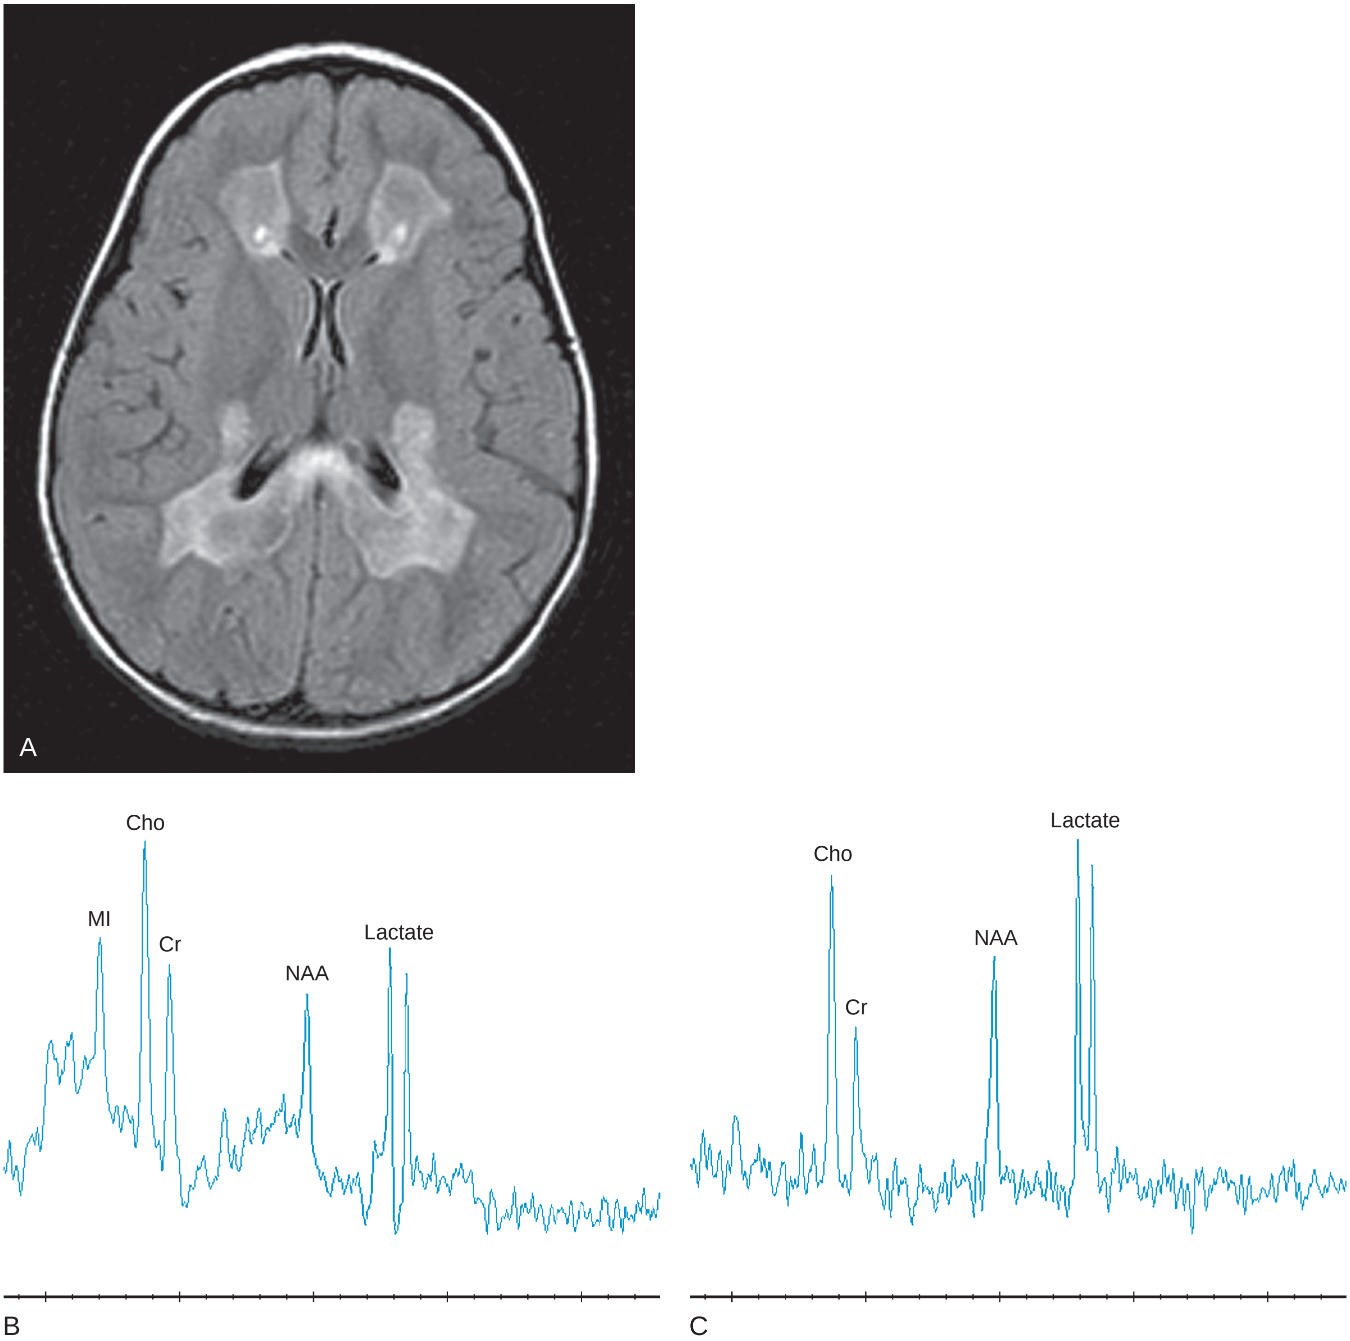
Leukoencephalopathy with brainstem and spinal cord involvement and elevated white matter lactate recently has been described based on the MRI characteristics. Initial childhood development is generally unremarkable, with motor deterioration occurring later in childhood. The MRI pattern is quite distinct. The progressive white matter abnormalities spread from the periventricular region outward with sparing of the subcortical U fibers (e-Fig. 33.20). The corpus callosum is affected with posterior preference. The pyramidal tracts are affected over their entire length from the posterior limb of the internal capsule and brainstem into the lateral corticospinal tracts of the spinal cord. The sensory tracts are involved from the dorsal columns in the spinal cord, the medial lemniscus through the brainstem up to the level of the thalamus, and the corona radiata above the level of the thalamus. The cerebellar involvement progresses over time to the point of significant volume loss. Clinical severity and the extent of neurologic abnormalities on MRI do not appear to correlate.[42]

## Galactosemia

Galactosemia is the result of a deficiency in galactose-1-phosphate uridyl transferase, an enzyme essential for the metabolism of galactose. It presents in infants soon after the introduction of cow's milk into the diet. Clinical features include failure to thrive, hepatomegaly with jaundice, vomiting and diarrhea, cataracts, increased ICP, and mental deterioration. It can be identified by the presence of increased reducing substances in the stool. Neurologic



**e-Figure 33.19. Megalencephalic leukoencephalopathy with subcortical cysts in a 7-month-old boy.** Axial T1-weighted (A), axial T2-weighted (B), and axial fluid attenuated inversion recovery (FLAIR) (C) MR images are shown. A decreased signal throughout the hemispheric white matter is demonstrated on the T1-weighted and FLAIR images, with a corresponding hyperintense signal on the T2-weighted images. The basal ganglia are spared.



**e-Figure 33.20. Leukodystrophy with brainstem and spinal cord involvement and high lactate levels in a 2-year-old girl.** Axial T2-weighted (A), short echo magnetic resonance spectroscopy (MRS) (B), and long echo MRS (C) images are shown. The T2-weighted image (A) reveals a confluent, hyperintense signal in the central white matter with sparing of subcortical U fibers. Elevated lactate, choline, and myo-inositol levels with diminished N-acetylaspartate are demonstrated in white matter regions with an abnormal signal. Not shown are normal spectra from unaffected gray matter. *(From Cecil KM. MR spectroscopy of metabolic disorders.* Neuroimaging Clin N Am*. 2006;16:87–116; used with permission.)*

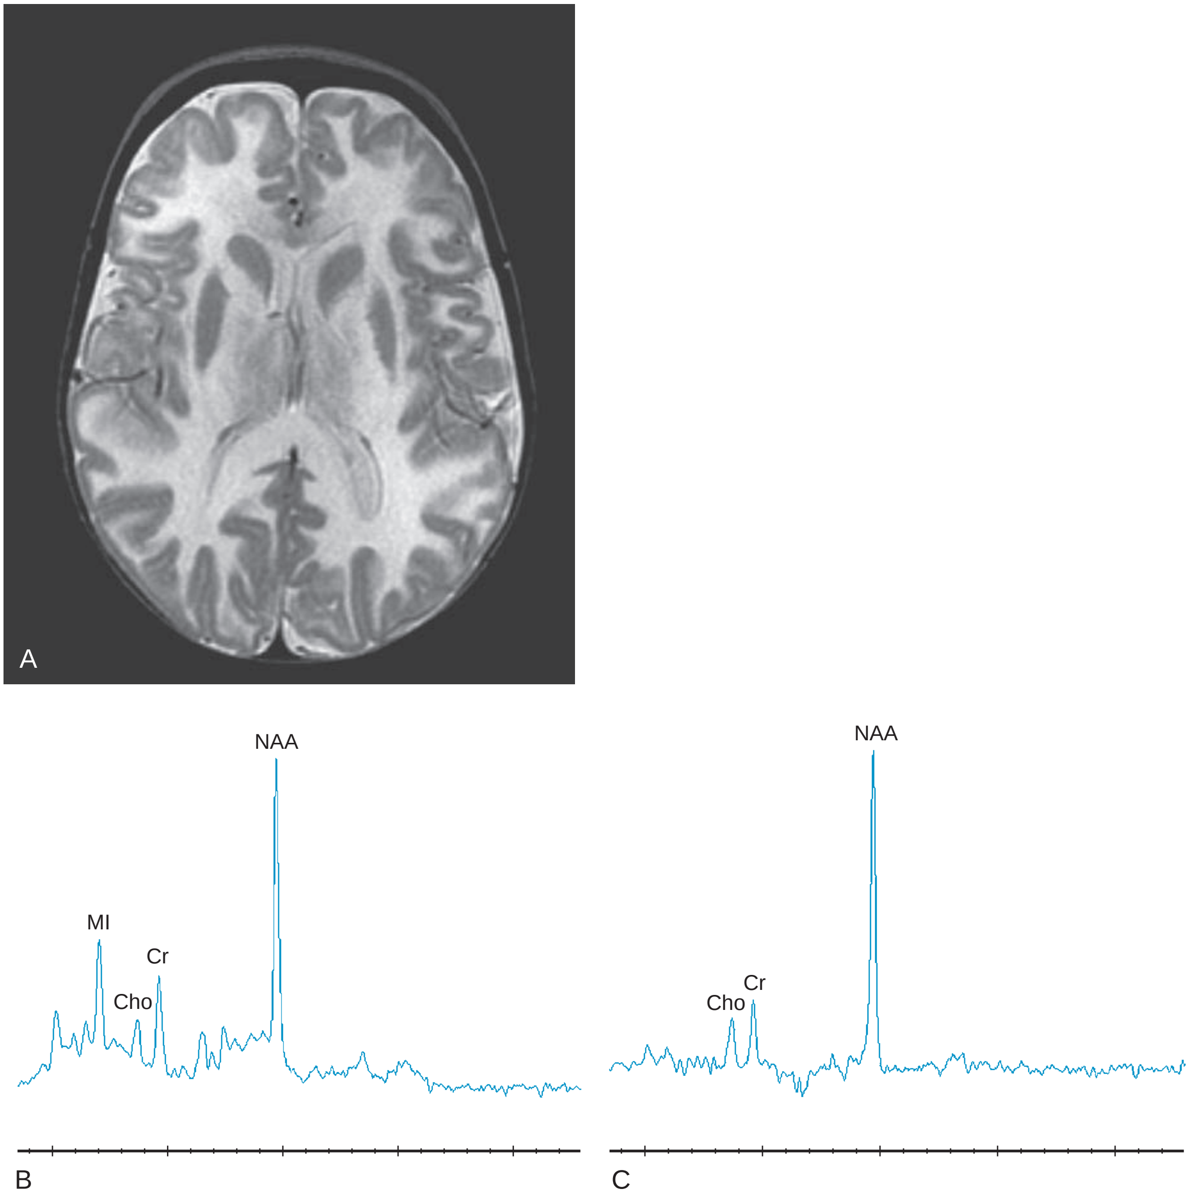


**Figure 33.17. Canavan disease in a 12-month-old girl.** Axial T2-weighted (A), short echo magnetic resonance spectroscopy (MRS) (B), and long echo MRS (C) images are shown. Diffuse hypomyelination is revealed on the T2-weighted image. Elevated N-acetylaspartate (NAA) is the key feature with secondary myo-inositol elevation representing gliosis. Because of the deficiency in aspartoacylase, NAA accumulates in the mitochondria, impairing myelin synthesis. *(From Cecil KM. MR spectroscopy of metabolic disorders.* Neuroimaging Clin N Am. *2006;16:87–116; with permission.)*

dysfunction is the result of hypoglycemia and the accumulation of galactose, galactose-1-phosphate, and galactitol in the brain and eye. In adult forms, low bone density often is observed.[43]

On CT, diffuse low attenuation of white matter mimicking diffuse edema often is present. The most consistent early MRI finding is a delay in myelination, which may appear as persistence of a hyperintense T2 signal in the peripheral white matter. These signal abnormalities may be more widespread in older children as a result of demyelination. Patchy areas of focal increased signal on T2-weighted images also have been reported and are thought to represent damaged areas of white matter. Eventually, a pattern of mild cerebral or cerebellar volume loss is found. Brain edema may occur in infants with galactosemia and has been associated with accumulation of galactitol.

## Creatine Deficiency

Inborn errors of creatine metabolism, specifically defects in creatine synthesis and transport, recently have been reported involving arginine glycine amidinotransferase (AGAT) and guanidinoacetate methyltransferase (GAMT).[44] Patients may have epilepsy and severe developmental delay. Proton MRS clinical studies have led to the discovery of three creatine deficiency syndromes: creatine transporter deficiency syndrome, AGAT deficiency, and GAMT deficiency. Several patients have been found to have a markedly diminished or absent creatine signal with proton MRS. If proton MRS reveals the absence of creatine in the brain, serum and urine creatine assessments may give a preliminary indication of whether there is a synthesis defect (diminished creatine) or a transport

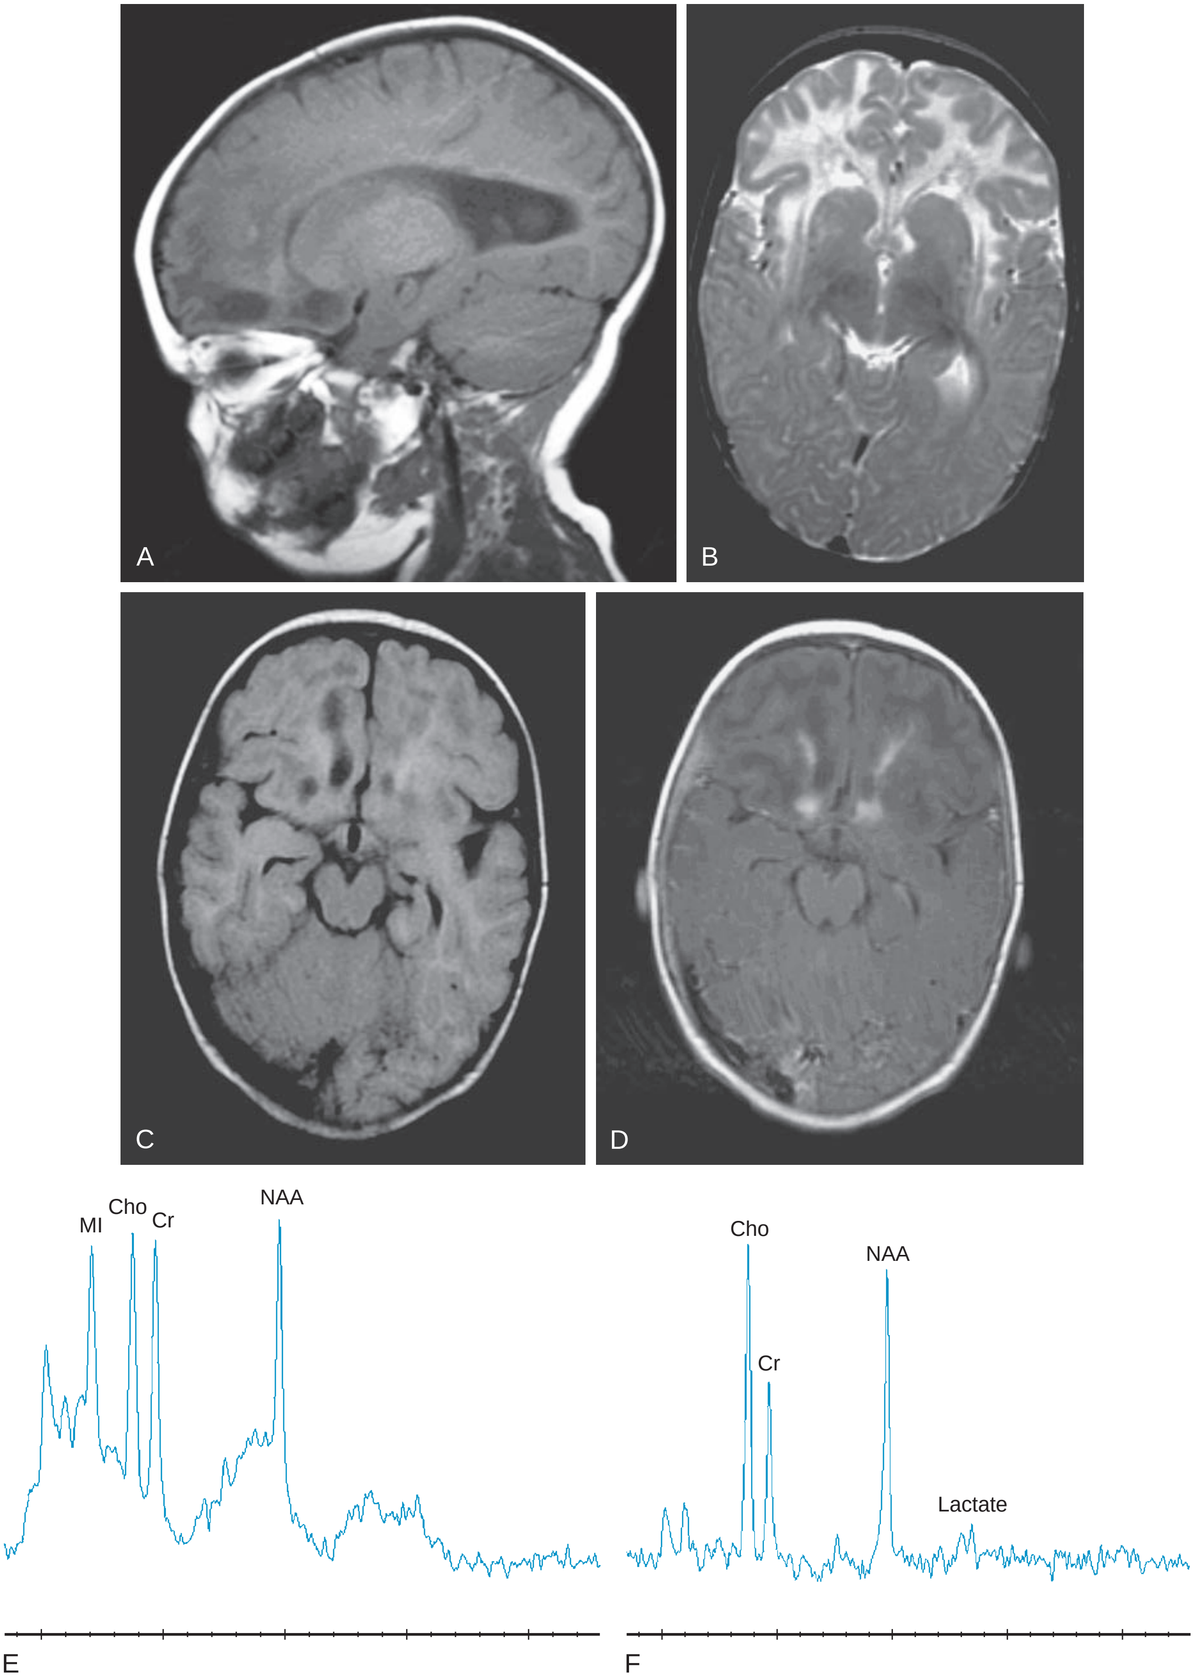

**Figure 33.18. Alexander disease in an 8-month-old girl.** Sagittal T1-weighted (A), axial T2-weighted (B), axial fluid attenuated inversion recovery (FLAIR) (C), axial T1-weighted postcontrast (D), short echo magnetic resonance spectroscopy (MRS) (E), and long echo MRS (F) MR images were acquired in the frontal white matter. The deep frontal and periventricular white matter demonstrate a hypointense T1-weighted and hyperintense T2-weighted signal. The frontal lobe cavitations are revealed on the FLAIR image with hypointense signal and demonstrate enhancement at the borders. Volume enlargement of the caudate heads is seen. Decreased N-acetylaspartate with lactate, choline, and myo-inositol elevations representing macrophage infiltration, demyelination, and astrocytosis are indicated from the MRS image.

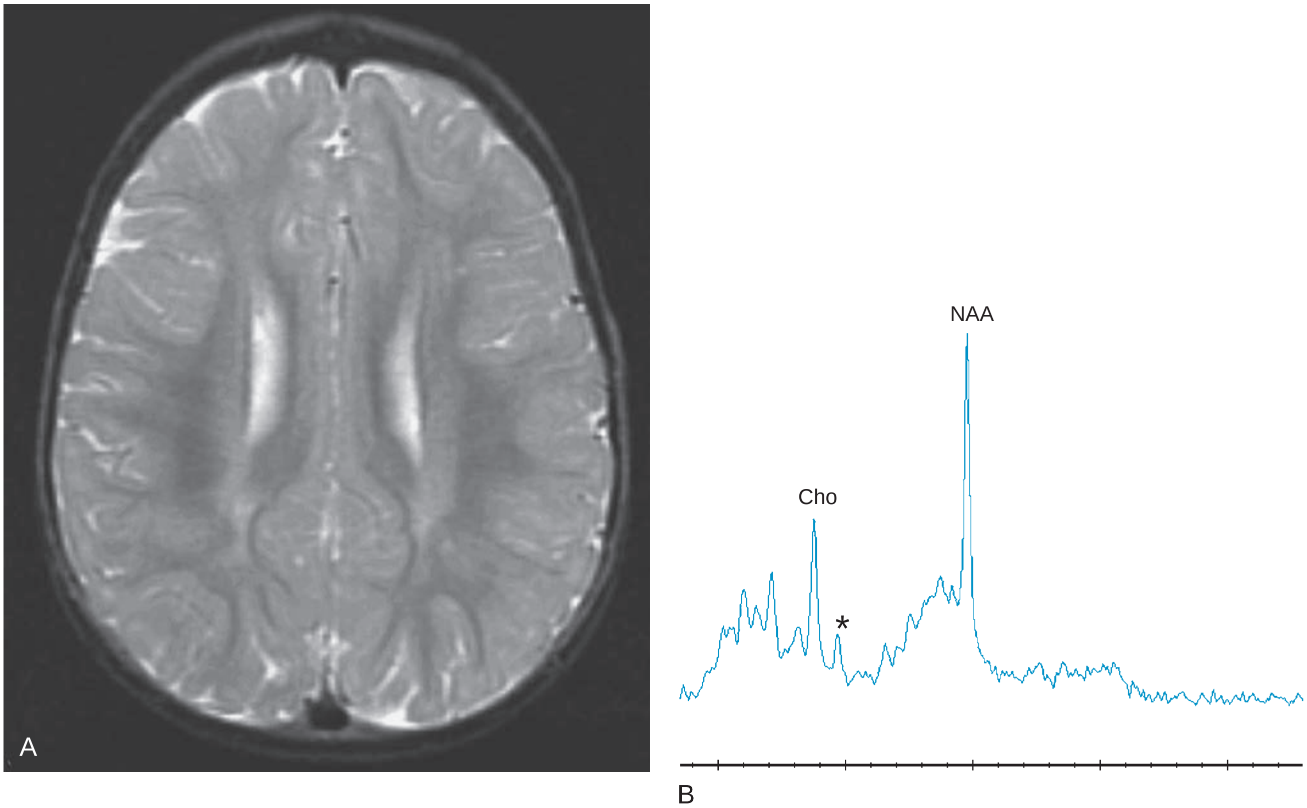

**Figure 33.21. Creatine transporter mutation in a 2-year-old boy.** Axial T2-weighted (A) and short echo magnetic resonance spectroscopy (MRS) (B) images reveal an abnormal signal within the periventricular white matter, representing hypomyelination. Short echo spectroscopy reveals a marked reduction of creatine signal *(asterisk)*.

defect (elevated creatine) (Fig. 33.21). In cases of synthesis defects, proton MRS can monitor increasing brain creatine concentration with oral supplementation, which offers improvement of some symptoms but not recovery of normal function.

## MISCELLANEOUS WHITE MATTER DISORDERS

### Pelizaeus-Merzbacher Disease and Disorders of Myelin Proteolipid Protein

PMD is condition that manifests as a primary defect in myelin formation. It is the prototypical hypomyelination syndrome, in that the imaging appearance is of an otherwise normal brain that is severely delayed in its formation of myelin.

Mutations or duplications of the gene-encoding myelin proteolipid protein (*PLP*; Xq22.2) produce variable clinical manifestations. Spastic paraplegia type 2 is characterized by lower limb spasticity alone. Persons with "complicated" spastic paraplegia type 2 exhibit cerebellar ataxia, nystagmus, and a pyramidal syndrome. The more severe phenotypic manifestations traditionally have been categorized as PMD and result in alterations of multiple functional systems, with symptoms including nystagmus and compromises in respiratory function, with associated severe disability and morbidity.

The classic descriptions of PMD divide it into several different subtypes. The most common presentation is that of the slowly progressive "classic" form that presents in infancy with early nystagmus ("dancing eyes"), poor head control, spasticity, ataxia or extrapyramidal movement disorders, and severe developmental delay. These findings slowly progress, usually leading to death in late adolescence or young adulthood. A second pattern (connatal, or the Seitelberger type) begins in the neonatal period and is more rapidly progressive, with death typically occurring in the first decade.

Imaging demonstrates a marked delay in myelination from the onset. Whereas many metabolic or neurodegenerative processes are associated with delayed myelination, the absence of other imaging findings is characteristic of the early stages of the *PLP* gene disorders. On CT, hypomyelination can be appreciated as diffuse low attenuation of white matter. The characteristic normal progression of myelination as detected by MRI in the first 2 years of life is entirely absent or severely slowed in persons with the *PLP* gene disorders. Myelination that does occur tends to be patchy, without the characteristic predictable distribution within the white matter tracts. In the later stages of disease, white matter volume may decrease, with thinning of the corpus callosum and excess mineralization in the basal ganglia.

Diffusion tensor imaging has been reported to be effective for detecting subtle changes in the microstructure of the white matter, such as abnormal myelination, even when findings of MRI and MRS are normal.[45]

Proton MRS has shown diminished values of NAA and mild elevations of choline, indicating axonal injury and secondary gliosis. Heterogeneous cerebral metabolite patterns have been found in patients with PMD and Pelizaeus-Merzbacher–like disease, indicating a mixture of nonspecific changes as a result of primary hypomyelination and secondary gliosis and demyelination.[46] However, neither MRI nor MRS provided unique patterns to allow differentiation between patients with PMD and Pelizaeus-Merzbacher–like disease.

# OTHER DISORDERS AFFECTING THE BASAL GANGLIA

## Huntington Disease

Huntington disease (HD) is an autosomal-recessive degenerative disorder, with most cases presenting after the fourth decade. HD is characterized by a movement disorder. Cerebellar symptoms, seizures, rigidity, and mental retardation are common. Caudate volume loss is demonstrated on MRI, although cortical changes also may be detected.[47] Bilateral areas of T2 hyperintensity may be seen in the basal ganglia. Global atrophy in persons with HD shows a disproportionate relationship to caudate involvement.[48] In preHD, gray matter change has been reported to be specific to basal ganglia-thalamocortical pathway regions, whereas white matter changes were much more generalized.[49] White matter diffusivity abnormalities also have been reported in the corpus callosum and external/extreme capsules.[50] In premanifest gene carriers, the white matter pathway of the sensorimotor cortex is impaired.[51] Changes in the hypothalamic region have been reported in prodromal HD and appear to be one of the earliest evident features of this disease.[52]

## Fahr Disease

Fahr disease comprises a group of disorders that have basal ganglia calcification. Mental deterioration and growth retardation have been described. MRI demonstrates areas of signal void within the basal nuclei and dentate nuclei on T1- and T2-weighted images. The appearances correlate with the areas of calcification on CT. Transcranial sonography also has been reported to be useful for visualizing calcifications of the basal ganglia.[53]

## Wilson Disease

Hepatolenticular degeneration, or Wilson disease, is an autosomal-recessive inborn error in copper metabolism. Ceruloplasmin, the serum transport protein for copper, is deficient, with resultant copper deposition in various sites. This disease typically presents in young adults with chronic hepatic insufficiency and neurologic deterioration. Copper fails to be excreted in the bile and thus accumulates in the body, especially in liver, brain, kidney, and red blood cells. The clinical presentation is primarily that of extrapyramidal signs, hepatic insufficiency, and the presence of Kayser-Fleischer corneal rings. Either the hepatic toxicity or the neurologic findings may predominate. Neurologic dysfunction begins with changes in mentation, abnormalities in speech or language, and difficulty swallowing, all of which may progress with time.

On CT, the basal ganglia are typically low in attenuation, especially the globus pallidus and putamen arising from copper accumulation. Volume loss of these structures eventually follows. The white matter also may appear low in attenuation, with volume loss eventually leading to compensatory dilatation of the lateral ventricles. On MRI, the basal ganglia are hyperintense on T1-weighted images and the first echo of the T2-weighted sequence, as seen with other causes of hepatic dysfunction. These same regions typically are hyperintense on T2-weighted images early in the course of the disease, but the hyperintense signal may decrease late in the disease associated with an increase in signal on the T1-weighted images. The white matter demonstrates progressive increase in T2-signal as a result of demyelination and gliosis. Corpus callosum abnormalities also have been reported.[54] The presence of signal changes involving the basal ganglia, thalami, and brainstem; the "face of giant panda" sign; midbrain tectal plate signal changes; or central pontine myelinolysis-like changes all can be considered to be diagnostic of Wilson disease.[55]

## KEY POINTS

### Clinical Features Suggestive of a Metabolic or Neurodegenerative Disorder

- Loss of developmental milestones or unexplained developmental delay
- Predisposing conditions are absent
- Basal ganglia symptoms such as hypotonia and hypertonia
- Progressive features of encephalopathy
- An unexplained clinical course inconsistent with imaging findings

### General Imaging Features of a Metabolic or Neurodegenerative Disorder

- Progressive changes with time coupled with clinical progression
- Progressive hypomyelination
- Symmetric involvement of white matter tracts
- Pervasive and symmetric involvement of white and gray matter
- Contrast enhancement appears in later stages of the disease course

### Clinical Indications for Incorporating MRS into the Imaging Evaluation

- Developmental regression or progressive condition
- Feeding difficulties
- Parental consanguinity
- Previously affected siblings
- Family history of mental retardation
- Multiple organ involvement
- Delayed myelination on conventional anatomic images

### Genetic Origins of Select Mitochondrial Disorders

- Deletions in mtDNA
  - Kearns-Sayre syndrome
- Mitochondrial DNA point mutations
  - Adenosine triphosphate 6 mutation
  - Maternally inherited myopathy/cardiomyopathy
  - MELAS
  - MERRF
  - Multiple inherited subcutaneous lipomatosis
  - Leber hereditary optic neuropathy
- Nuclear DNA abnormalities
  - Infantile cytochrome oxidase deficiency
- Leigh syndrome
- Mitochondrial myopathy, peripheral neuropathy, gastrointestinal encephalopathy

## BRAIN INFECTIONS

Bacterial, viral, fungal, and parasitic organisms are all causative factors in central neurologic system (CNS) infection. Brain infection manifests as encephalitis, cerebritis, and meningitis. Encephalitis refers to diffuse infection of the brain parenchyma, whereas cerebritis is due to a more focal parenchymal infection. Meningitis refers to infection of the pia, arachnoid, and dural membranes as well as the cerebrospinal fluid (CSF). Ventriculitis is often present in cases of meningitis. Infectious complications most often include abscess and/or empyema. These infectious collections, in association with infectious symptomatology, are straightforward in their diagnosis. Infection in the setting of tumor or hemorrhage often presents a diagnostic conundrum.

Imaging of CNS infection is most often initially performed by means of computed tomography (CT) to assess for hydrocephalus or increased intracranial pressure before the performance of a lumbar puncture. Nonspecific parenchymal hypoattenuation indicative of edema on CT is sometimes appreciated in cases of more focal infection. In more complicated cases, CT is superior in the evaluation of bone erosion and destruction. More advanced imaging utilizing magnetic resonance imaging (MRI) is warranted in the assessment of infectious complications such as abscess, empyema, vasculitis, and/or ischemia in the setting of a worsening clinical condition or lack of clinical improvement. Infection is most often manifested on MRI by hyperintense signal abnormality on T2-weighted and proton density sequences. The most sensitive magnetic resonance (MR) sequence is fluid-attenuated inversion–recovery (FLAIR). There is often corresponding hypointense signal on T1-weighted sequences. Postcontrast T1-weighted images are essential in the evaluation for infectious collections and meningeal enhancement. Postcontrast images or magnetic resonance venography (MRV) sequences help to visualize suspected venous sinus thrombosis as a complication of infection. Diffusion-weighted imaging (DWI) and apparent diffusion coefficient (ADC) maps help in localizing abscess collections and infection associated with ischemia and can at times help distinguish lymphoma from abscess, especially in immunocompromised patients. DWI may also demonstrate lesions earlier than conventional sequences in detecting viral infections such as herpes and West Nile virus (e-Fig. 34.1). MR spectroscopy (MRS) may be helpful in distinguishing pyogenic abscesses from those composed of more atypical organisms, with the former often demonstrating the presence of amino acids and lack of choline.

## BACTERIAL INFECTIONS

Nearly two-thirds of cases of bacterial meningitis in the United States occur in children. Routes of transmission include hematogenous, direct traumatic, congenital, as well as via direct extension from adjacent sinus or mastoid disease (e-Fig. 34.2, Figs. 34.3 and 34.4, and e-Fig. 34.5). Imaging plays a key role in determining the course of treatment for bacterial infection. It is essential to distinguish between a focal cerebritis (Fig. 34.6), in which surgery is contraindicated and tends to respond to antibiotics, and frank abscess that often requires surgical intervention in addition to antibiotic therapy.

Hypoattenuation on CT, indicative of edema, and corresponding hyperintense T2-weighted and hypointense T1-weighted signal on MRI with patchy nonspecific postcontrast enhancement are typical imaging characteristics of cerebritis. Mild to moderate mass effect is often present. Sequential imaging is essential in the assessment of the response to antibiotics or progression to an abscess. Progression from cerebritis to an abscess generally takes 1 to 2 weeks but can progress more rapidly in the neonatal population. *Citrobacter*, *Serratia*, and *Proteus* are the most common causes of neonatal brain abscess. *Citrobacter* and *Serratia* infections may cause neonatal medullary vein thrombosis and associated hemorrhage (Fig. 34.7). In general, abscesses tend to be situated at gray-white matter junctions in the region where the diameter of the end arterioles changes (Fig. 34.8). Opportunistic organisms are common culprits in immunocompromised neonates. Differential considerations of a peripherally contrast-enhancing fluid-filled structure in the brain includes infectious abscess and tumor. DWI is often helpful when evaluating for an abscess, as lesions on DWI will appear hyperintense (and dark on ADC), indicating restricting material. On both MRI and CT, abscesses tend to have smooth regular inner margins and are often thinner-walled along their medial edge than along their lateral margins. Intraventricular rupture of an abscess portends a poor outcome. MRS of abscesses is notable for the presence of amino acids and lactate (Fig. 34.9) and the absence of normal metabolite peaks. In neonates, ultrasound (US) may depict a hypoechoic abscess with peripheral hyperechogenicity, which at times may contain dependent echogenic debris.

Bacterial meningitis is the most common form of pediatric CNS infection (Fig. 34.10). Although not diagnosed by imaging, imaging is warranted if a diagnosis is unclear, persisting seizures are present, and/or symptoms persist despite treatment. It is more common in preterm infants as well as full-term infants within the first month of life. The subarachnoid space tends to resist infection in older normal children, making meningitis in this age group a rarity. Most cases of neonatal meningitis in the United States are caused by group B streptococcus (GBS) (Fig. 34.11) and *Escherichia coli*. Other less common organisms (e.g., *Serratia*, enterococci, and *Listeria*) tend to inflict more extensive destruction. In infants greater than 1 month of age, the most common causative organisms are *Haemophilus influenza* type b, *Streptococcus pneumonia* (Fig. 34.12), *Neisseria meningitides*, and *E. coli*. Complications of meningitis include cerebritis, abscess, empyema, hydrocephalus, venous thrombosis, infarction (venous and/or arterial), ventriculitis (e-Fig. 34.13), mycotic aneurysms (e-Fig. 34.14), and sensorineural hearing loss (Fig. 34.15).

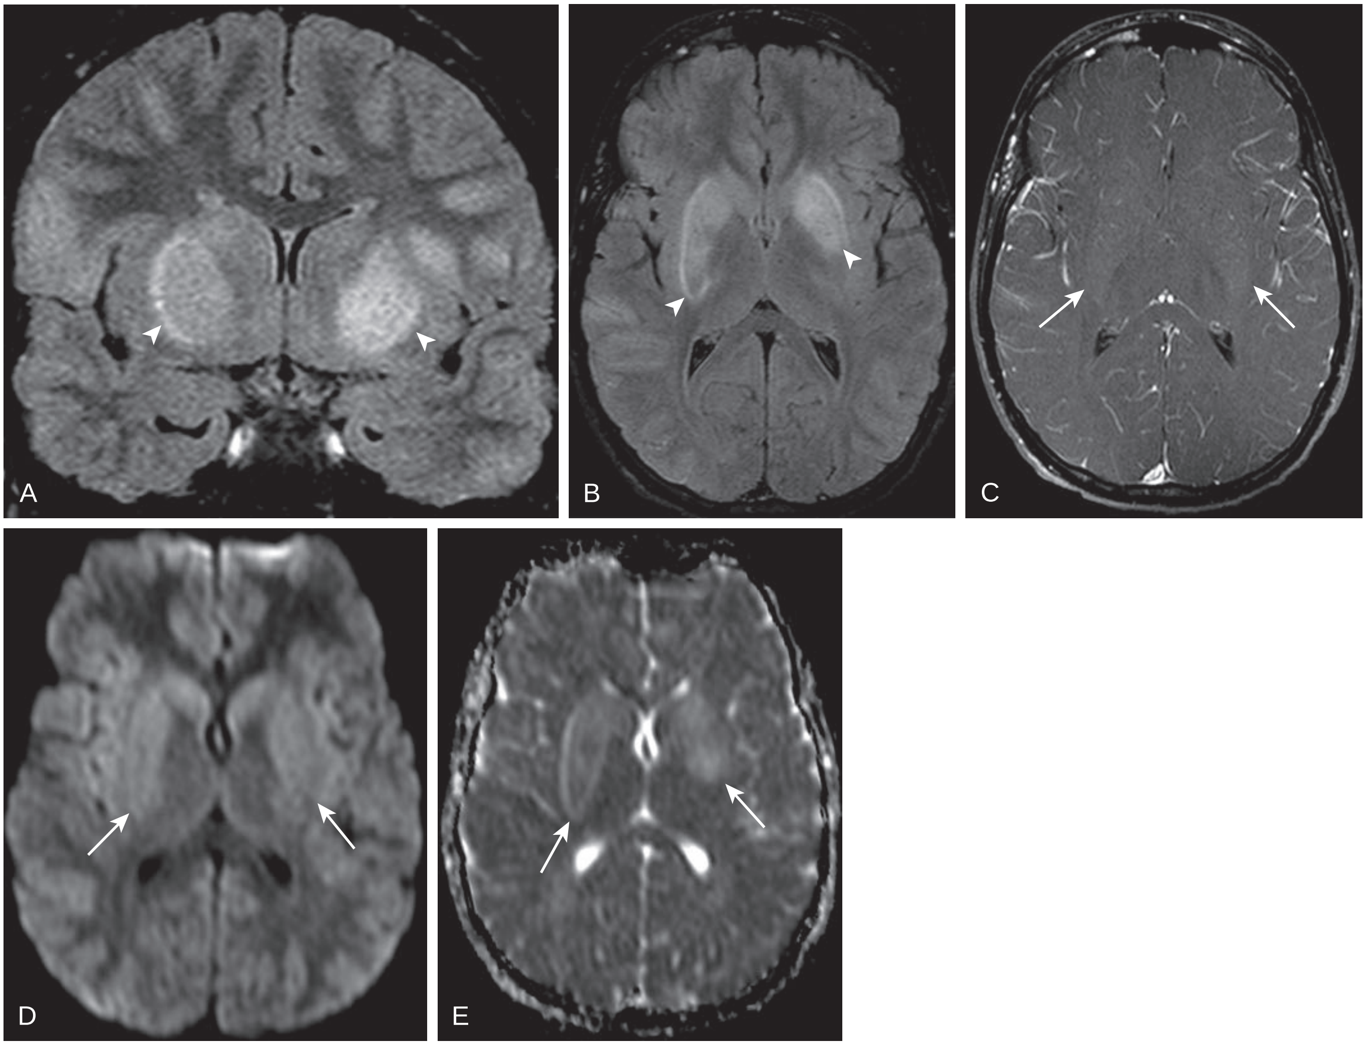
### Tuberculosis Infection

CNS infection with *Mycobacterium tuberculosis* (TB) differs clinically and radiographically from pyogenic infection. Other granulomatous and fungal organisms are rare in the pediatric age group and often present with similar imaging characteristics as TB. The pathogenesis of tuberculous meningitis is different from that of other bacterial meningitides. Hematogenous spread to the CNS may produce miliary tuberculosis (rare in children) but more typically produce tuberculomas in the meninges and/or brain at the gray-white junction, spinal cord, or rarely in the choroid plexus. After a variable period of time, organisms from one or more of these foci are discharged into the CSF/subarachnoid space and causing meningitis. Isolated meningeal tuberculomas tend to localize in the region of the Sylvian fissures, producing meningitis in the basal

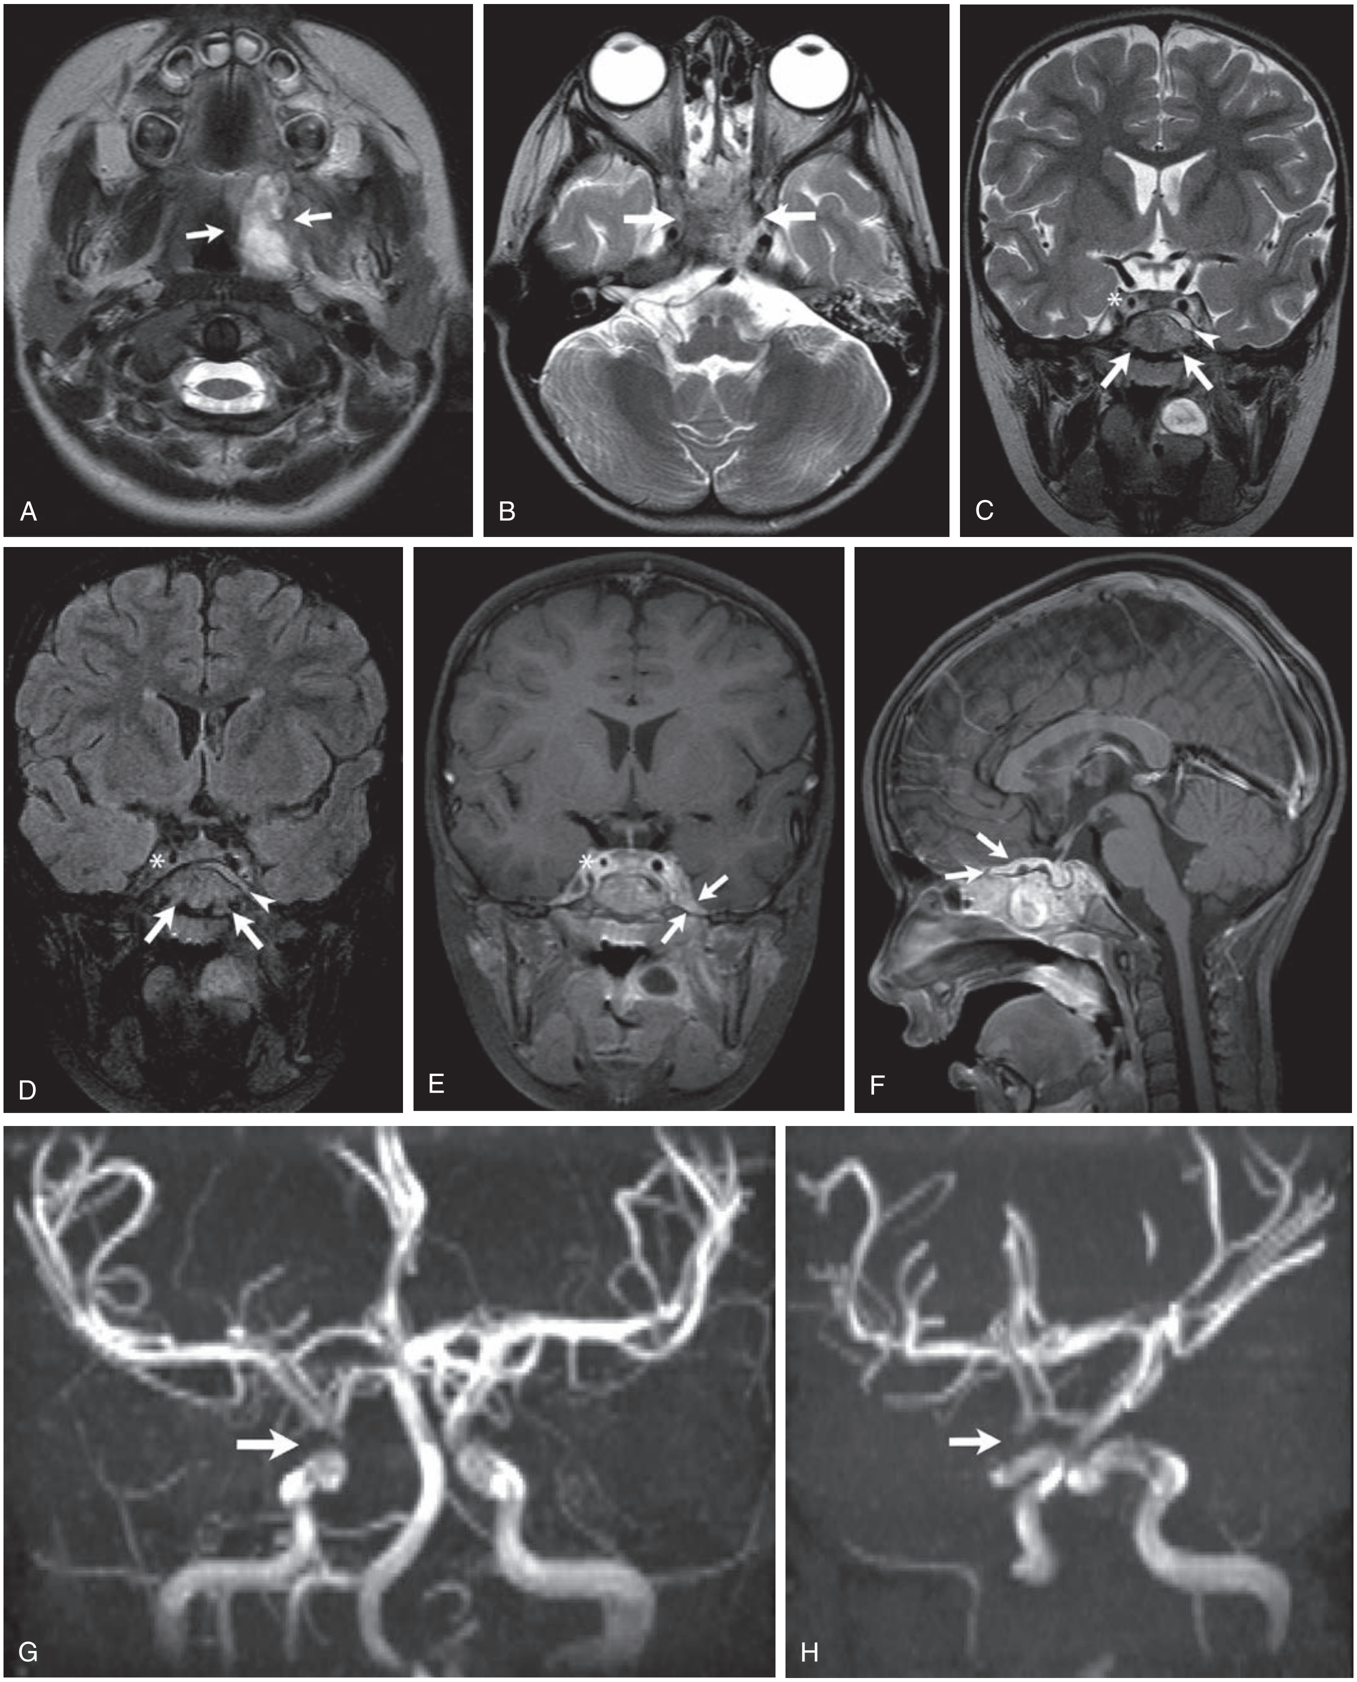
*Text continued on p. 334*

## Abstract:

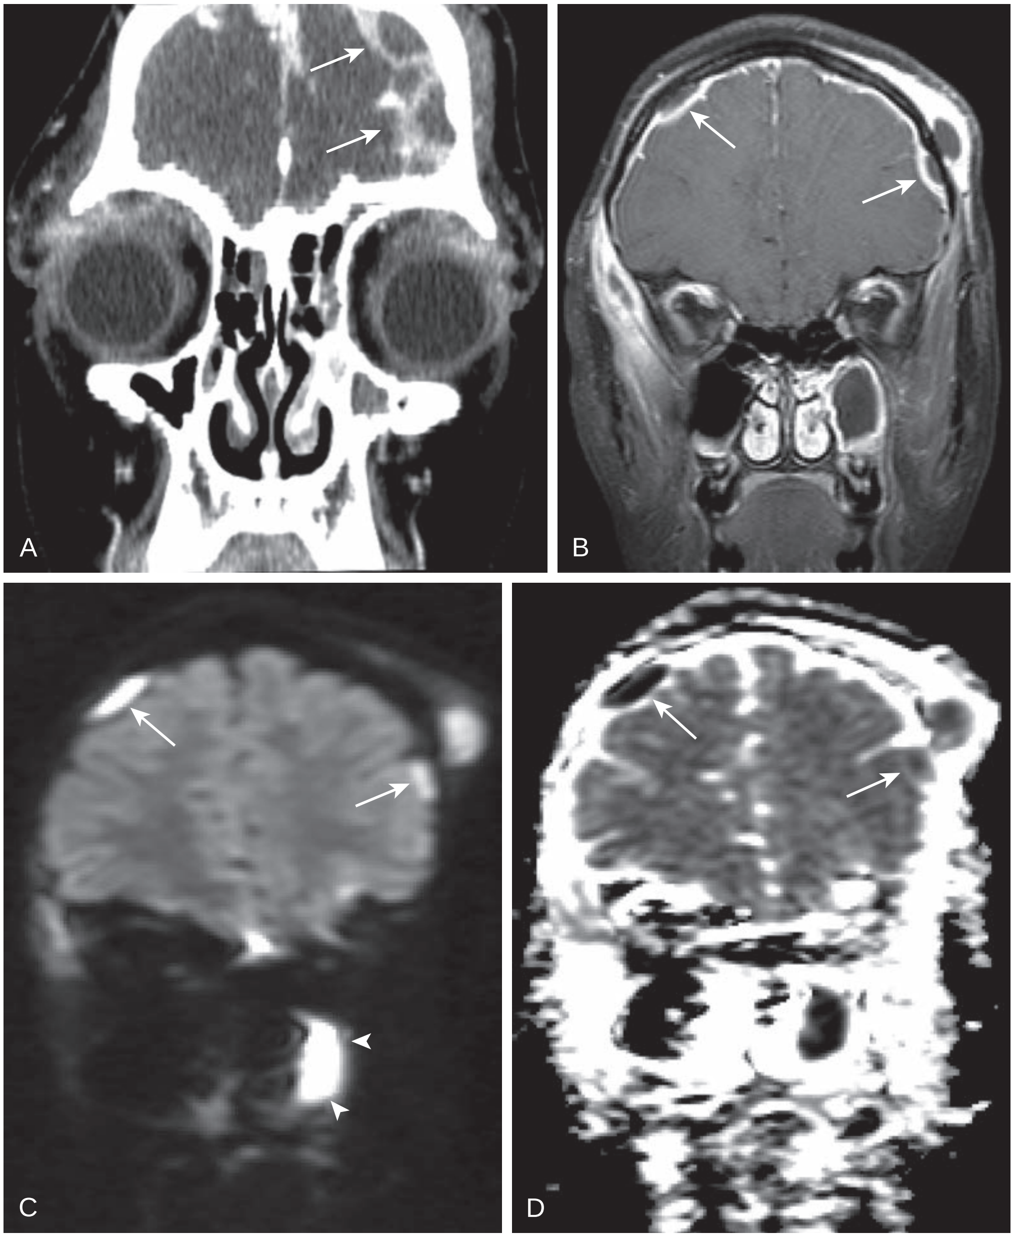
Brain infections in children may manifest as encephalitis, cerebritis, or meningitis. Causative pathogens may be bacterial, viral, fungal or parasitic, and their incidence is dependent upon where in the world the child lives.



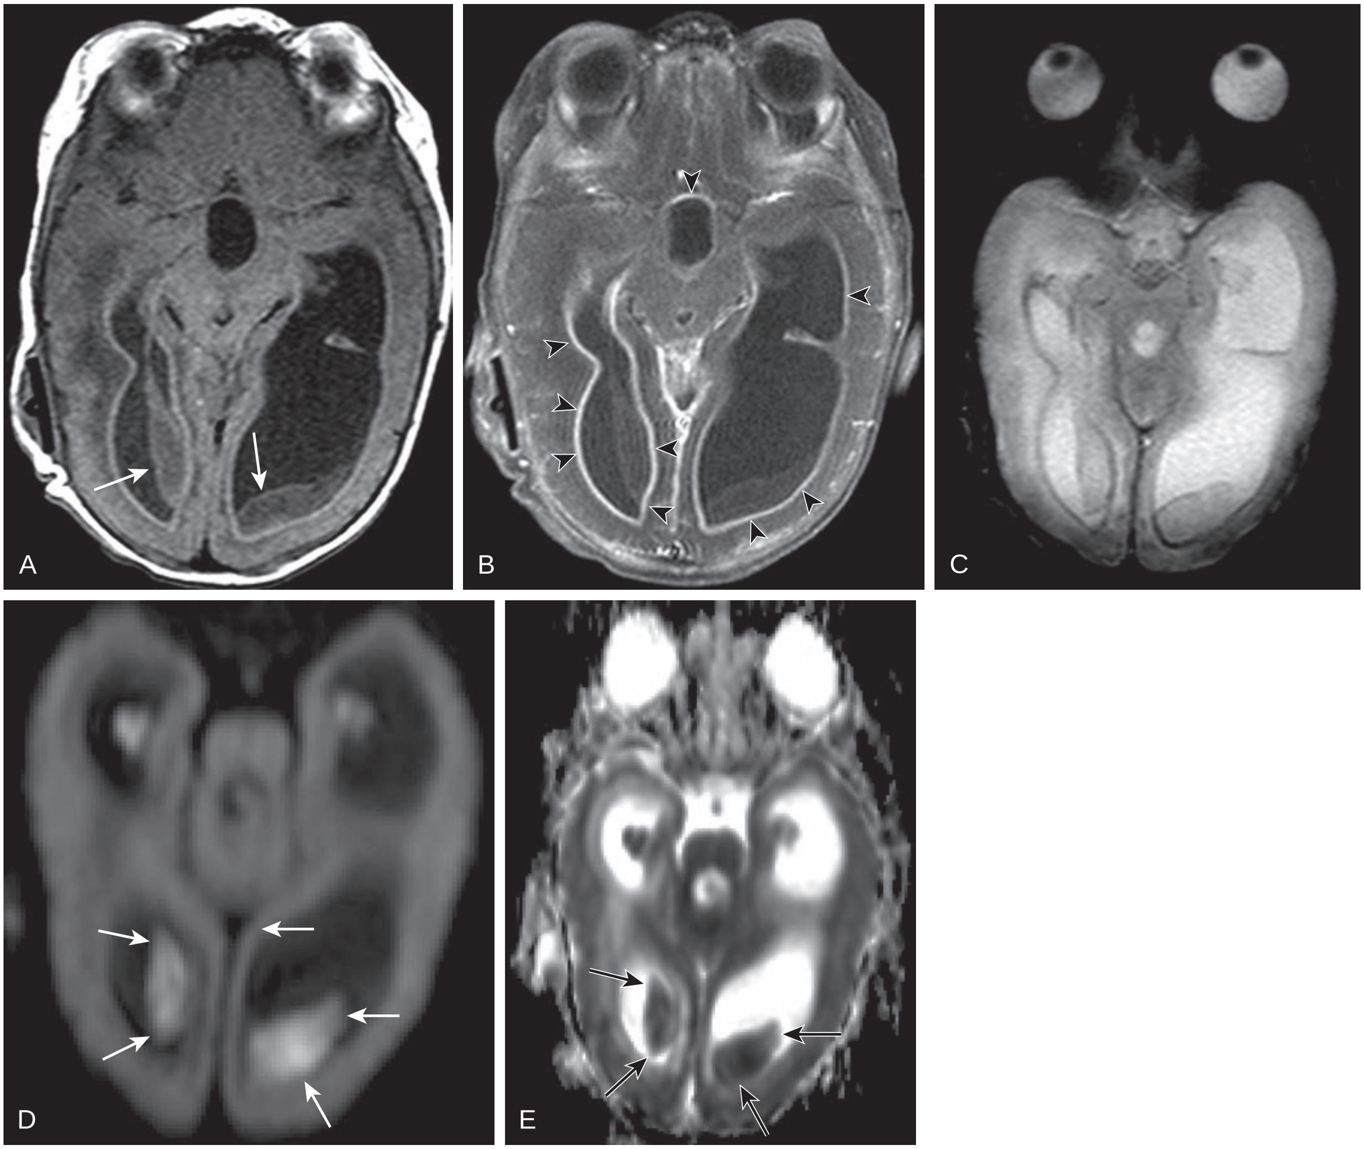
**e-Figure 34.1. West Nile virus.** Patient with loss of consciousness and questionable history of mosquito bite. (A) Coronal, (B) axial fluid-attenuated inversion–recovery, (C) axial contrast-enhanced T1-weighted, (D) axial diffusion-weighted imaging (DWI), and (E) apparent diffusion coefficient (ADC) map MR images show T2 prolongation within the basal ganglia bilaterally (*arrowheads* in A and B), with some questionable contrast enhancement or magnetization transfer effect as seen on postcontrast images (C). There is increased signal on DWI as well as ADC maps (*arrows* in D and E), in keeping with T2 shine-through.



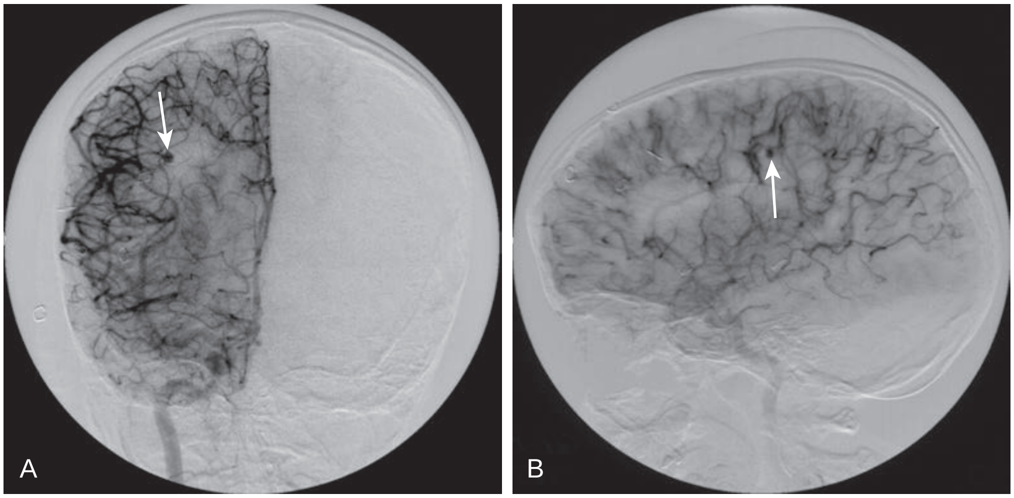
**e-Figure 34.2. Parameningeal spread of retropharyngeal infection.** Three-year-old female with retropharyngeal abscess, now with fever, headache, emesis, and left sixth nerve palsy. Axial T2-weighted MR images at the level of the (A) adenoids and (B) sphenoid bone. (C) Coronal T2-weighted and (D) fluid-attenuated inversion–recovery (FLAIR) (E) coronal and (F) contrast-enhanced T1-weighted MR images, as well as 3D time of flight (TOF) MRA in the (G) frontal and (H) left anterior oblique (LAO) projections. Note the inflammatory process within the left retropharyngeal region (*arrows* in A). There is abnormal marrow signal within the sphenoid bone (*arrows* in B, C, and D). In addition, there is abnormal soft tissue seen extending superior to the sphenoid bone on the coronal T2-weighted and FLAIR sequences (*arrowhead* in C and D). There is corresponding abnormal contrast enhancement along the region of the skull base and planum sphenoidale seen on the postcontrast images (*arrows* in E and F). Note the diminution in size of the right internal carotid artery (*asterisks* in C, D, and E) with corresponding narrowing of the right supraclinoid carotid artery (*arrows*



**e-Figure 34.5. Pott puffy tumor, with associated intracranial and extraaxial pus.** Eleven-year-old female with orbital swelling, preseptal cellulitis, and increase in forehead swelling associated with pansinusitis. The patient initially presented with syncope, fever, and bilateral orbital swelling. (A) Coronal contrast-enhanced CT, (B) coronal fat-saturated contrast-enhanced T1-weighted MRI through the frontal region, and (C) coronal diffusion-weighted image (DWI) with (D) apparent diffusion coefficient map. Note the abnormal extraaxial collections (*arrows* in A, B). There is corresponding restricted diffusion in the extraaxial space over the right cerebral hemisphere (*arrows* in C, D). Note also that corresponding to the area of apparent fluid collection within the left maxillary sinus, there is an area of corresponding restricted diffusion on the DWI (*arrowheads* in C), corresponding to pus within the left maxillary sinus.



**e-Figure 34.13. Ventriculitis.** Four-month-old, ex-24-week preterm infant with IVH, ventricular peritoneal shunt, status postshunt revision for *E. coli* meningitis and ventriculitis. (A) Axial T1-weighted pre- and (B) postcontrast MR images, (C) axial gradient echo, and (D) axial diffusion-weighted image (DWI) with (E) apparent diffusion coefficient map demonstrate intraventricular soft tissue masses (*arrows* in A–E), which fail to demonstrate contrast enhancement (B), and do not show significant T2* effect on the gradient echo image (C). These masses demonstrate restricted diffusion on the DWI (*arrows* in D, E), in keeping with infected ependyma and clot. There is avid contrast enhancement along the lining of the ventricles (*arrowheads* in B), indicating ventriculitis.



**e-Figure 34.14. Mycotic aneurysm.** Nine-year-old male with complex congenital heart disease and subacute bacterial endocarditis who presents with hemorrhage and left-sided hemiparesis, with a normal angiogram 2 weeks earlier. (A) Frontal and (B) lateral views from digital subtraction angiogram demonstrate a small outpouching from a right middle cerebral artery branch *(arrows),* indicating a mycotic aneurysm secondary to hematogenous spread of *Staphylococcus aureus*.

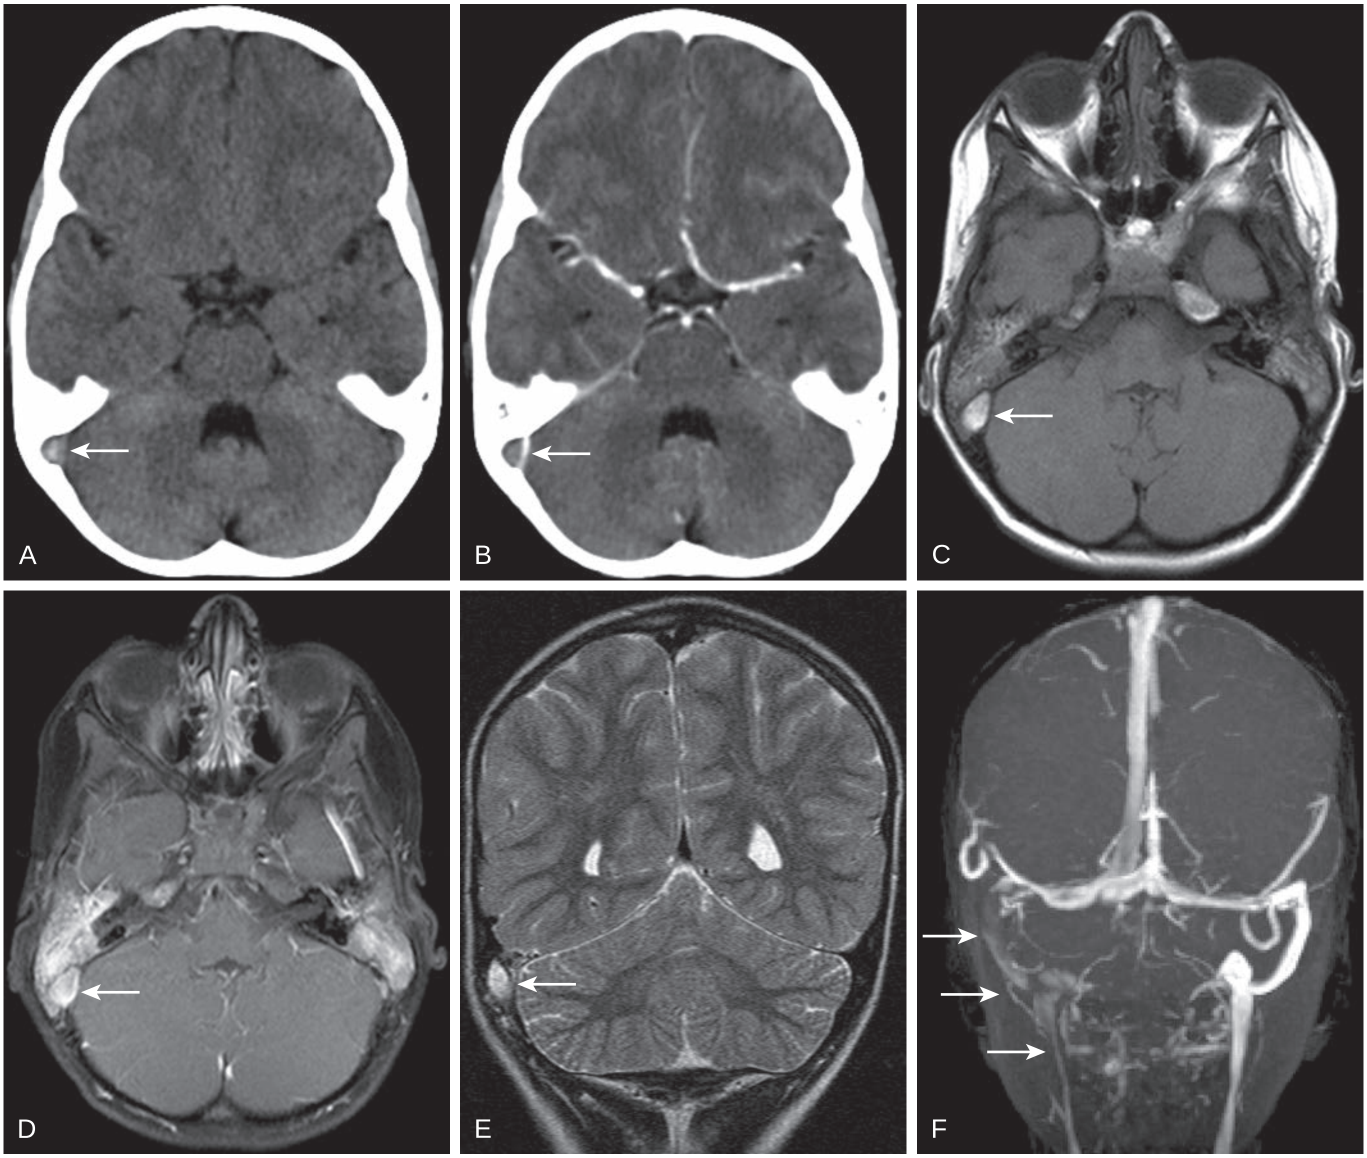


**Figure 34.3. Transverse sinus thrombosis associated with otomastoiditis and middle ear disease.** Patient presented with otitis media, headache, and papilledema. (A) Axial noncontrast and (B) contrast-enhanced CT of the head through the level of the posterior fossa, axial magnetization transfer T1-weighted MRI (C) precontrast and (D) fat-saturated postcontrast, (E) coronal T2-weighted, and (F) coronal multiple intensity projection (MIP) image from a 3D TOF MRV were obtained. Note the dense appearance of the dural sinus within the right transverse sinus region (*arrow* in A), with corresponding lack of contrast filling within the same region on the contrast-enhanced CT study (*arrow* in B). There is corresponding T1 shortening on the precontrast MRI (*arrow* in C), with corresponding abnormal signal on the postcontrast images indicating clot/slow flow within the region of the right transverse sinus/sigmoid sinus region (*arrow* in D). There is corresponding T2 prolongation on the coronal T2-weighted image (*arrow* in E). Note the striking asymmetry of flow within the right posterior fossa dural venous system/internal jugular vein on (*arrows* in F).

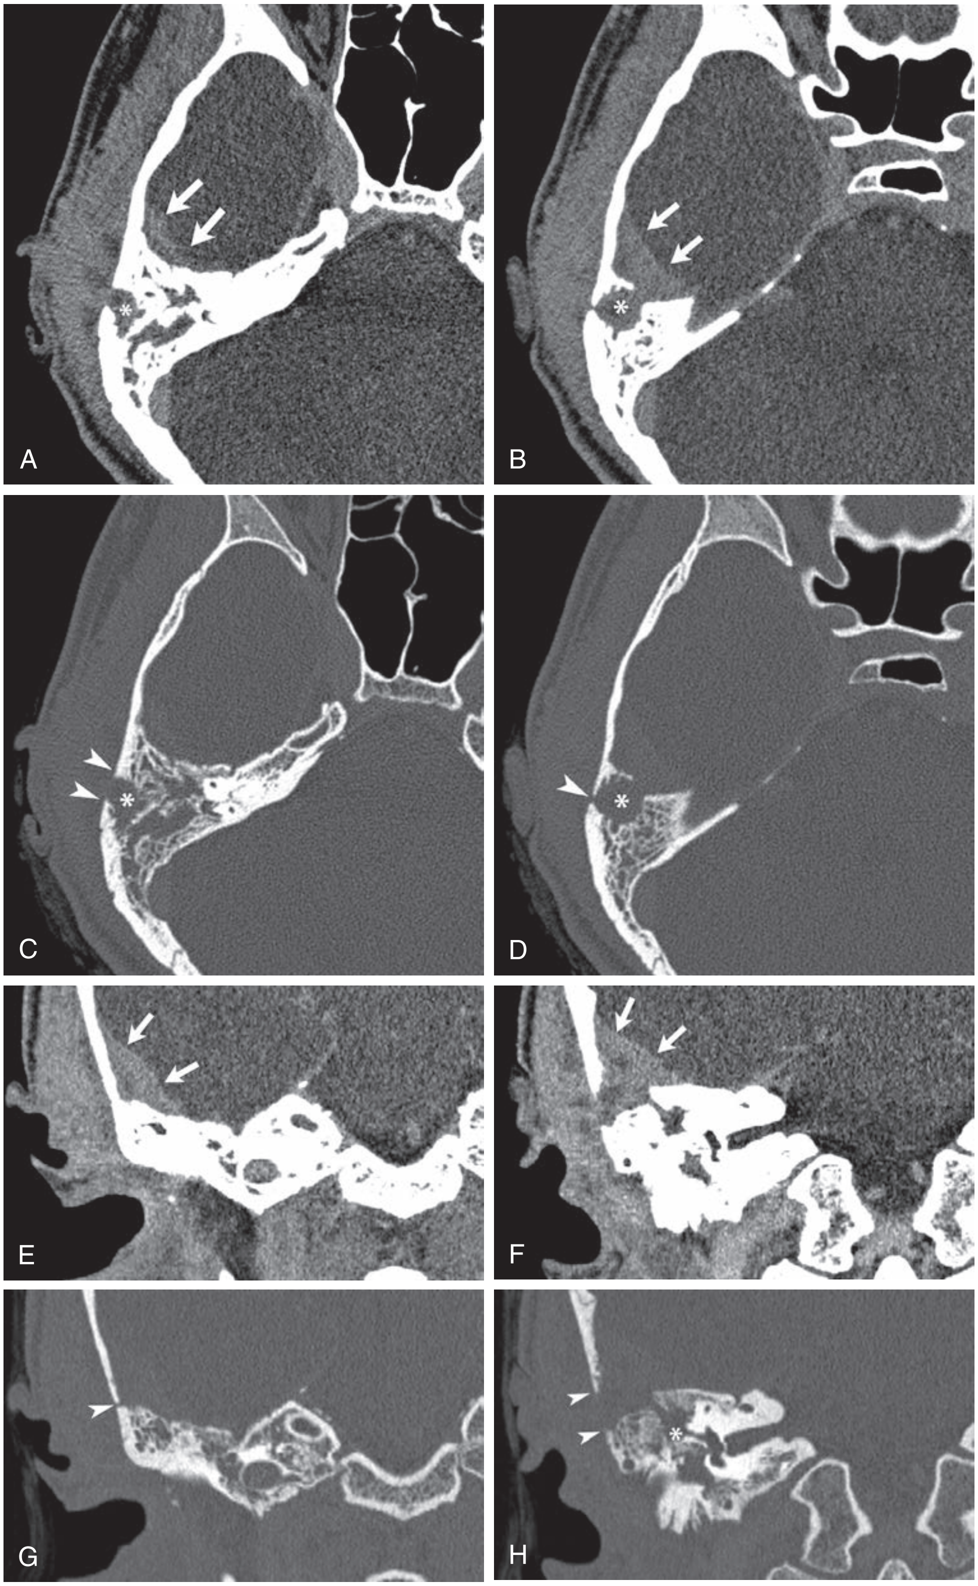

**Figure 34.4. Mastoiditis with associated epidural abscess.** A 17-year-old male with 5-month history of otitis media, now with severe right-sided mastoid pain. Axial contrast-enhanced CT images through the right mastoid region, including soft tissue (A and B), as well as bone windows (C and D), and direct coronal images in soft tissue (E) and (F), and bone windows (G and H). Note the abnormal soft tissue opacification within the right mastoid region (*asterisks* in A–D). There is associated abnormal soft tissue swelling along the external surface of the skull/scalp with an abnormal soft tissue component seen extending intracranially (*arrows* in A, B, E, F), corresponding to epidural abscess formation. There is bony resorption and breakdown seen within the mastoid cortex laterally (*arrowheads* in C, D, G, H). In addition, note the erosion of the lateral semicircular canal (*asterisk* in H).

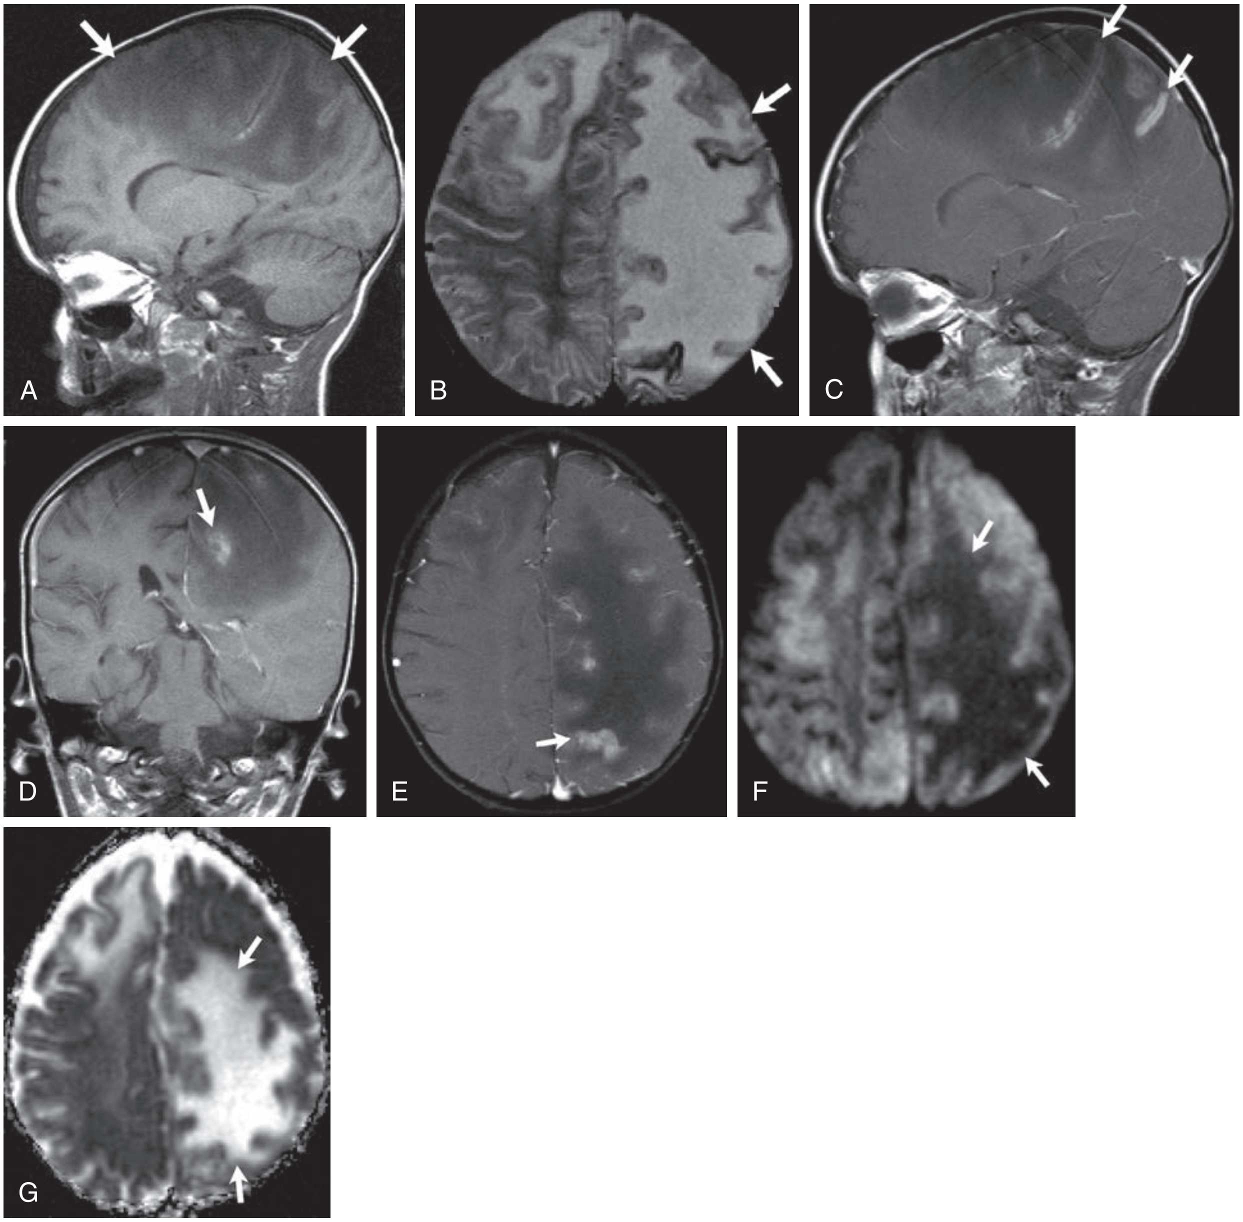

**Figure 34.6. Cerebritis.** A 2-year-old male with *Staphylococcus aureus* bacteremia and persistent fevers with new onset of hypertension. (A) Sagittal T1-weighted, (B) axial T2-weighted, and (C) sagittal, (D) coronal, and (E) axial contrast-enhanced spin echo MR images, as well as (F) axial diffusion-weighted image (DWI) and (G) apparent diffusion coefficient maps demonstrate T1 and T2 prolongation (*arrows* in A and B, respectively), with some mild cortical enhancement (*arrows* in C, D, E), and increased diffusion *(arrows)* as evidenced by decreased signal on DWI and increased signal on the DWI images.

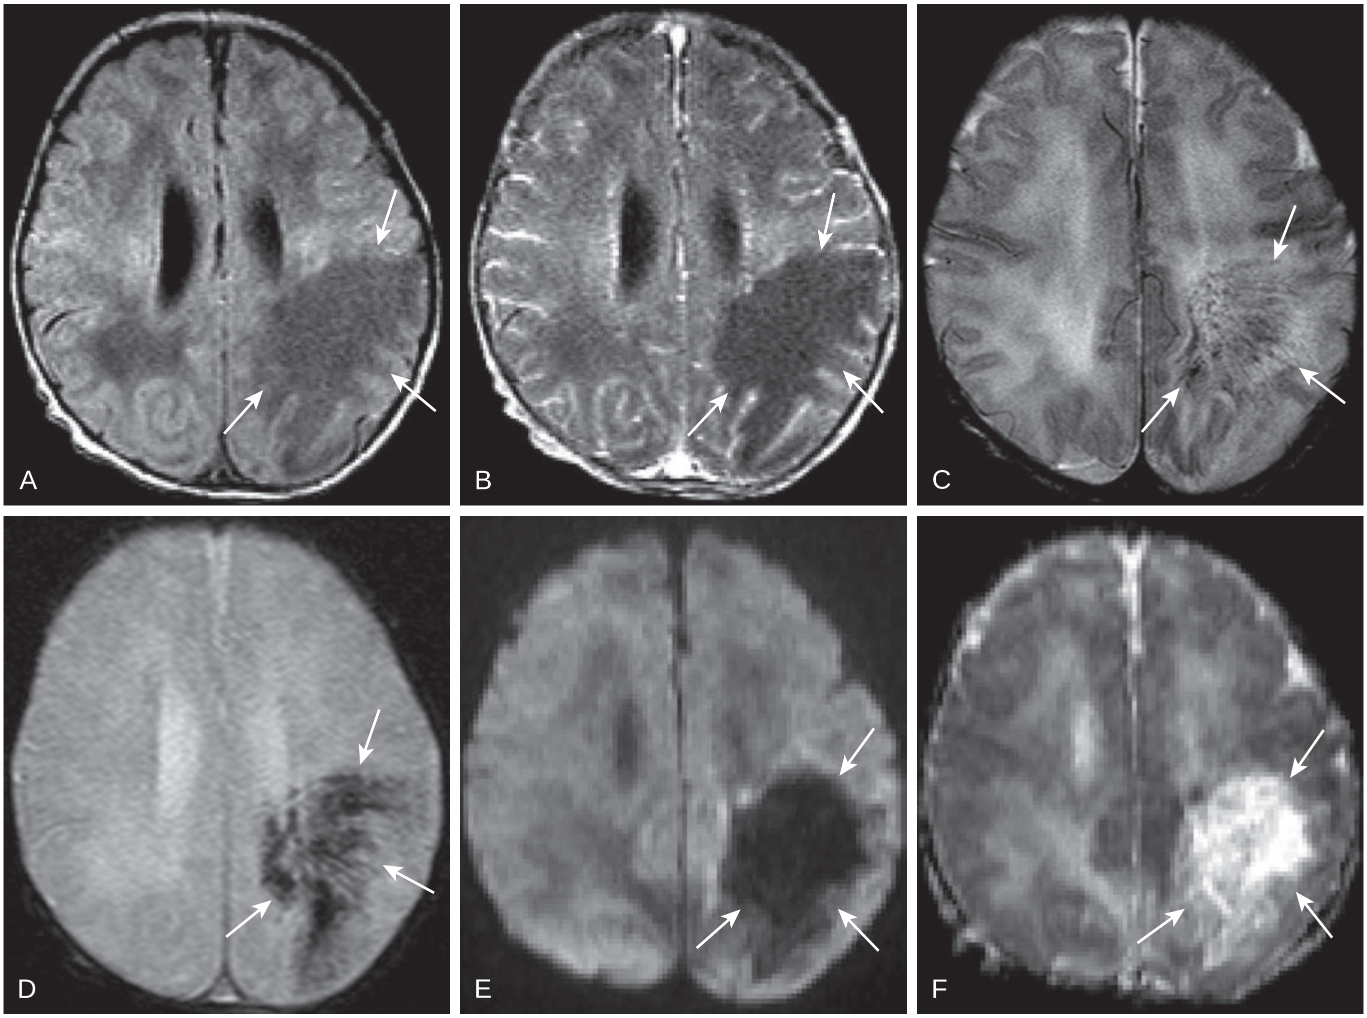

**Figure 34.7.** ***Citrobacter*** **infection with secondary venous thrombosis.** Seven-day-old full-term female neonate with seizures, gram-negative sepsis, and increased white blood cell count on lumbar puncture. Axial pre- (A) and postcontrast (B) T1-weighted MR images, (C) axial T2-weighted, (D) axial gradient echo MR images, as well as (E) axial diffusion-weighted image (DWI) and (F) apparent diffusion coefficient map. Note the area of T1 prolongation within the left posterior frontal parietal region (*arrows* in A, B), corresponding to areas with linear signal voids on both T2-weighted and gradient echo sequences (*arrows* in C, D), corresponding to distended medullary veins. Note that there is no diffusion restriction, but rather increase in diffusion on the corresponding area on DWI (*arrows* in E, F).

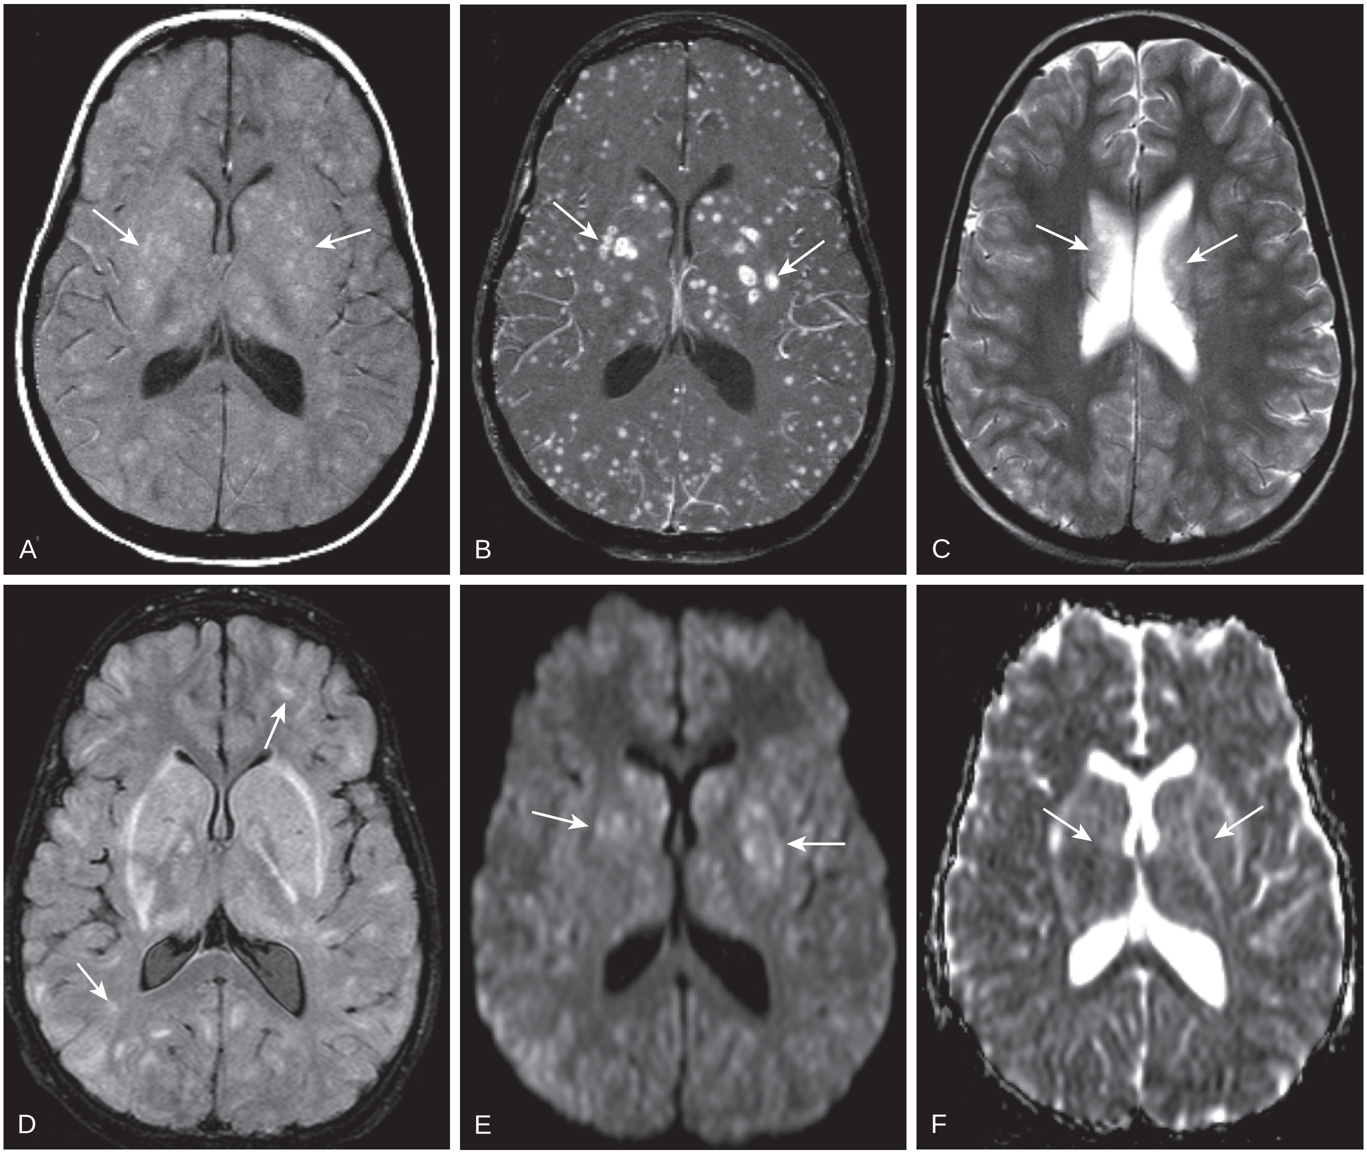

**Figure 34.8. Streptococcus viridans abscesses.** Twelve-year-old female with acute myelogenous leukemia and mental status changes. Axial T1-weighted magnetization transfer MR images, (A) pre- and (B) postcontrast, (C) axial T2-weighted and (D) fluid-attenuated inversion–recovery (FLAIR), and (E) axial diffusion-weighted imaging with (F) apparent diffusion coefficient map. Note the areas of T1 shortening on precontrast (*arrows* in A), and the corresponding marked gadolinium enhancement within multiple bilateral intraparenchymal nodules of differing size (*arrows* in B). There is T2 prolongation noted on the axial T2W and FLAIR sequences in some corresponding areas (*arrows* in C, D), but this is markedly less conspicuous than on the postcontrast images. There is subtle restricted diffusion noted in some of the nodular areas, specifically within the basal ganglia, corresponding to the largest lesions seen on postcontrast images (*arrows* in E, F).

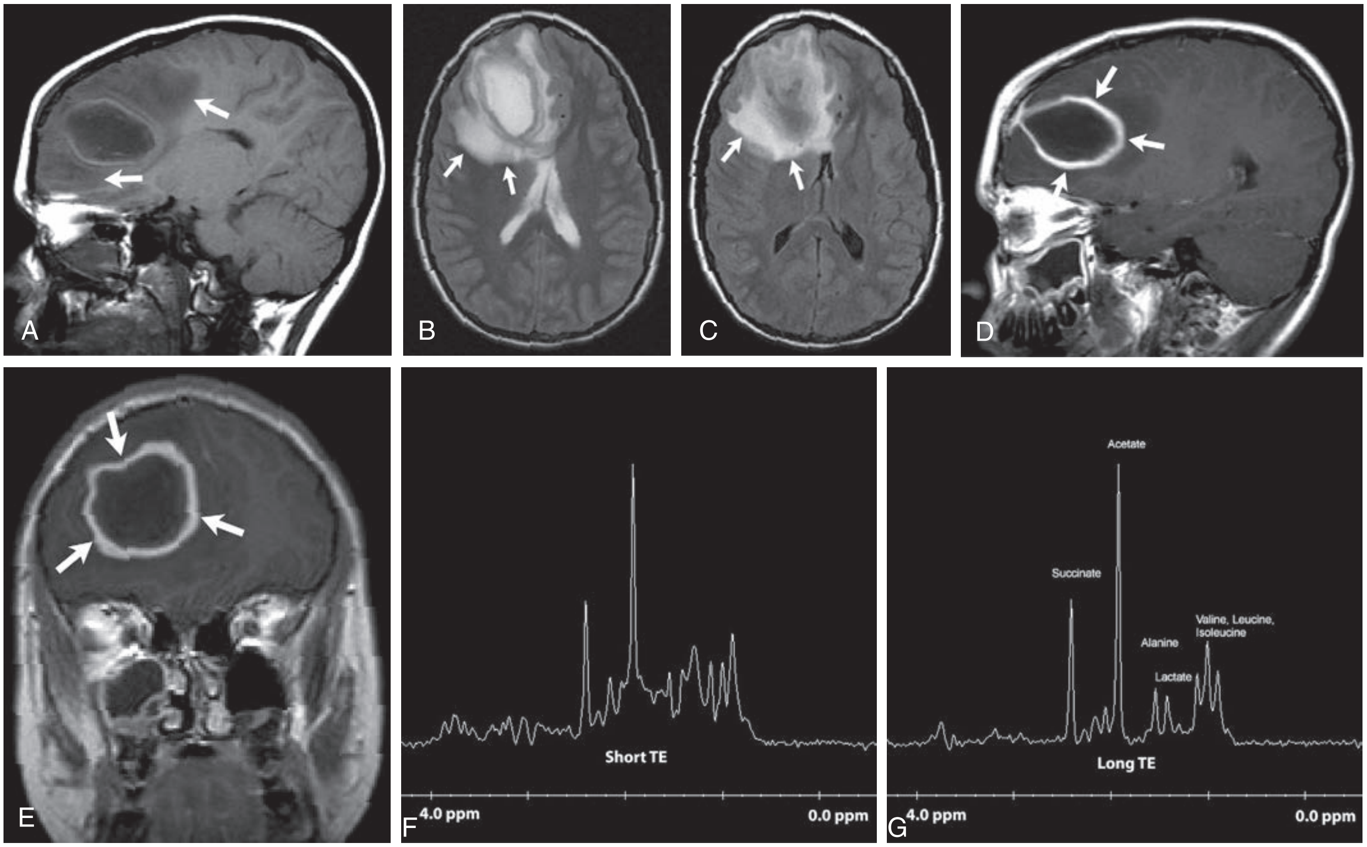

**Figure 34.9. Cerebral abscess.** Patient with seizures and fever. (A) Sagittal T1-weighted, (B) axial T2-weighted, (C) axial fluid-attenuated inversion–recovery, postcontrast, (D) sagittal, and (E) coronal spin echo MR images, as well as (F) short TE and (G) long TE magnetic resonance spectroscopy (MRS) images. Note the areas of T2 prolongation (*arrows* in B, C), with some central low signal intensity (C) in the region of abscess with surrounding vasogenic edema. There is thick, rindlike enhancement of the periphery of the right frontal abscess (*arrows* in D, E). MRS images demonstrate abnormal amino acid peaks, at around 1 ppm, and a doublet lactate peak deflected upward at 1.33 ppm. *(Case courtesy Kim M. Cecil, PhD, Cincinnati, OH.)*

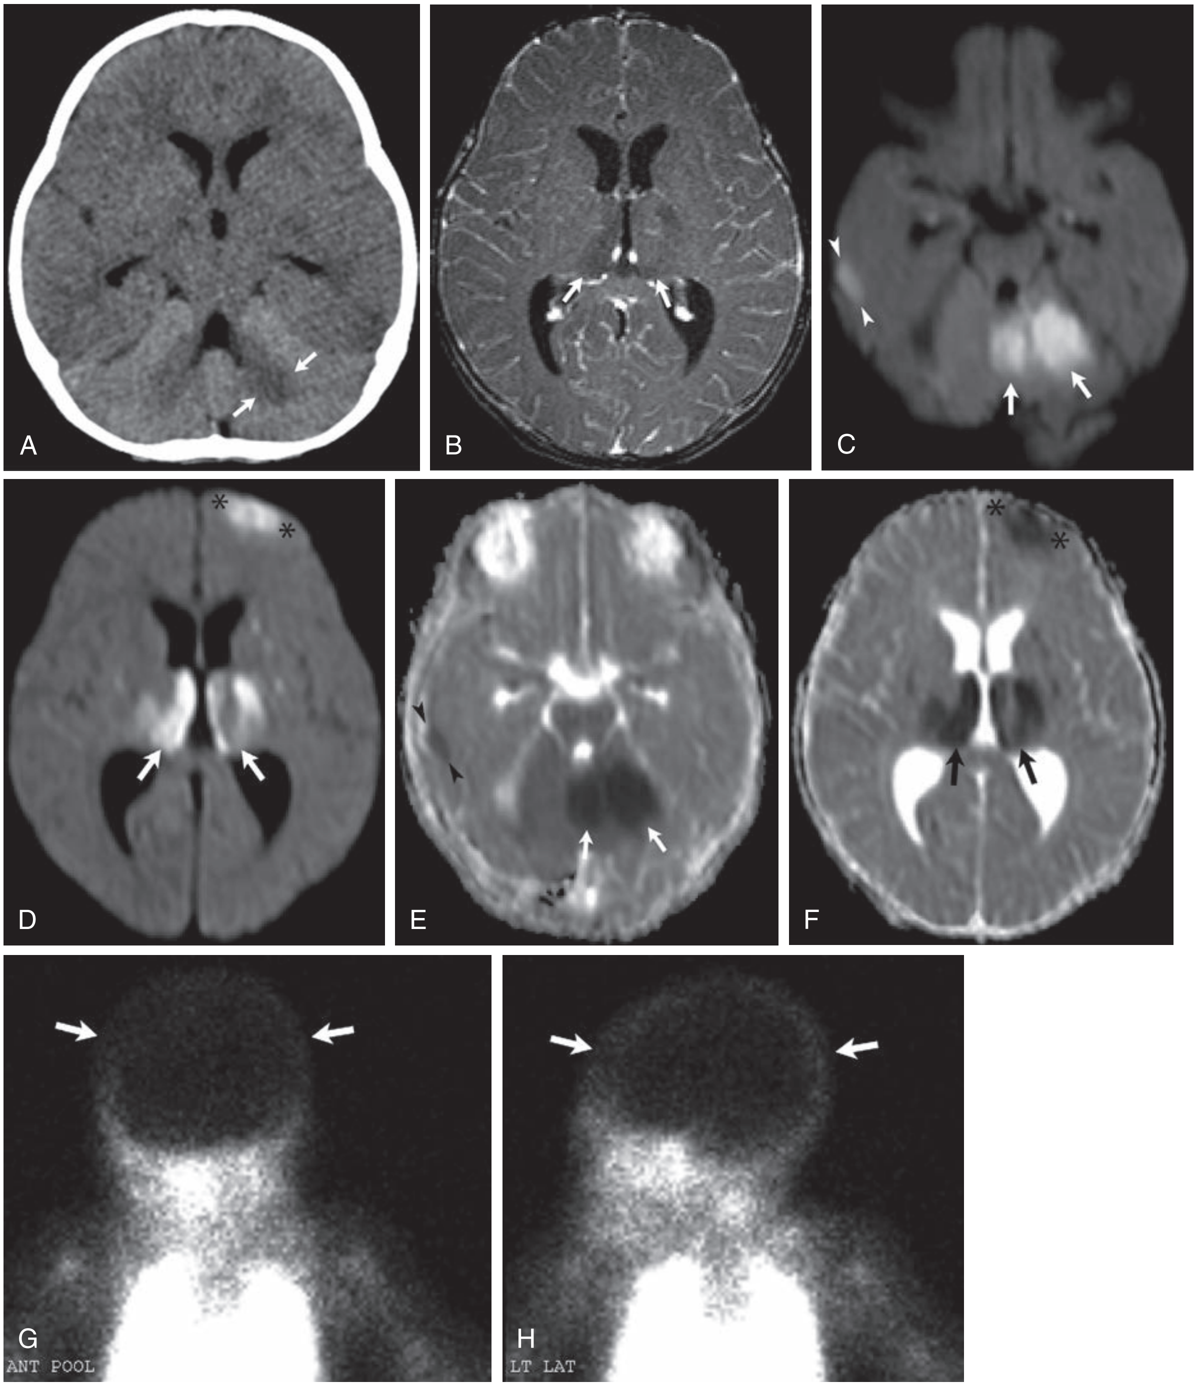

**Figure 34.10. Meningitis and brain death.** Six-month-old male with seizures and fever due to gram-positive cocci meningitis. (A) Axial noncontrast CT, (B) axial postcontrast T1-weighted spin echo, axial diffusion-weighted images (DWI) at the level of the (C) posterior fossa and (D) thalami, and (E and F) axial ADC maps at the same levels as C and D, and (G) frontal and (H) lateral Neurolite nuclear medicine brain flow study. Note the subtle decreased attenuation within the left cerebellar hemisphere (*arrows* in A), and the areas of T1 prolongation within the thalami (*arrows* in B). There are corresponding areas of restricted diffusion on the DWI and apparent diffusion coefficient images (*arrows* in C–F). In addition, there are areas of restricted diffusion within the right temporal lobe *(arrowheads),* and left frontal lobe *(asterisks)* on the diffusion-weighted sequences (C–F). There is no identifiable perfusion to the brain, as evidenced by lack of accumulation of radiotracer (*arrows* in G, H).

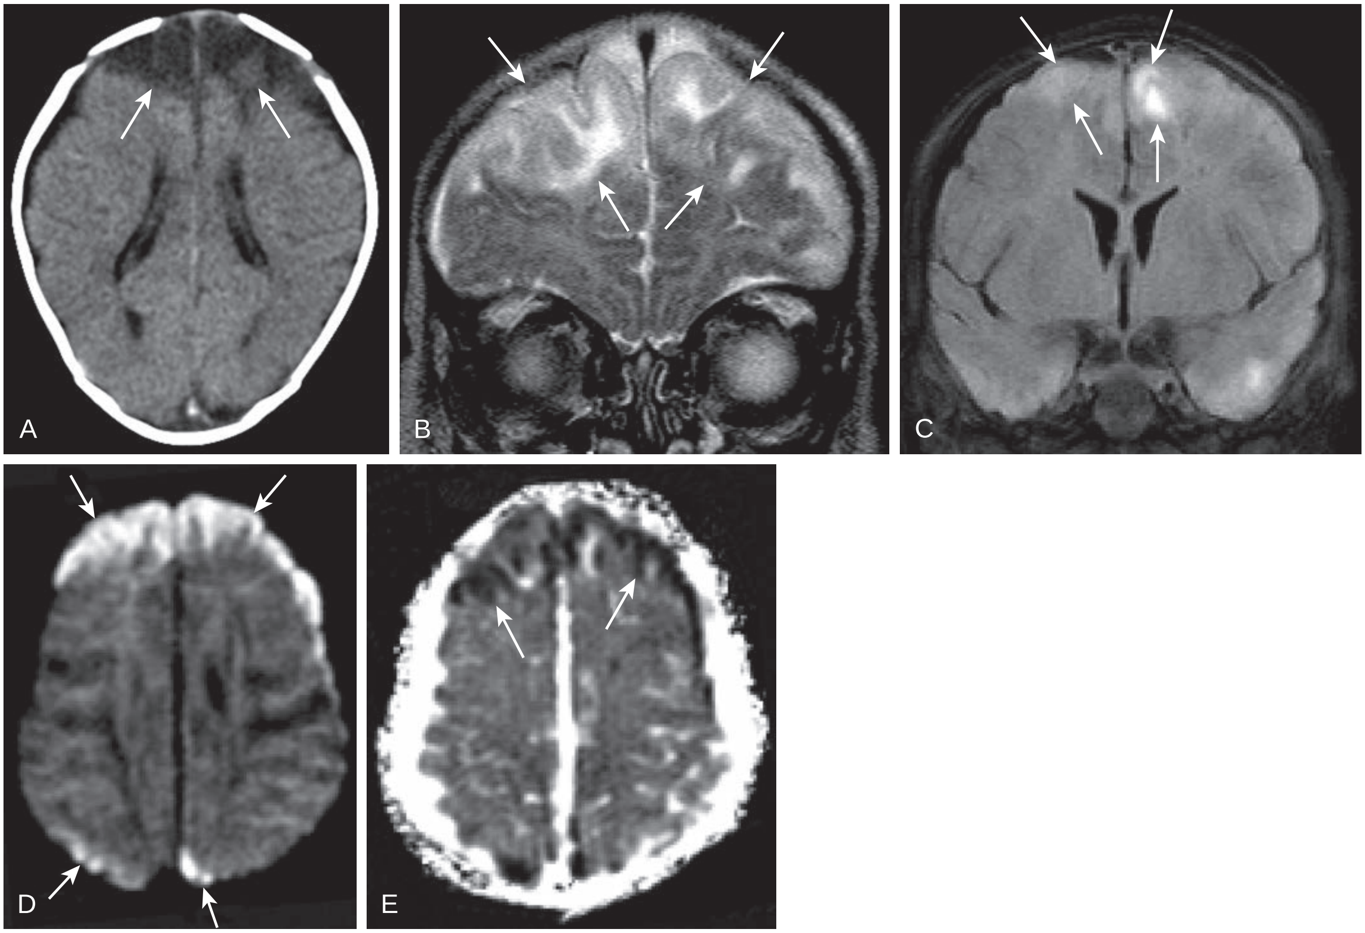

**Figure 34.11. Group B streptococcus (GBS) meningitis.** A 10-week-old female with GBS sepsis and meningitis. (A) Axial noncontrast CT of the head, (B) coronal T2-weighted and (C) fluid-attenuated inversion–recovery (FLAIR) MR images, and (D) diffusion-weighted image with (E) apparent diffusion coefficient (ADC) maps. Note the low attenuation within the frontal lobes bilaterally (*arrows* in A), with corresponding T2 prolongation and abnormal increased FLAIR signal (*arrows* in B, C). In addition, there is restricted diffusion within the frontal and parietal regions bilaterally (*arrows* in D, E), in keeping with ischemic changes secondary to meningitis.

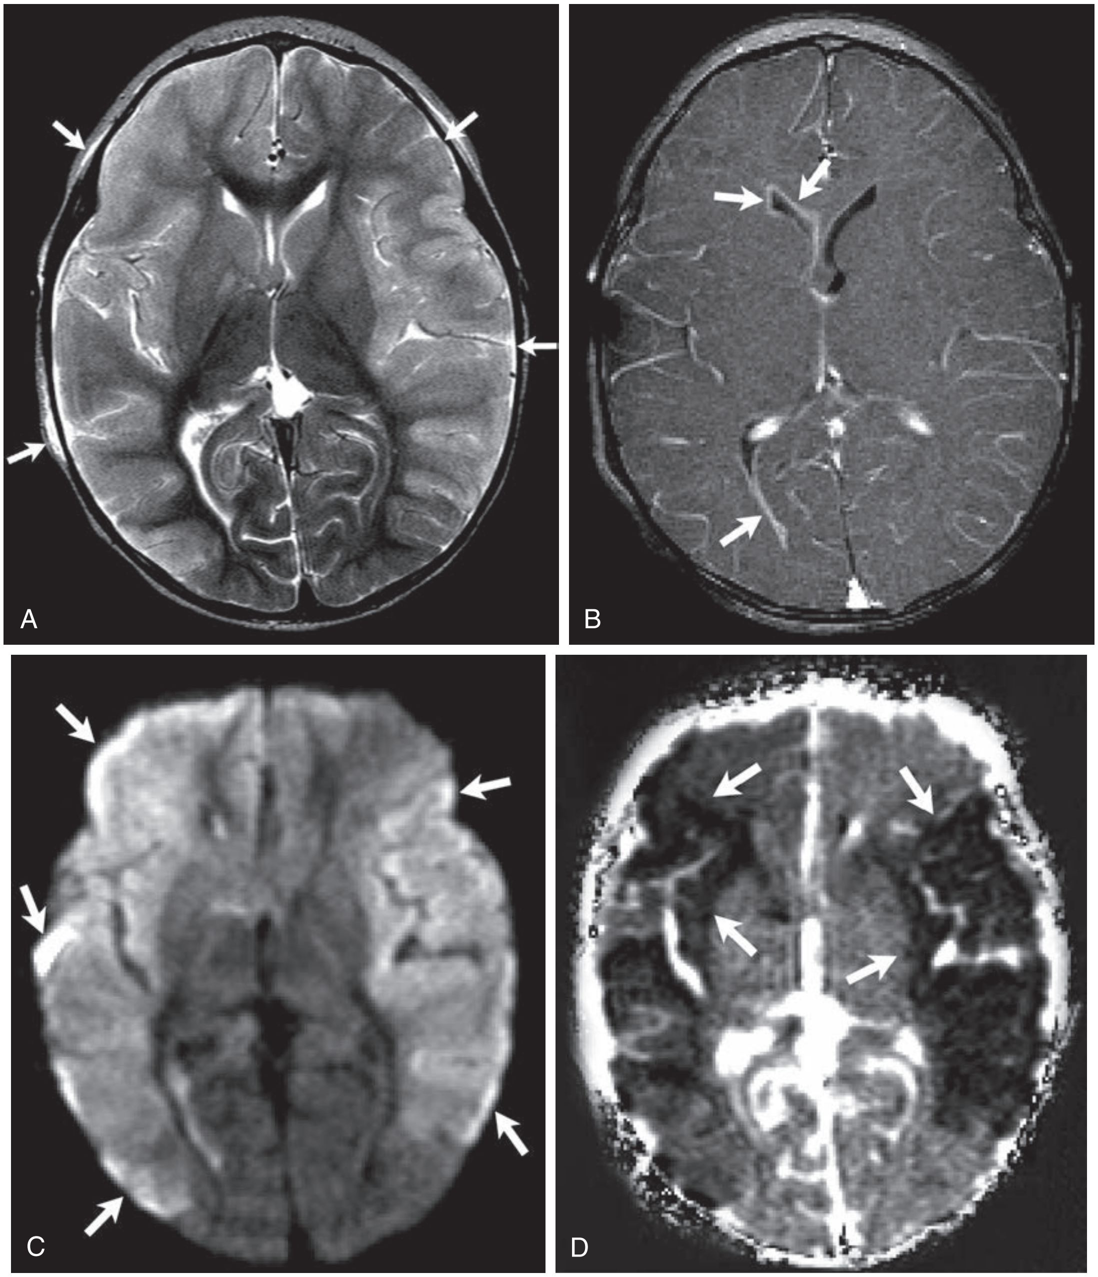

**Figure 34.12. Pneumococcal meningitis with infarctions.** Eleven-month-old female with ventriculostomy and mental status changes, with suspected meningitis. (A) Axial T2-weighted, (B) axial postcontrast T1-weighted MR images, (C) axial diffusion-weighted image and (D) apparent diffusion coefficient maps, and (E) 3D time of flight MRA frontal and (F) compressed cranio-caudad views. There is diffuse T2 prolongation within the cerebral cortex bilaterally (*arrows* in A), with associated abnormal enhancement along the ventricular lining (*arrows* in B), indicating ventriculitis. Note the marked restricted diffusion within both hemispheres (*arrows* in C, D) in keeping with cytotoxic edema secondary to infection. There is bilateral middle cerebral artery narrowing, right greater than left *(arrows),* and narrowing of the supraclinoid carotid arteries bilaterally (*arrowheads* in E).

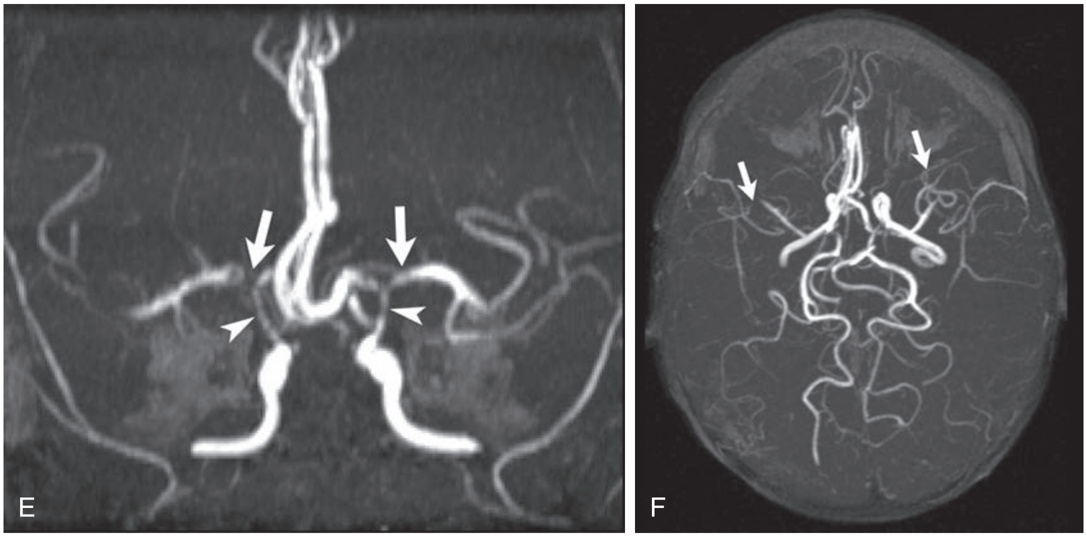

**Figure 34.12, cont'd.**

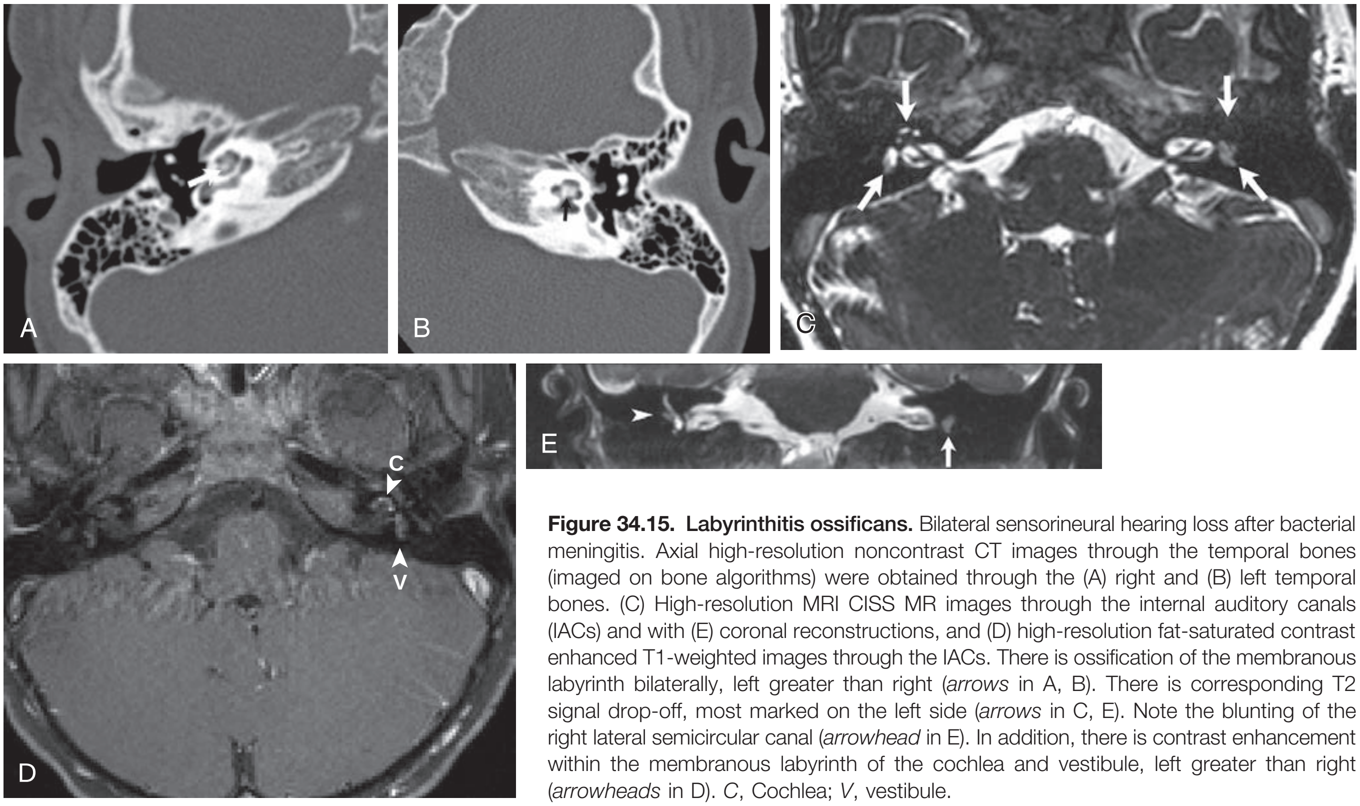

**Figure 34.15. Labyrinthitis ossificans.** Bilateral sensorineural hearing loss after bacterial meningitis. Axial high-resolution noncontrast CT images through the temporal bones (imaged on bone algorithms) were obtained through the (A) right and (B) left temporal bones. (C) High-resolution MRI CISS MR images through the internal auditory canals (IACs) and with (E) coronal reconstructions, and (D) high-resolution fat-saturated contrast enhanced T1-weighted images through the IACs. There is ossification of the membranous labyrinth bilaterally, left greater than right (*arrows* in A, B). There is corresponding T2 signal drop-off, most marked on the left side (*arrows* in C, E). Note the blunting of the right lateral semicircular canal (*arrowhead* in E). In addition, there is contrast enhancement within the membranous labyrinth of the cochlea and vestibule, left greater than right (*arrowheads* in D). *C*, Cochlea; *V*, vestibule.

cisterns. This leads to secondary complications including cranial nerve palsies, infarction consequent to vasculitis, and hydrocephalus secondary to blockage of fourth ventricular outlet foramina.

Hematogenous dissemination of tuberculous bacilli is believed to occur about 1 week after the infected inhalation. Three stages of tuberculous meningitis have been described that progress over approximately a 3-week period. Clinical presentation ranges from personality change and anorexia to coma and death, with nuchal rigidity being the most common presenting clinical sign. Pathologically, tuberculous exudate fills the subarachnoid spaces. Most affected patients demonstrate hydrocephalus. On CT, exudate within the cisterns is manifested by attenuation greater than CSF. On contrast-enhanced MRI there is marked subarachnoid and cisternal enhancement on T1-weighted sequences (Fig. 34.16), with T2-weighted sequences demonstrating obscuration of the cisterns due to inherent hyperintense signal within these affected regions. Microinfarctions are common. Tuberculomas often manifest at gray-white junctions and are more common above the tentorium cerebelli. On CT, they demonstrate high attenuation and ring enhancement (Fig. 34.17), yet on MRI they demonstrate hyperintense T1-weighted and hypointense T2-weighted signal. When less than 2 cm, tuberculomas enhance uniformly, and when greater than 2 cm, they show more peripheral enhancement. The rare tuberculous abscess can be differentiated from a tuberculoma by its central hyperintense T2-weighted signal and more pronounced associated vasogenic edema. While DWI is not particularly helpful in making a diagnosis, lipid detection on MRS has been reported as helpful in certain cases.

## Lyme Disease

Lyme disease is the most common tick-borne disease in the United States and Europe. More than one in five cases have been reported in children or adolescents. This multisystemic disorder involves the neurologic system in approximately one-fifth of affected children, manifesting as lymphocytic meningitis, meningoencephalitis, pseudotumor cerebri-like syndrome, or cranial neuropathy. It is unclear whether the mechanism of CNS involvement is a result

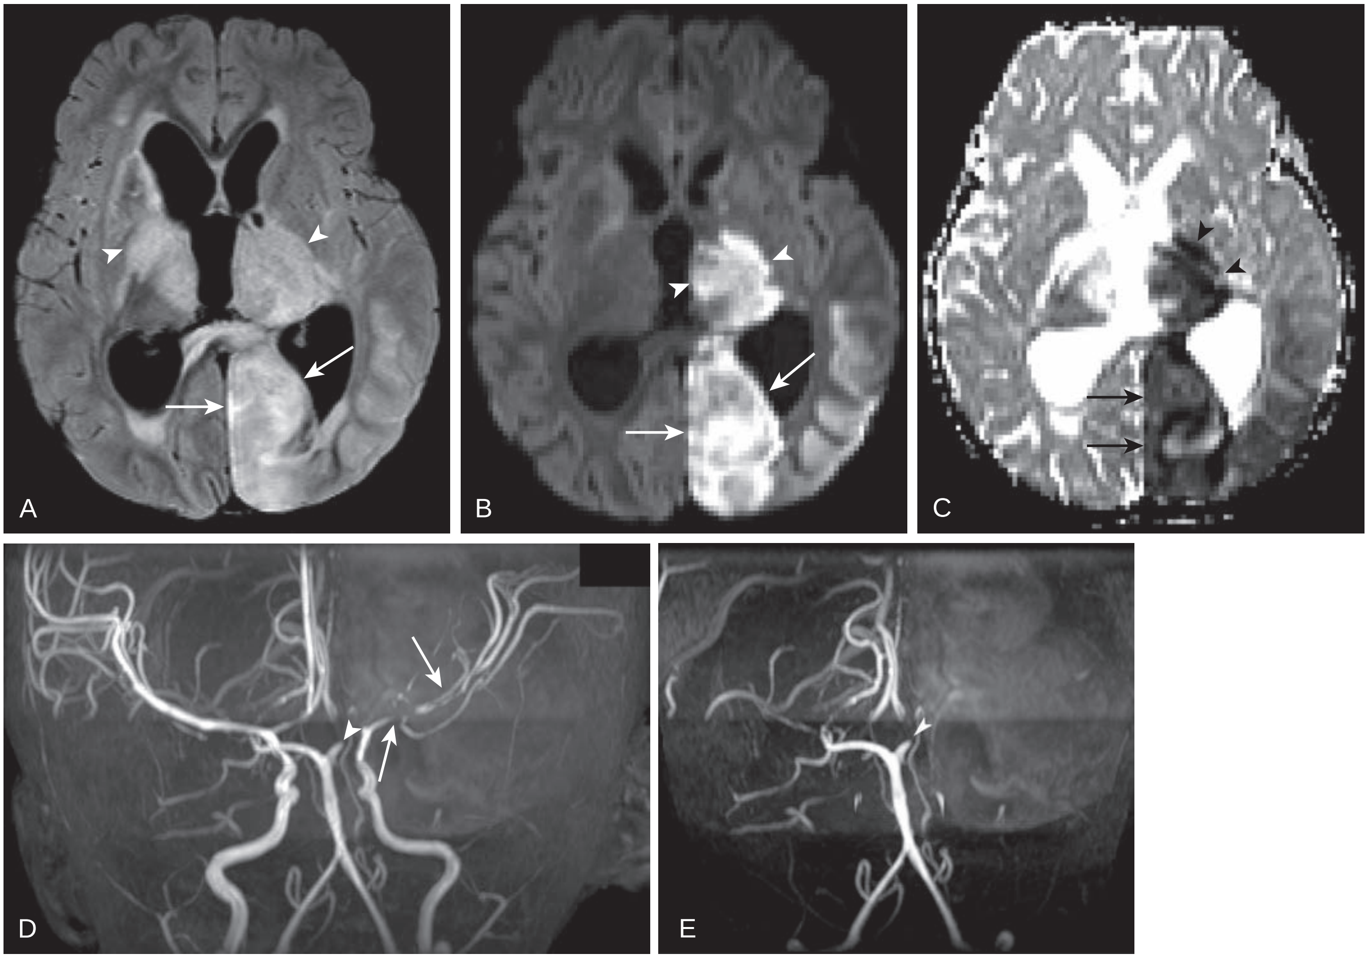

**Figure 34.16. Tuberculous (TB) meningitis.** Two-year-old female with suspected TB meningitis and left-sided posterior cerebral artery territory stroke. (A) Axial fluid-attenuated inversion–recovery (FLAIR) MR image, (B) axial diffusion-weighted image (DWI) and (C) apparent diffusion coefficient (ADC) map, and 3D time of flight MRA in the (D) anterior projection and (E) craniocaudad collapsed view, (F) frontal angiographic view of the posterior cerebral arteries (PCA) circulation, as well as sequential axial contrast-enhanced T1-weighted images through the level of the brainstem (G–I) demonstrating worsening changes of tuberculous meningitis over time. Note the abnormal FLAIR signal seen within the left occipital lobe *(arrows)* and bilateral thalami *(arrowheads)* on the axial FLAIR sequence. There is corresponding restricted diffusion within the left thalamus *(arrowheads)* and occipital lobes *(arrows)* as seen on DWI sequences. There is marked irregularity of the left middle cerebral artery (*arrows* in D, F), as well as cutoff of the left PCA (*arrowheads* in D–F). Note the marked abnormal contrast enhancement along the basal meninges bilaterally, outlining the base of the brain (*arrows* in G–I), secondary to TB meningitis.

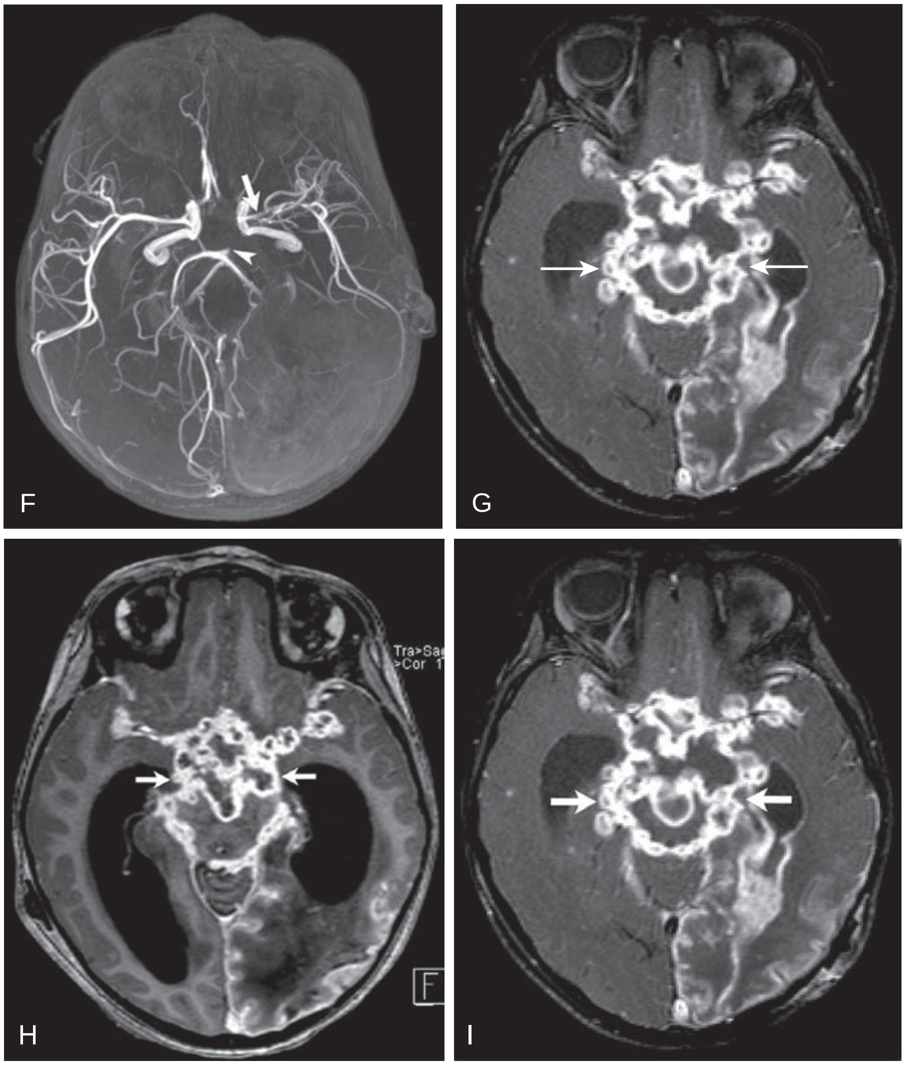

**Figure 34.16, cont'd.**

of direct invasion by the *Borrelia burgdorferi* organism or due to an autoimmune phenomenon.

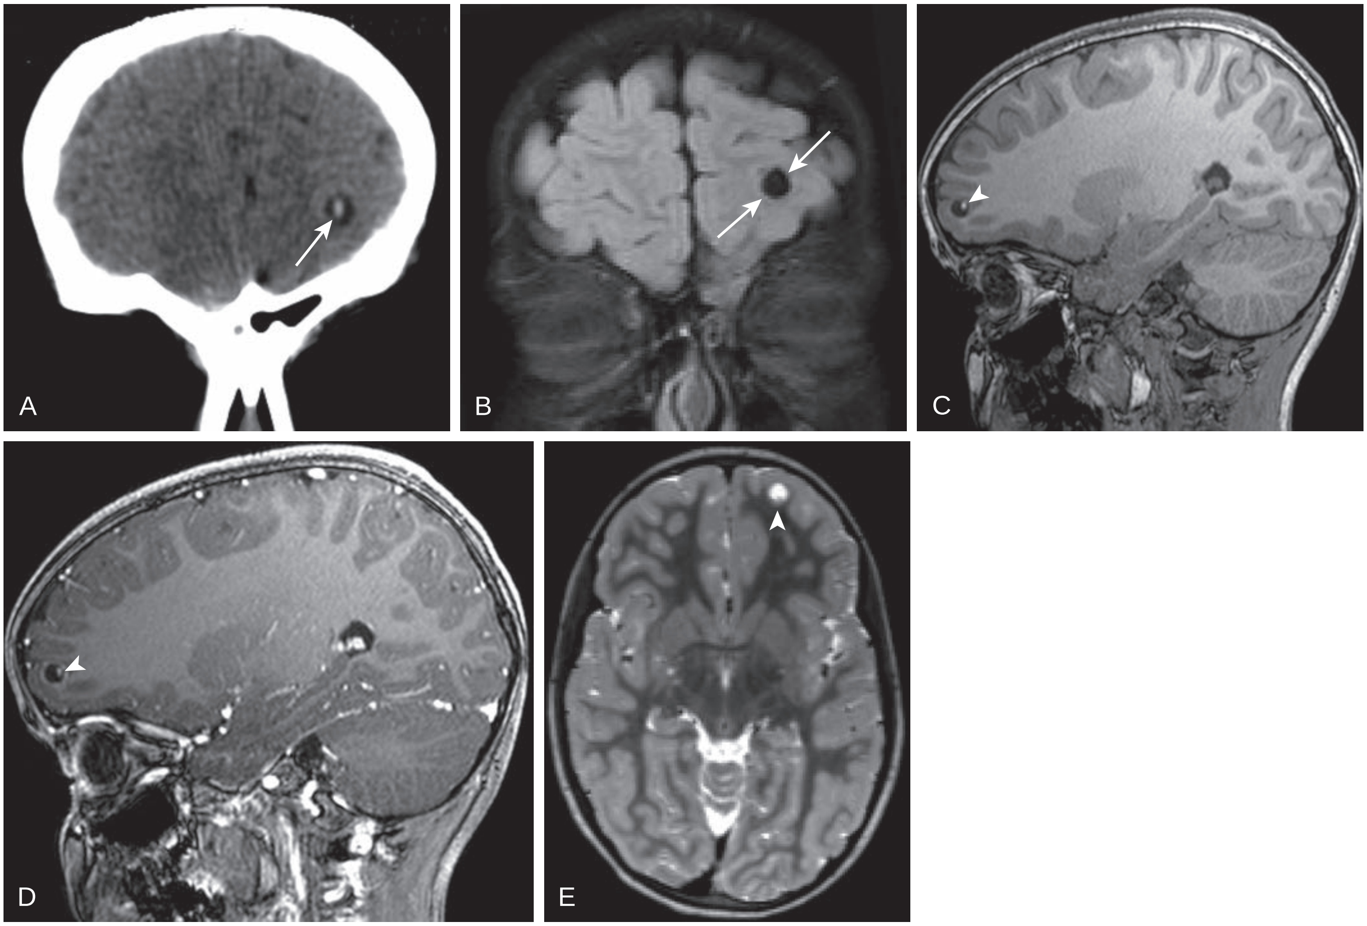
CT scans are usually normal in Lyme disease, although focal areas of hypoattenuation have been reported. Focal white matter lesions, which are hyperintense on T2-weighted images, are seen in about one in four neurologically affected patients. Contrast-enhanced MRI may show leptomeningeal enhancement, with or without enhancement of the affected cranial nerves, in children with cranial neuropathy (Fig. 34.18).

## PARASITIC INFECTIONS

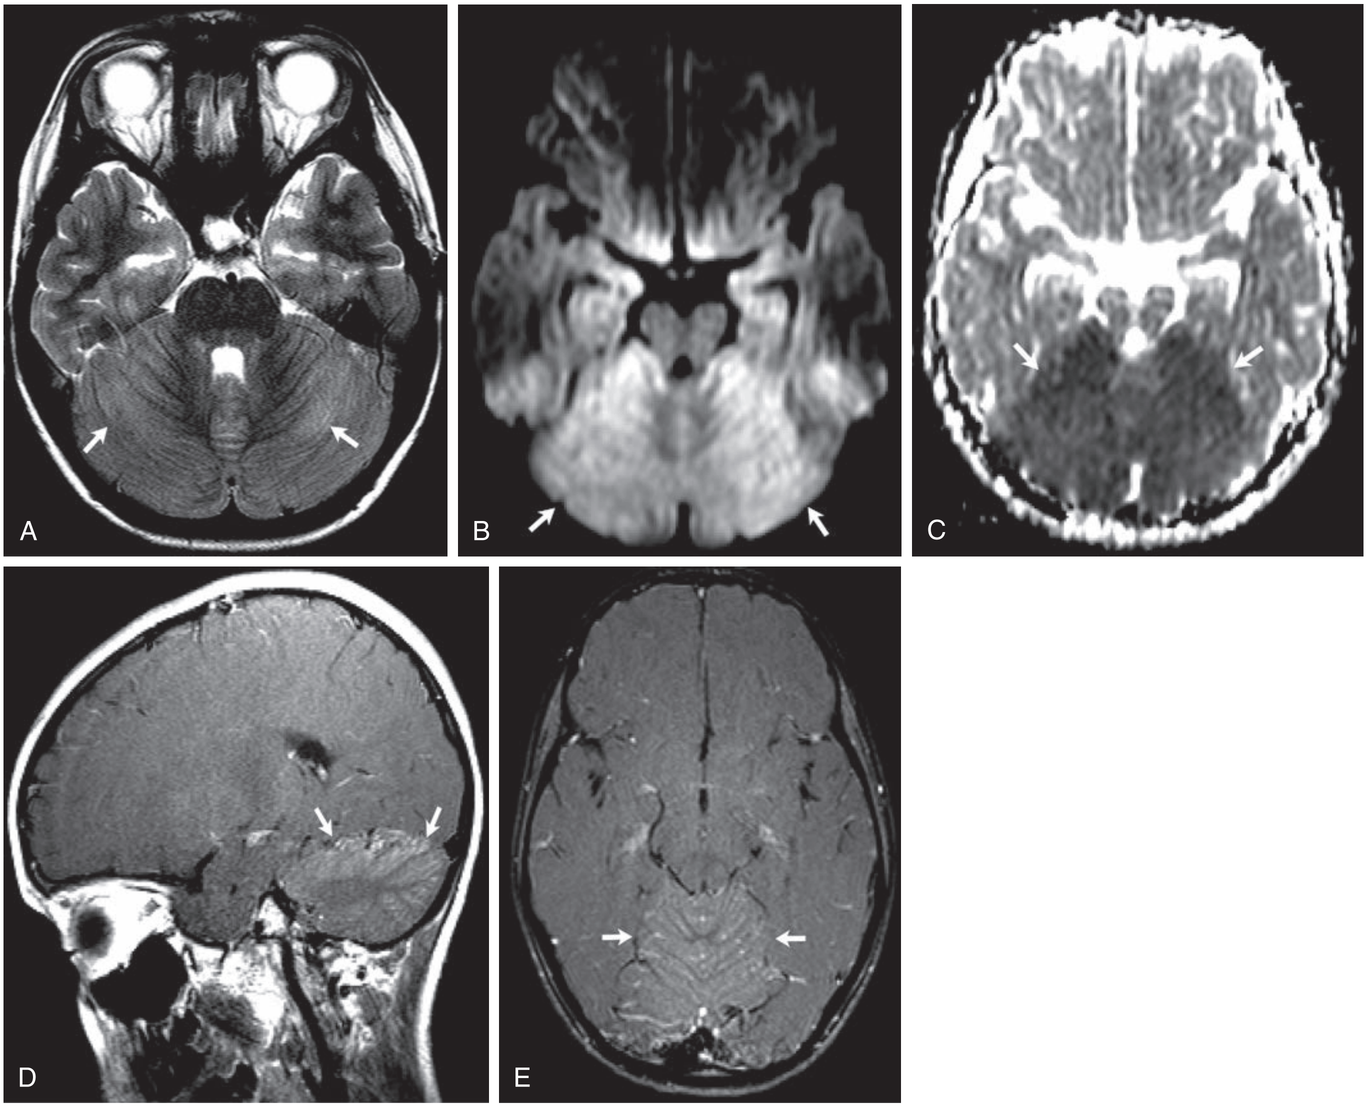
In the United States, parasitic CNS infection in children is rare. While cysticercosis is not very common per se, it often presents in immigrants from endemic regions. The most common presenting symptoms of pediatric neurocysticercosis include seizures, developmental delay, and hydrocephalus. The most common form, parenchymal cysticercosis, is caused by inflammatory reaction secondary to the death of the parasite. Focal lesions are cystic and solid and present with peripheral enhancement and calcification, respectively. They are most often situated at the cortex and/or gray-white matter junction (Fig. 34.19). Parenchymal lesions follow CSF signal intensity on DWI, which helps differentiate them from pyogenic abscesses. The typical calcification seen in adults is not always seen in children. Surrounding inflammatory reaction demonstrates hyperintense T2-weighted signal. Intraventricular cysterci often cause obstructive hydrocephalus. Thin-slice T1-weighted imaging best depicts the causative intraventricular scolex (e-Fig. 34.20). The leptomeningeal form of cysticercosis mimics the radiographic appearance of TB, with marked postcontrast subarachnoid enhancement. Subarachnoid granulomata mimic their parenchymal counterparts. Hydrocephalus and vasculitis are common associated findings. Racemose cysts are large cysts that are most often found in the cerebellopontine angle, Sylvian fissures, as well as the basilar and suprasellar cisterns. Multiple coexisting forms of cysticercoids often suggest the diagnosis. On MRI, clusters of cysts are most commonly depicted.

## VIRAL INFECTIONS

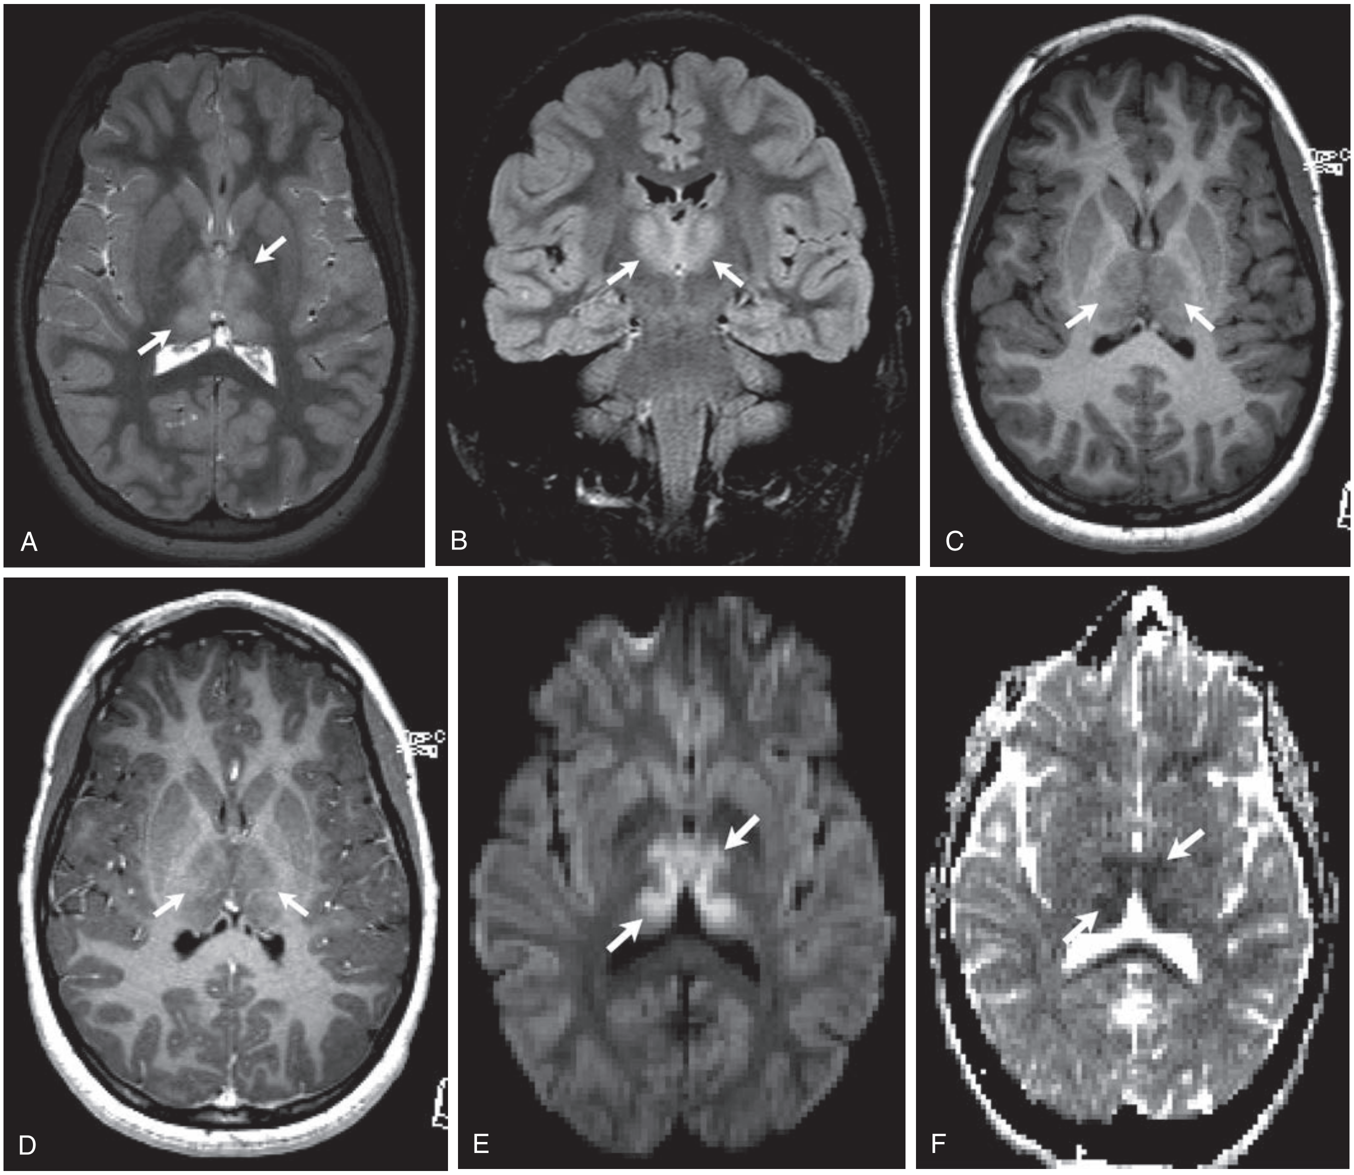
Viruses affecting the brain (e-Fig. 34.21) all produce inflammation and neuronal necrosis to a greater or lesser extent. Some viruses such as herpes simplex virus (HSV) and Coxsackieviruses may also produce white matter necrosis, whereas the primary inflammatory process involves the parenchyma. There is usually a meningeal inflammatory reaction or even ventriculitis. In general, acute viral infection typically causes marked edema (e-Fig. 34.22). Hyperechogenicity on US, hypoattenuation on CT, as well as hyperintense signal on T2-weighted and FLAIR sequences are typical imaging findings of CNS viral infection. Restricted diffusion on DWI is the earliest sign of viral encephalitis. Fortunately differences in presentation and location help suggest one viral



**e-Figure 34.20. Cysticercosis.** Seven-year-old female with left frontal cystic lesion. (A) Coronal noncontrast CT of the head, (B) coronal fluid-attenuated inversion–recovery MR image, sagittal (C) pre- and (D) contrast-enhanced 3D-SPGR images through the level of the left frontal lobe, and (E) reconstructed axial 3D T2-weighted image through the same area. Note the area of high attenuation within the center of the lesion (*arrow* in A), corresponding to the scolex within a cystic rim (*arrows* in B). Note the bright appearance of the scolex on the sagittal images (*arrowheads* in C, D) and the subtle area of T2 shortening at the base of the cyst within the frontal lobe (*arrowhead* in E).



**e-Figure 34.21. Cerebellitis.** Ten-year-old female with headache, fever, and dysmetria. (A) Axial T2-weighted, (B) axial diffusion-weighted image (DWI), and (C) apparent diffusion coefficient (ADC) map, and (D) sagittal and (E) axial contrast-enhanced magnetization transfer T1-weighted MR images were obtained. Note the subtle T2 prolongation within the cerebellum (*arrows* in A). There is corresponding restricted diffusion on the DWI and ADC (*arrows* in B, C). There is gyriform type enhancement within the cerebellar hemisphere (*arrows* in D), and within the cerebellar vermis (*arrows* in E).



**e-Figure 34.22. Thalamic viral encephalitis.** Nine-year-old boy with new onset of seizures and fever, as well as disorientation, with concern for encephalitis. (A) Axial T2-weighted, (B) coronal fluid-attenuated inversion–recovery, (C) axial pre- and (D) contrast-enhanced reconstructed T1-weighted 3D SPGR images, and axial (E) diffusion-weighted image and (F) apparent diffusion coefficient map were obtained on a 3T system. Note the T2 prolongation within the thalami bilaterally (*arrows* in A, B), with corresponding T1 prolongation in similar areas (C, D). There is diffusion restriction within the thalami bilaterally (*arrows* in E, F).

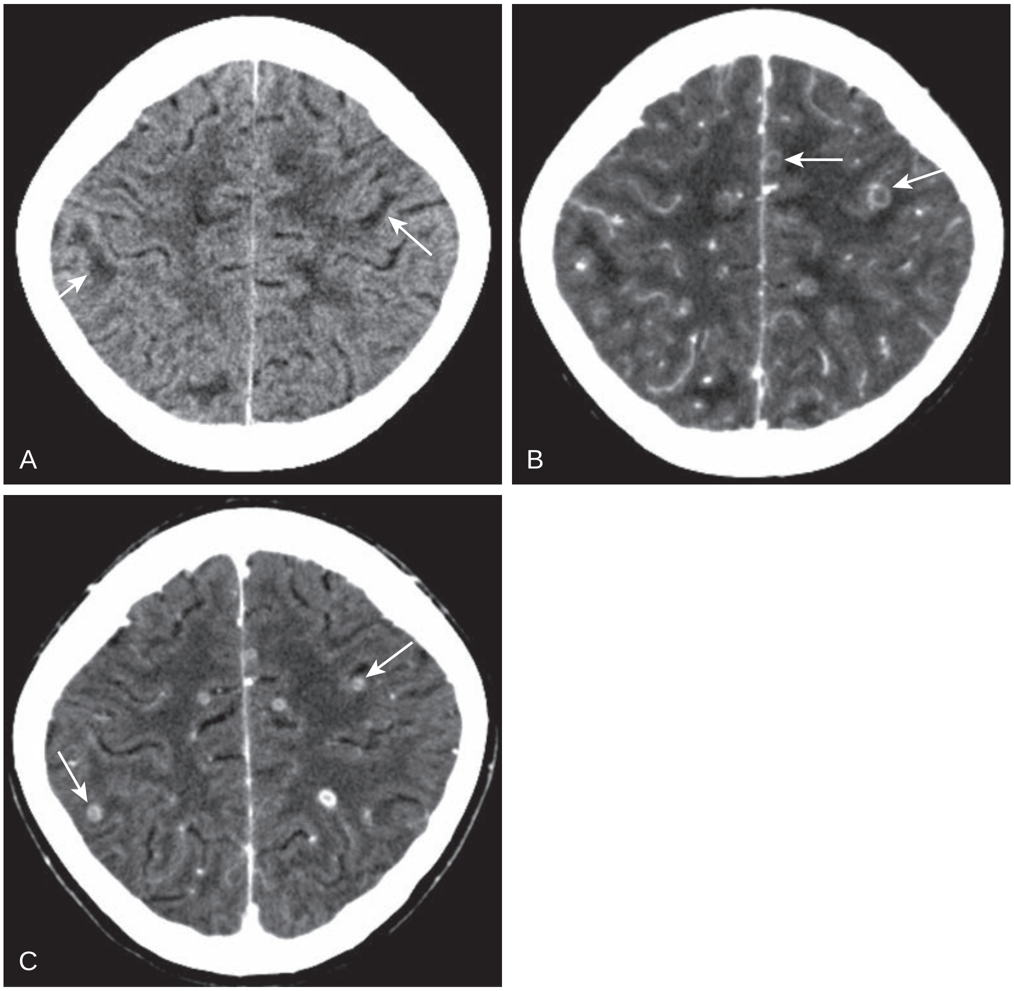


**Figure 34.17. Tuberculosis and microabscesses.** Thirteen-year-old female with headaches, vomiting, and vertigo. Patient also has a positive PPD and abnormal chest x-ray. (A) Axial noncontrast CT and (B) contrast-enhanced CT of the head, and (C) contrast-enhanced CT image 1 month later. Note the areas of low attenuation at the gray-white matter junction at the time of presentation (*arrows* in A). There are multiple ring enhancing lesions noted bilaterally within the gray-white matter junction (*arrows* in B, C), corresponding to multiple microabscesses, secondary to TB.

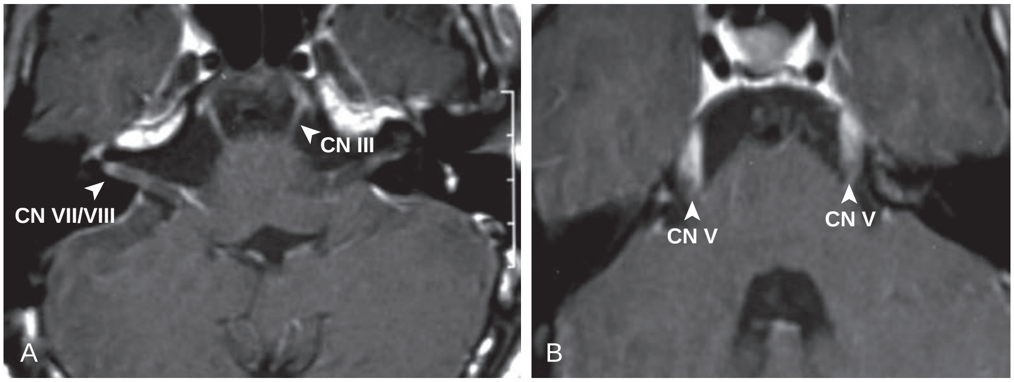

**Figure 34.18. Lyme disease.** Fifteen-year-old male with multiple cranial nerve neuropathies and suspected tuberculosis exposure. (A and B) Axial contrast-enhanced T1-weighted MR images were obtained through the region of the posterior fossa. Note the symmetric abnormal contrast enhancement along the cranial nerves *(CN)* as labeled by their respective numbers adjacent to the *arrowheads*.

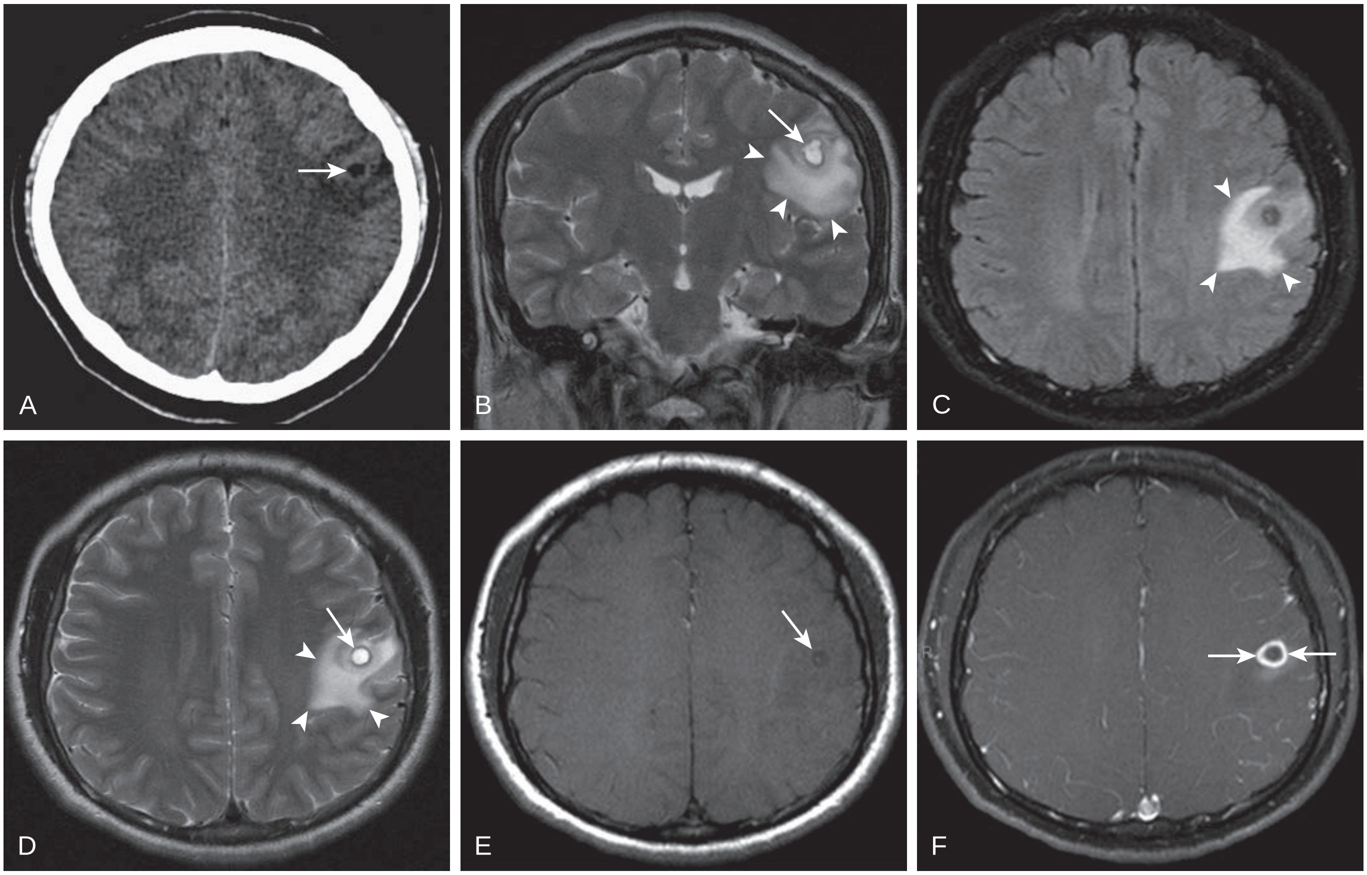

**Figure 34.19. Cysticercosis.** History of ingestion of uncooked pork. (A) Axial noncontrast CT of the head, (B) coronal T2-weighted MR image, (C) axial fluid-attenuated inversion–recovery and (D) T2-weighted sequences, and (E) axial pre- and (F) contrast-enhanced T1-weighted MR images. Note the area of decreased attenuation on CT (*arrow* in A). There is corresponding cystlike T2 prolongation within the center of this region (*arrows* in B, D). This is surrounding vasogenic edema (*arrowheads* in B–D). In addition, there is a subtle area of T1 shortening within the center of the lesion (*arrow* in E) corresponding to the scolex. Note the thick reactive rim enhancement around the area of the parasite (*arrows* in F).

etiology over another. Viral-like syndromes with autoimmune associations, such as acute disseminated encephalomyelitis (ADEM) and posttransplantation lymphoproliferative disorders (PTLD) (e-Fig. 34.23), often demonstrate imaging characteristics similar to viral infections.

## Herpes Simplex Virus 1

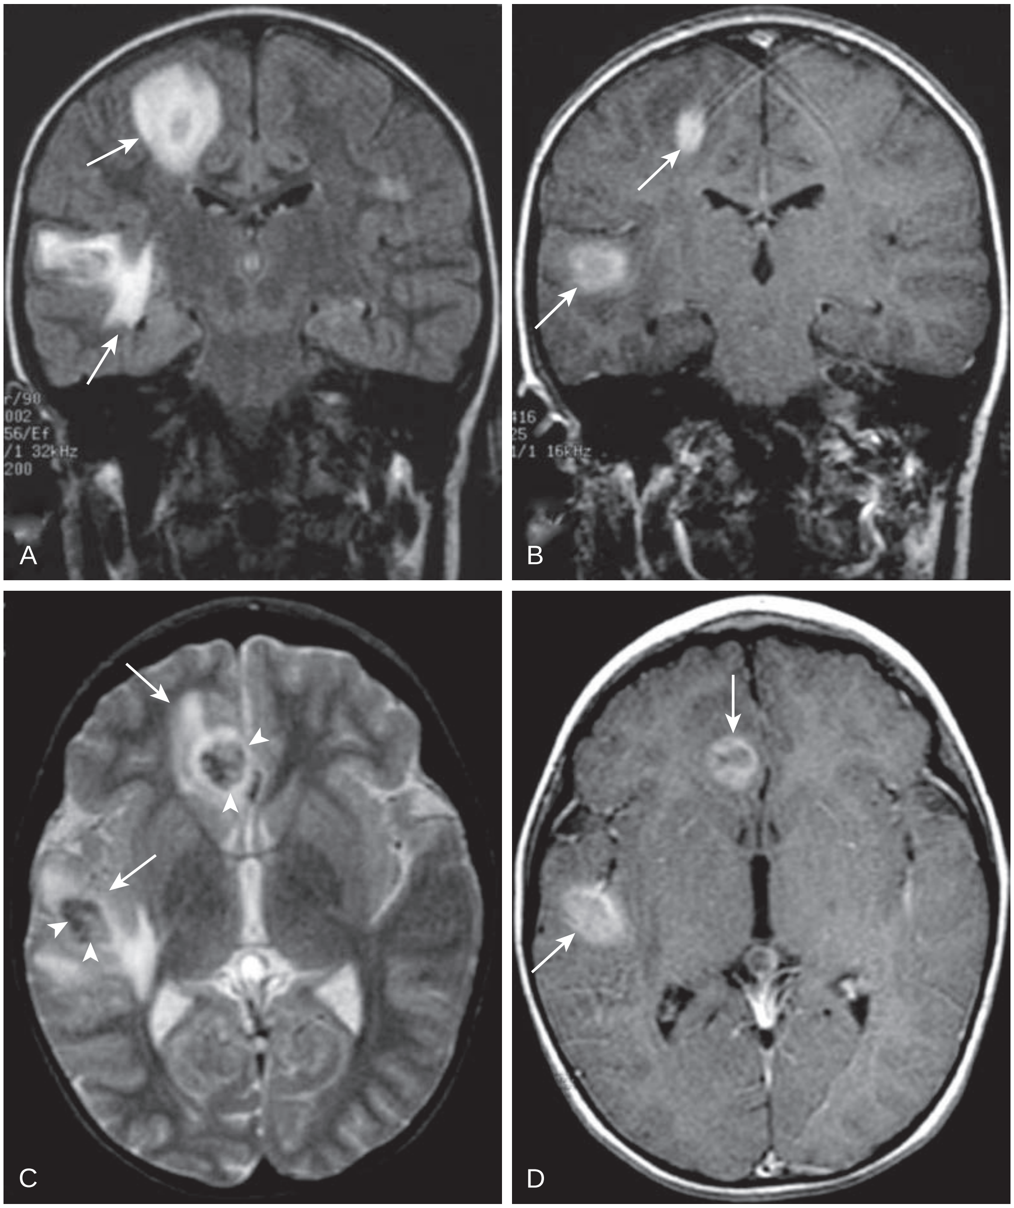
Herpes simplex virus 1 (HSV-1), as opposed to the perinatally acquired HSV-2 (see later), is a spontaneous infection most often caused by reactivation of an orofacial HSV infection, which occurs in all ages but has a pediatric predominance. Early symptoms of fever and malaise can progress to seizures and hemiparesis. Restricted diffusion on MRI is the earliest radiologic manifestation with unilateral or bilateral medial temporal lobe hyperintense signal on T2-weighted and FLAIR sequences, with more heterogeneous diffusion appearing several days later. CT findings of low attenuation within the temporal lobe and insular cortex do not manifest until several days after the onset of symptoms. Leptomeningeal and cortical enhancement, as well as foci of calcification and hemorrhage, may also be present.

## Human Immunodeficiency Virus

In the United States, greater than 90% of children with human immunodeficiency virus (HIV) are infected as a result of maternal transmission to the fetus. Radiologic CNS manifestations of congenital HIV include atrophy with resultant ventricular and subarachnoid space prominence, as well as basal ganglia and subcortical calcifications. The calcifications are best seen on CT (Fig. 34.24). Superinfection and neoplasm, which are not uncommon in the adult HIV population, are seldom seen in children. In children, progressive multifocal leukoencephalitis (PML) caused by the Jakob-Creutzfeldt polyomavirus, is radiologically identical to its presentation in adults. PML demonstrates white matter hypoattenuation on CT, as well as hyperintense signal on T2-weighted and FLAIR MRI sequences. These lesions characteristically lack mass effect and do not enhance after contrast administration. HIV infection can also lead to vasculitis (Fig. 34.25).

## Acute Disseminated Encephalomyelitis

ADEM is a monophasic focal or multifocal, perivascular inflammatory and demyelinating disorder often affecting both the brain and spinal cord after a vaccination or viral infection. Lesions are generally hyperintense on T2-weighted sequences and have corresponding hypointensity or isointensity on T1-weighted sequences. MRI characteristics of ADEM (Fig. 34.26) are variable, with enhancement patterns including solid or ringlike enhancement, to no enhancement at all, in lesions that range from small to large, and that affect gray matter, white matter, or both. A clinical history



**e-Figure 34.23. Posttransplant lymphoproliferative disease (PTLD).** Seven-year-old male, status post heart transplant for underlying complex congenital heart disease, now with headache and visual changes. (A) Coronal fluid-attenuated inversion–recovery, (B) coronal postcontrast T1-weighted, (C) axial T2-weighted, and (D) axial postcontrast T1-weighted MR images were obtained. Note the multiple areas of T2 prolongation within the right cerebral hemisphere (*arrows* in A and C). There is central T2 shortening, suggesting an element of hemorrhage (*arrowheads* in C). There is avid contrast enhancement evidenced on the postcontrast images (*arrows* in B and D).

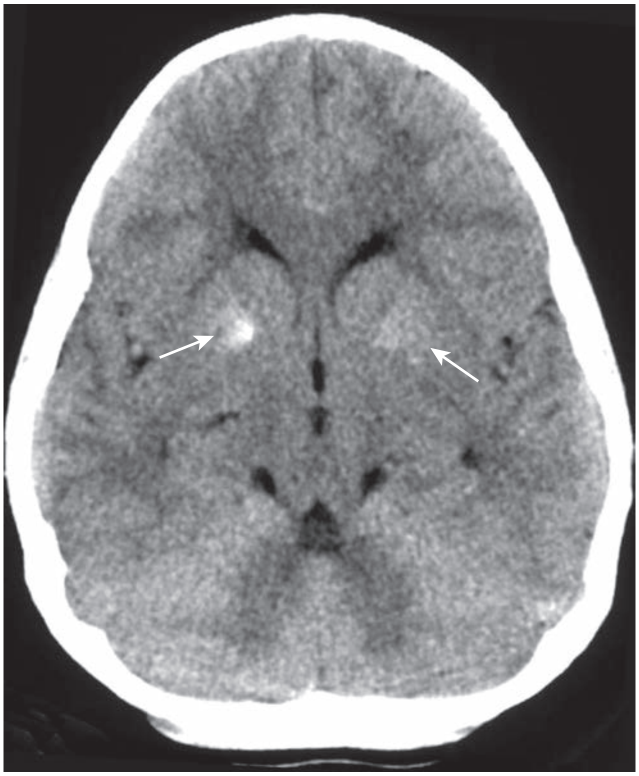


**Figure 34.24. Human immunodeficiency virus (HIV).** Nine-year-old male with known HIV infection. Noncontrast CT of the head at the level of the basal ganglia demonstrates calcific areas within the basal ganglia bilaterally *(arrows),* right greater than left, commonly seen in patients with HIV.

of a recent viral illness or vaccination is the key to properly diagnosing these lesions.

## Subacute Sclerosing Panencephalitis

Subacute sclerosing panencephalitis is believed to represent a response to reactivation of the measles virus years after an infection. MRI reveals cortical and basal ganglia predominant hyperintense signal on T2-weighted and FLAIR sequences.

## Rasmussen's Encephalitis

Rasmussen's encephalitis is one of the leading causes of intractable epilepsy in children, presenting between 1 and 15 years of age, and is characterized by seizures, progressive hemiplegia, and progressive psychomotor deterioration. It is characteristically localized to one hemisphere. Initial imaging studies are normal, with MRI later demonstrating hemispheric atrophy (Fig. 34.27) and hyperintense signal on T2-weighted and FLAIR sequences in the frontal and temporal lobes, predominantly within the white matter as well as the basal ganglia.

## Congenital Infections

Transplacental, and less often, transvaginal transfer of infection to the fetus is often the result of TORCH (Toxoplasmosis, Other, Rubella, Cytomegalovirus, Herpes) infection (e-Fig. 34.28). Insults occurring during the first two trimesters most often manifest as severe congenital malformations. Those occurring during the third trimester often result in destructive lesions.

## Cytomegalovirus

Cytomegalovirus (CMV) is the most common serious viral infection to affect newborns in the United States, occurring in nearly 1% of all live births. Up to 25% of infected infants develop neurologic or developmental abnormalities in the first year of life, which include microcephaly, hearing impairment, chorioretinitis, and seizures. Neonatal US in affected patients often demonstrates nonspecific mineralizing vasculopathy of the basal ganglia (Fig. 34.29). MRI and CT demonstrate the sequelae of infection in the third trimester as periventricular calcification and/or hemorrhage, ventricular and sulcal prominence, as well as periventricular and subcortical white matter changes. Intrauterine infection with this virus is associated with polymicrogyria, especially in the region of the Sylvian fissures (Figs. 34.30 and 34.31).

## Toxoplasmosis

Symptomatic congenital toxoplasmosis infection is far less common than CMV. The parasite *Toxoplasma gondii* is believed to be transmitted to the pregnant mother by ingestion of uncooked oocysts in infected birds and/or mammals. Principle clinical findings include hydrocephalus, abnormal CSF, bilateral chorioretinitis, and intracranial calcifications. Fetal infection before 20 weeks' gestation leads to severe neurologic deficits; infection between 20 and 30 weeks leads to a more variable outcome. Beyond 30 weeks, CT manifestations often include intracerebral and periventricular calcifications, which are nearly identical to the distribution in CMV-affected children and is rarely accompanied by ventricular dilatation. Cortical malformations, which are fairly typical with CMV infection, are most often absent in cases of toxoplasmosis.

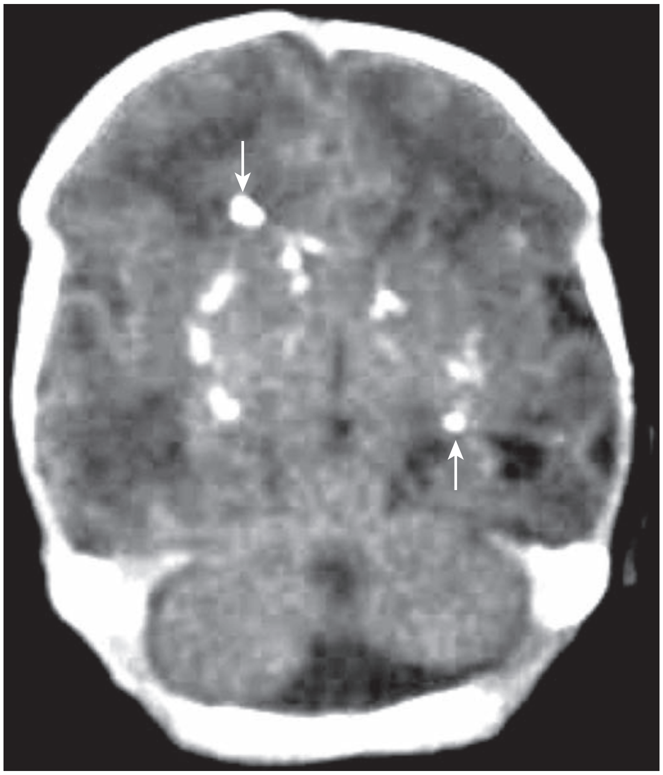
## Herpes Simplex Virus 2

Most cases of neonatal HSV-2 are contracted transvaginally as the child passes through the birth canal. Neonatal CNS HSV infection is believed to occur in approximately 1 in 10,000 births. CNS manifestations generally present between 2 to 4 weeks of life and include meningoencephalitis with seizures, lethargy, and fever. Sequelae include mental retardation, severe neurologic deficits, or even death, secondary to virulent destruction of the brain. The disease may progress to produce ischemic infarction of parts of or all of the brain, necrosis, atrophy, encephalomalacia, demyelination, and gliosis. Watershed distribution ischemia is also fairly common in areas remote from the primary herpetic lesions. Hypointense signal on ADC images, which may be multifocal or limited to the temporal lobes, brainstem, or cerebellum, is the first MRI sign of HSV brain destruction (Fig. 34.32). CT changes in early disease are either normal or demonstrate mild abnormalities. Later, patchy white matter low attenuation on CT and corresponding hyperintense T2-weighted MRI signal with rapid progression is demonstrated. Meningeal enhancement reflects the extent of the disease. Also of note is classic persisting hyperattenuation of cortical gray matter on CT (Fig. 34.33) and corresponding T1 and T2 shortening on MRI. Eventually, diffuse cerebral and cerebellar (in about 50% of cases) atrophy and encephalomalacia ensue. It should be noted that HSV-1 encephalitis, which affects older children and adults (Fig. 34.34), is different from neonatal HSV infection (see previous section).

## Zika Virus

Zika virus infection or exposure in pregnancy has recently been described in association with increased risk of microcephaly and intracranial calcifications in affected fetuses. The center of the epidemic is in Brazil, where the majority of the cases have been

*Text continued on p.344*



**e-Figure 34.28. Toxoplasmosis, other, rubella, cytomegalovirus, herpes (TORCH) infection.** Newborn female with seizures and questionable intracranial hemorrhage. Noncontrast CT of the head demonstrates multiple scattered punctate calcifications *(arrows)* seen bilaterally, slightly greater on the right than on the left, in a more random fashion than is expected with cytomegalovirus infection. This likely represents calcification from another TORCH-type infection, such as toxoplasmosis.

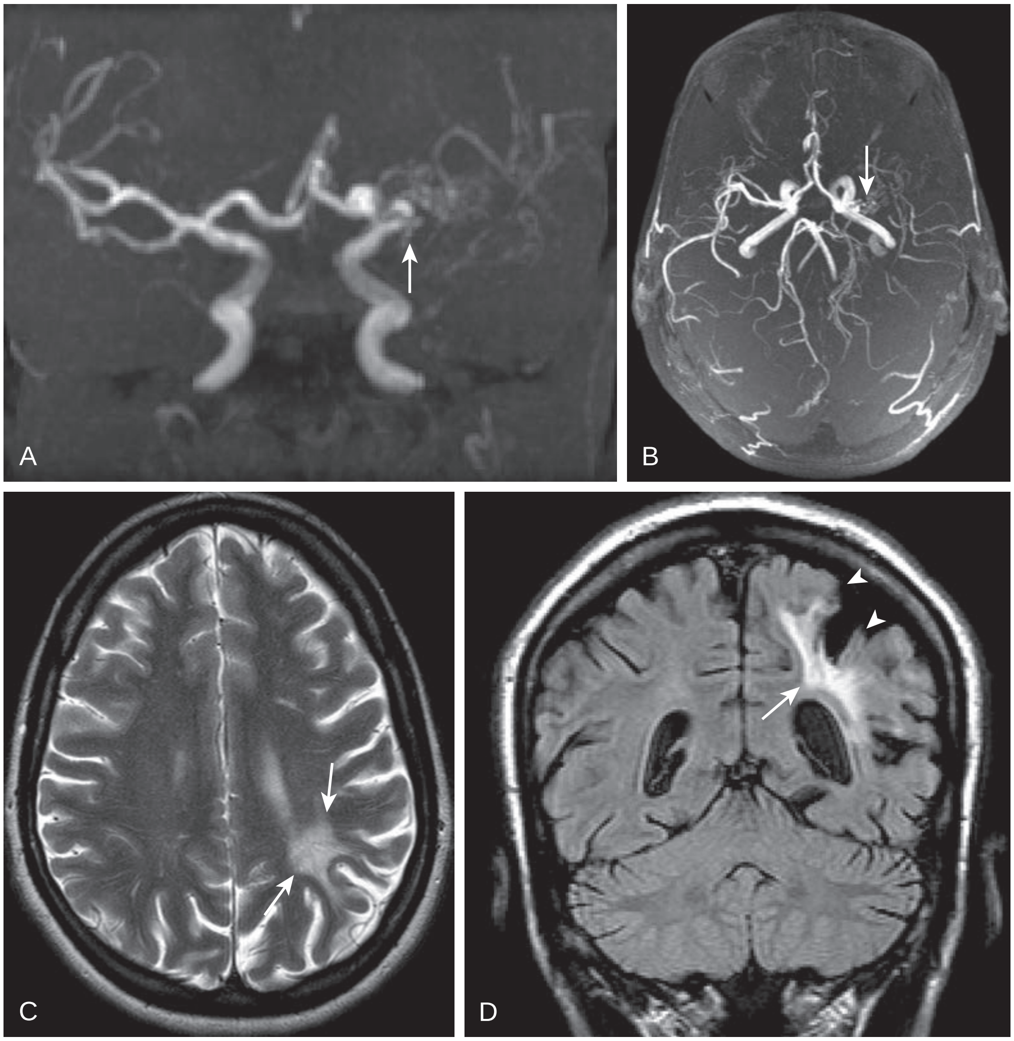


**Figure 34.25. Human immunodeficiency virus (HIV) vasculitis.** Eighteen-year-old female with HIV and right hemiplegia. Coronal and collapsed CC view of the intracranial circulation from a 3D time of flight (TOF) MRA (A and B, respectively), axial T2-weighted (C), and coronal fluid-attenuated inversion–recovery (D) MR images. Note the marked narrowing of the left MCA on the TOF MRA (*arrows* in A and B). There is corresponding T2 prolongation within the left parietal subcortical white matter (*arrows* in C and D), corresponding to gliosis. There is associated overlying cortical volume loss (*arrowheads* in D).

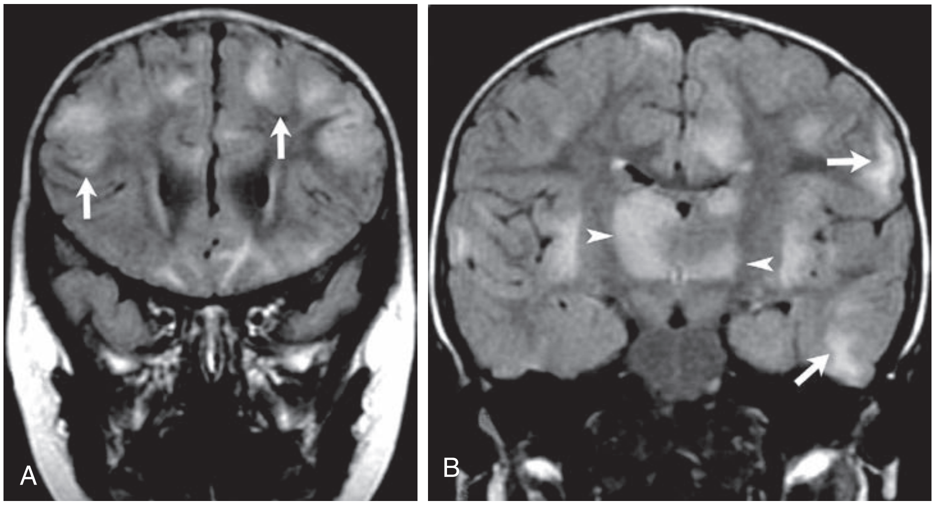

**Figure 34.26. Acute disseminated encephalomyelopathy (ADEM).** Twenty-two-month-old male with lethargy, hypotonia, ataxia, and decreased righting reflexes preceded by an antecedent upper respiratory illness. Sequential coronal fluid-attenuated inversion–recovery images from anterior to posterior (A–C), (D) axial T2-weighted, and (E) axial postcontrast T1-weighted MR images. There are patchy areas of bilateral subcortical white matter T2 prolongation (*arrows* in A–D), as well as abnormal T2 prolongation within the central gray structures (*arrowheads* in B and D). There is no significant contrast enhancement noted; however, the central gray structures appear to standout in relief on the postcontrast images (*arrows* in E) likely secondary to abnormal T1 prolongation.

*Continued*

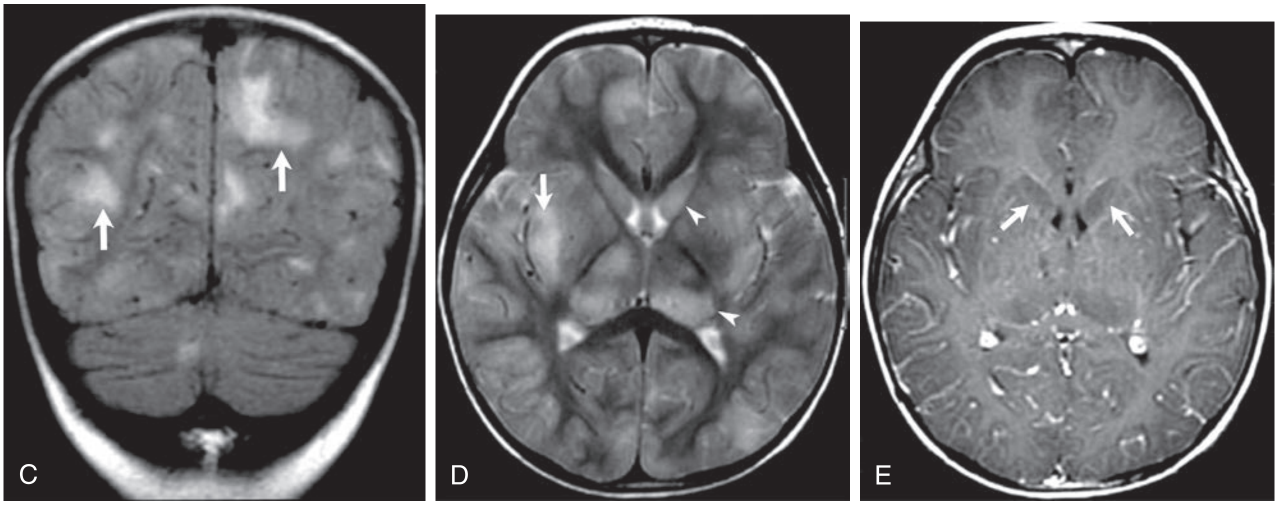

**Figure 34.26, cont'd.**

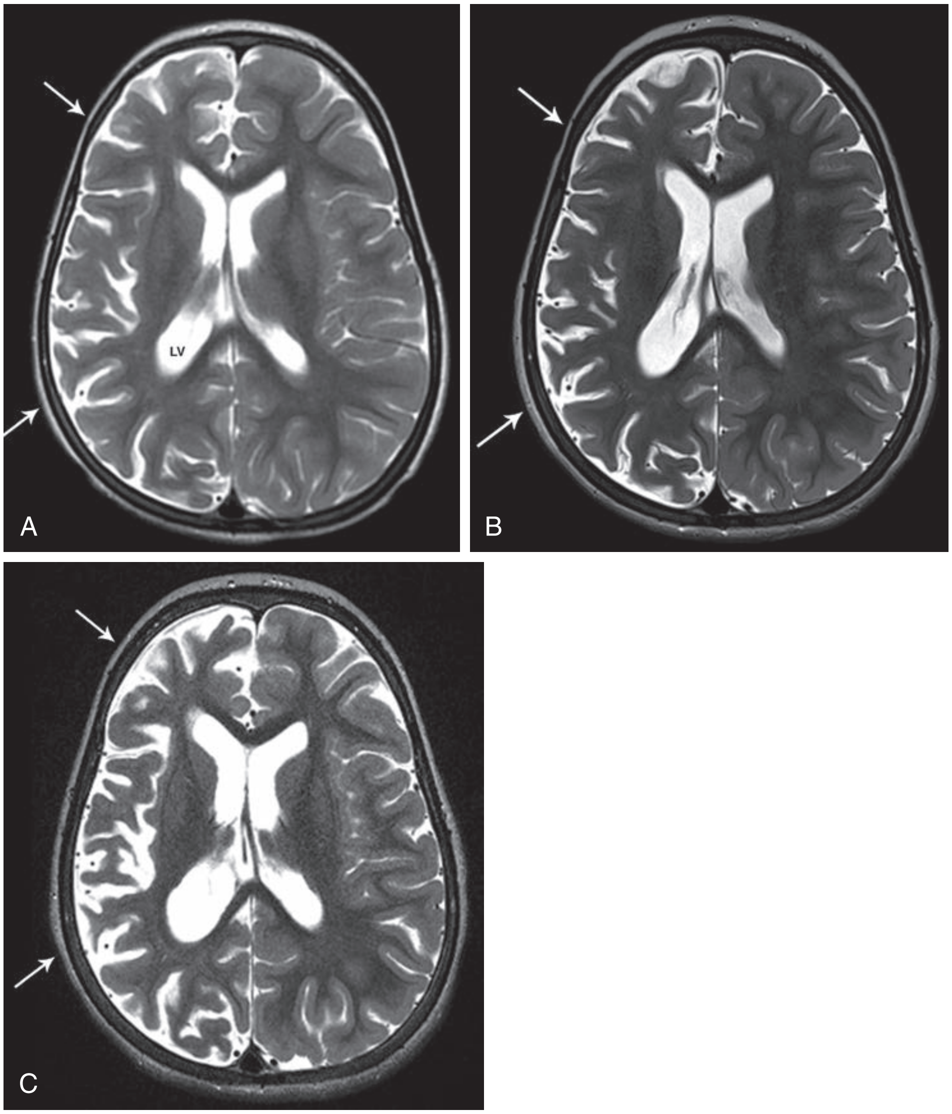

**Figure 34.27. Rasmussen's encephalitis.** Three-year-old female with recent explosive onset of simple partial seizures left hemiparesis and epilepsia partialis continua on EEG. (A) Axial T2-weighted MR images obtained at presentation, (B) at 4 months, and (C) 6 months from original MRI. There is diffuse right hemispheric volume loss *(arrows)* with associated *ex vacuo* prominence of the right lateral ventricle *(LV)*. Note the mild progression on the 4- and 6-month follow-up studies.

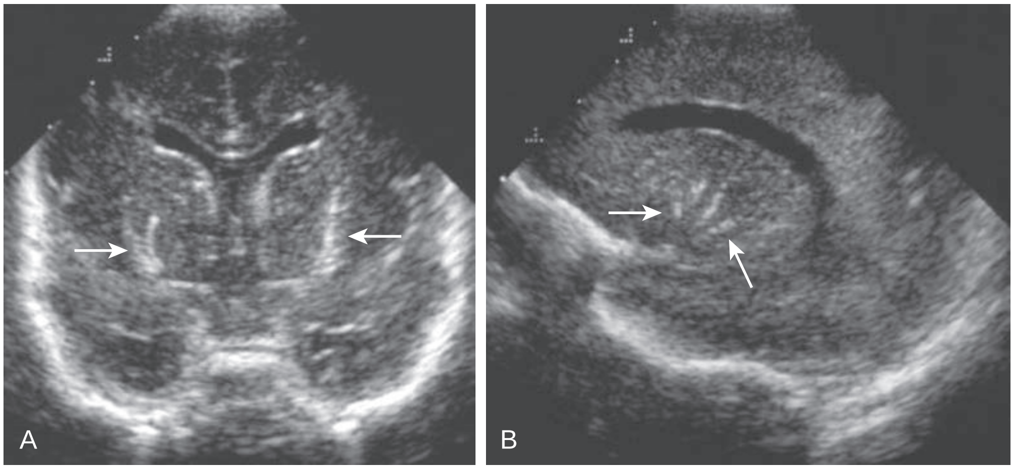

**Figure 34.29. Mineralizing vasculopathy.** Three-week-old, former preterm infant with positive cytomegalovirus titers. (A) Coronal and (B) sagittal US images through the anterior fontanelle were obtained. Note the linear branching areas of increased echogenicity seen within the distribution of the perforating vessels *(arrows)*.

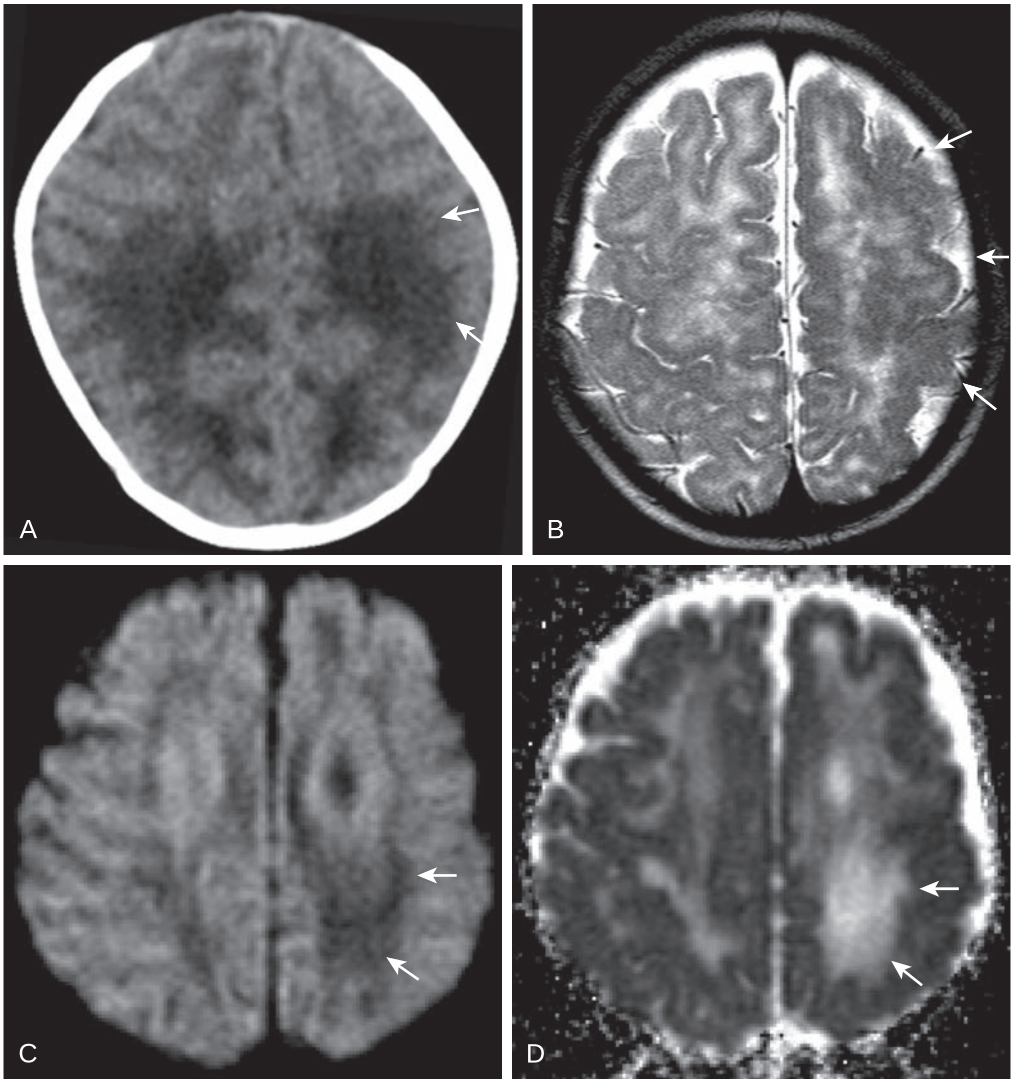

**Figure 34.30. Cytomegalovirus (CMV).** Patient with congenital CMV, pale left optic nerve, and failed hearing test. (A) Axial noncontrast CT of the head, (B) axial T2-weighted MR image, and (C) axial diffusion-weighted imaging and (D) apparent diffusion coefficient map. Note the abnormal low attenuation within the white matter (*arrows* in A). Note the abnormal sulcal pattern of the left hemisphere in (B) in keeping with associated polymicrogyria (*arrows* in A). Note that there is, in fact, increased diffusion within the corresponding white matter, left greater than right (*arrows* in C and D).

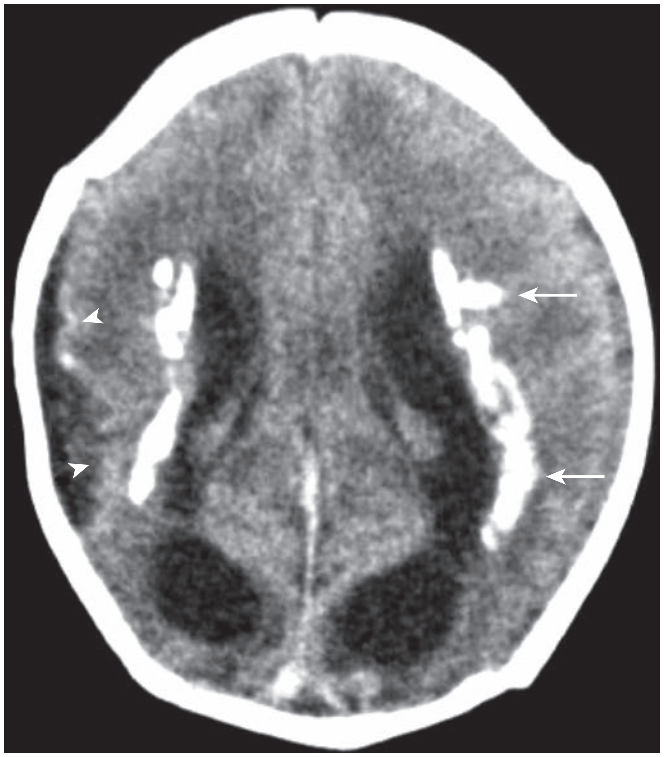

**Figure 34.31. Cytomegalovirus (CMV).** One-day-old with congenital CMV infection. Noncontrast CT of the head demonstrates multiple areas of confluent calcifications within the periventricular regions bilaterally (*arrows),* typical of the expected distribution of calcification secondary to CMV. Note the abnormal sulcal pattern of the right hemisphere, indicating associated polymicrogyria *(arrowheads)*.

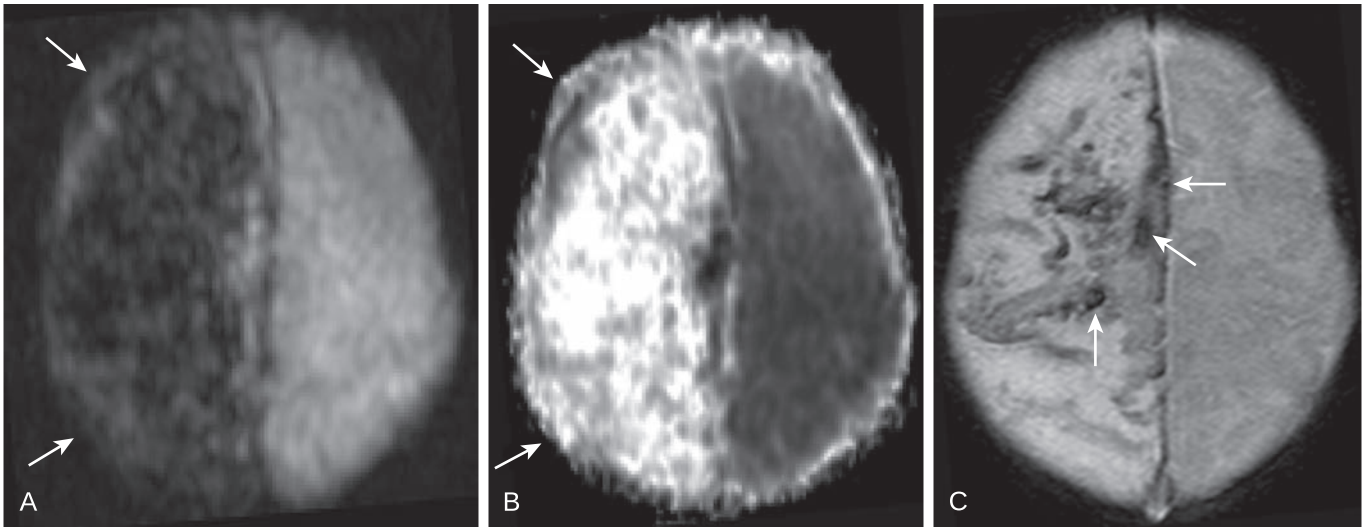

**Figure 34.32. Herpes simplex virus cerebritis/encephalitis (hemorrhagic type).** One-month-old female with several-day history of seizures and positive cerebrospinal fluid herpes simplex virus culture. (A) Diffusion-weighted image and (B) apparent diffusion coefficient map, (C) axial gradient echo, (D) sagittal T1-weighted, (E) axial fluid-attenuated inversion–recovery, and (F) axial fat-saturated postcontrast T1-weighted MR images. Note the increased diffusion throughout the right cerebral hemisphere (*arrows* in A and B). There is corresponding T2* effect within the superior right cerebral hemisphere corresponding to hemorrhage (*arrows* in C). There is corresponding T1 shortening near the midline midline (*arrows* in D) corresponding to mineralization. Note the mass effect due to edema of the right cerebral hemisphere (*arrows* in E), and the paucity of abnormal contrast enhancement (F).

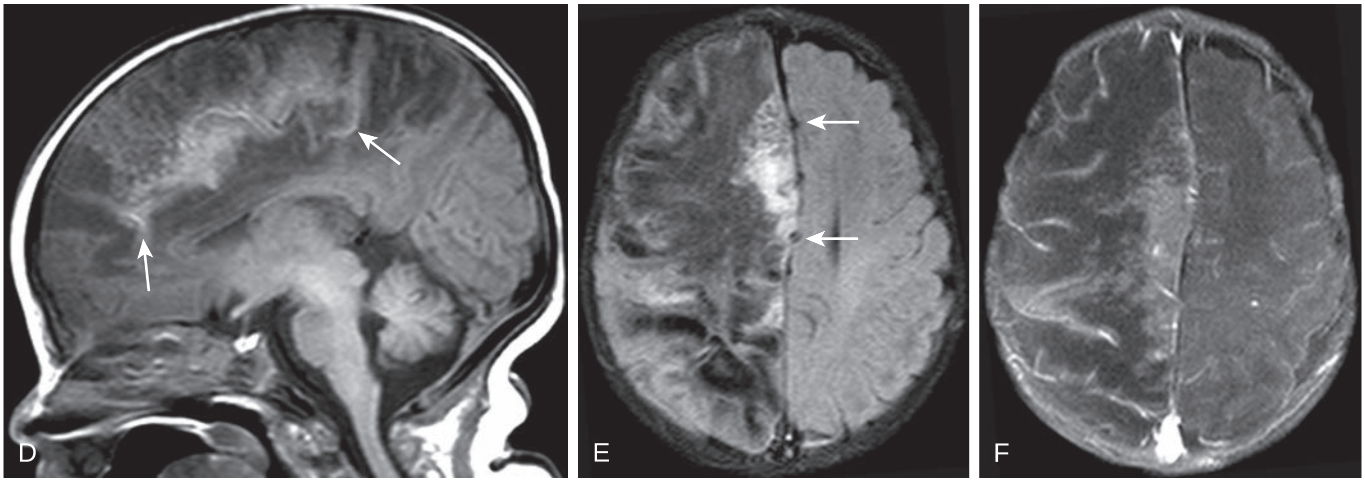

**Figure 34.32, cont'd.**

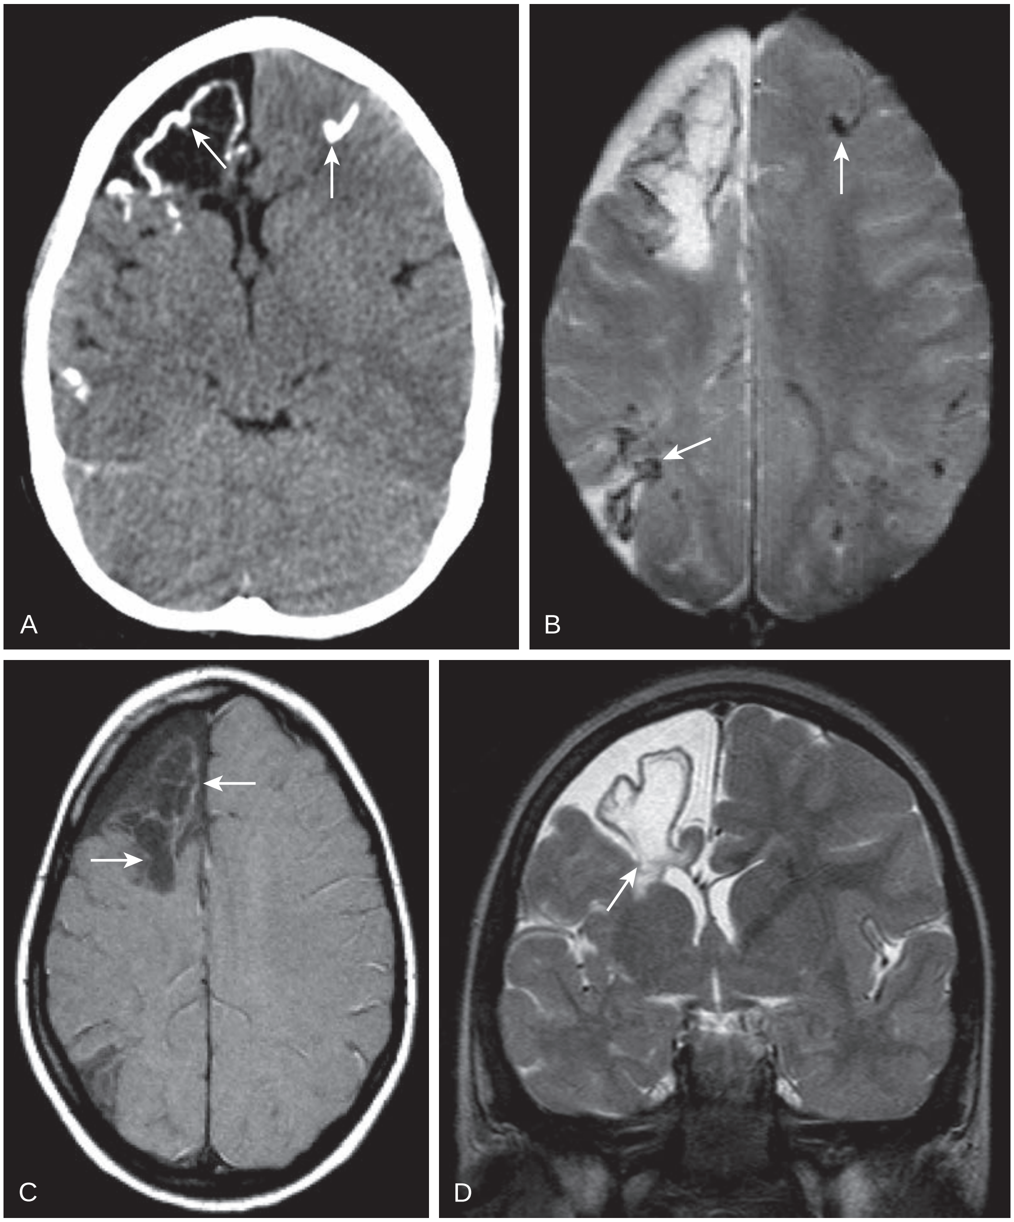

**Figure 34.33. Chronic changes of herpes simplex virus (HSV).** Five-year-old female with fulminant hepatic failure, renal failure, and lethargy with a prior history of HSV encephalitis. (A) Axial noncontrast CT of the head, (B) axial gradient echo, (C) axial magnetization transfer T1-weighted, and (D) coronal T2-weighted MR images. Note the calcification seen within both hemispheres (*arrows* in A), with corresponding areas of T2* effect within both cerebral hemispheres (*arrows* in B), in keeping with mineralization. There is slight T1 shortening effect (*arrows* in C), corresponding to mineralization. There is volume loss within the frontal lobe and associated T2 prolongation (*arrows* in D).

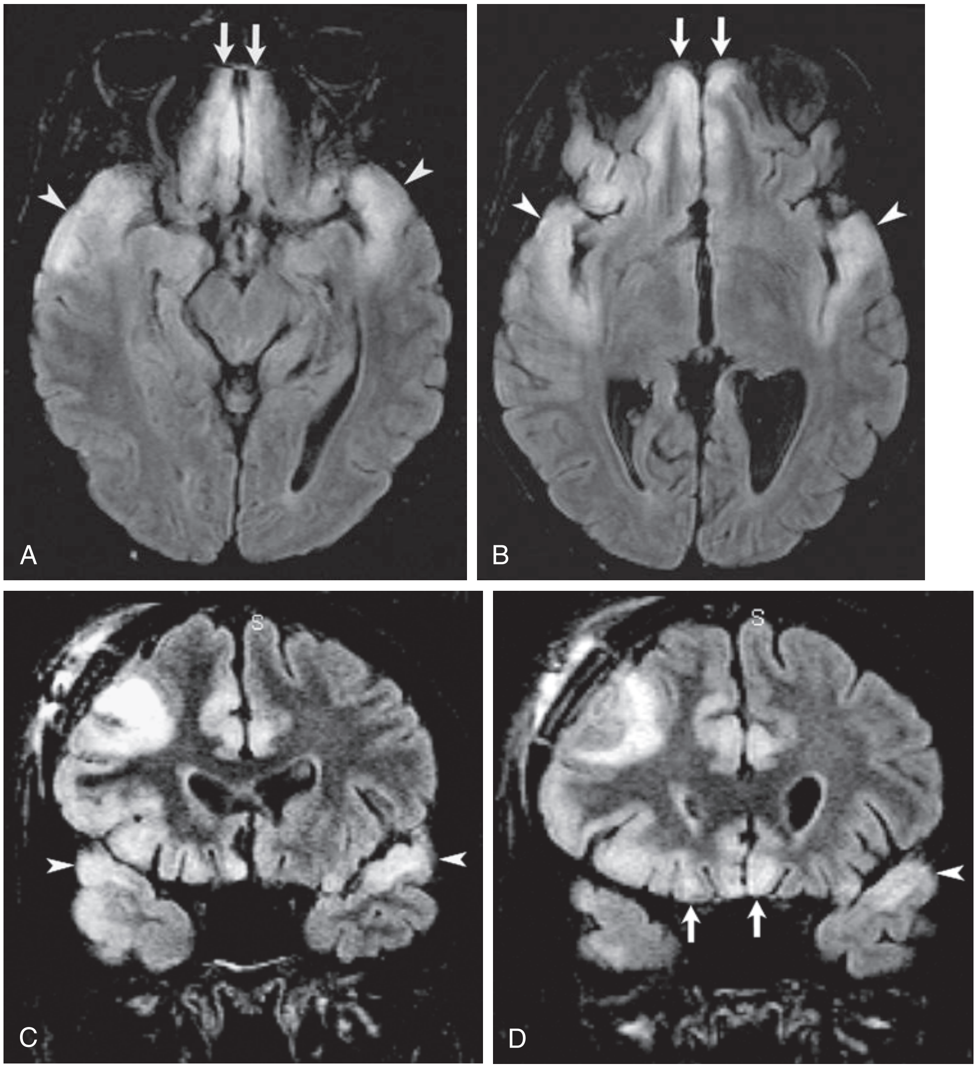

**Figure 34.34. Herpes simplex virus (HSV).** Patient with seizures and decreased level of consciousness. Axial fluid-attenuated inversion–recovery (FLAIR) (A and B) and coronal FLAIR (C and D) MR images were obtained. There is abnormal signal intensity within both frontal lobes *(arrows)* and temporal lobes *(arrowheads)* indicative of HSV encephalitis. The bilateral temporal lobe involvement is a clue to the underlying causative agent.

reported. The World Health Organization declared Zika virus to be a global health emergency in February 2016. Imaging findings reported in association with Zika virus include ventriculomegaly, cortical abnormalities (simplified gyral pattern, polymicrogyria, pachygyria), corpus callosum abnormalities, cerebellar abnormalities, and brainstem hypoplasia/atrophy (Fig. 34.35). Zika virus can be confirmed by molecular and serologic testing.

## Congenital Rubella, Varicella, and Syphilis

Congenital rubella is rare in western countries and now has an incidence in the United States of about 1 in 1,000,000 births. Congenital varicella is also rare, as even when the pregnant mother is affected with varicella zoster, the fetus is most often unaffected. Congenital syphilis is unlikely to cause neurologic symptoms in the neonatal period.

### KEY POINTS

- In bacterial CNS infections, imaging plays a role in differentiating cerebritis from abscess.
- Tuberculous meningitis often involves the basilar cisterns and can result in cranial nerve palsies, infarctions, and hydrocephalus.
- Restricted diffusion on MRI is the earliest imaging sign of viral brain infections.
- HSV-1 usually occurs in older children and is related to reactivation of orofacial infections, whereas HSV-2 infections are acquired perinatally and affect infants.
- Cytomegalovirus is the most common serious viral infection of newborns.

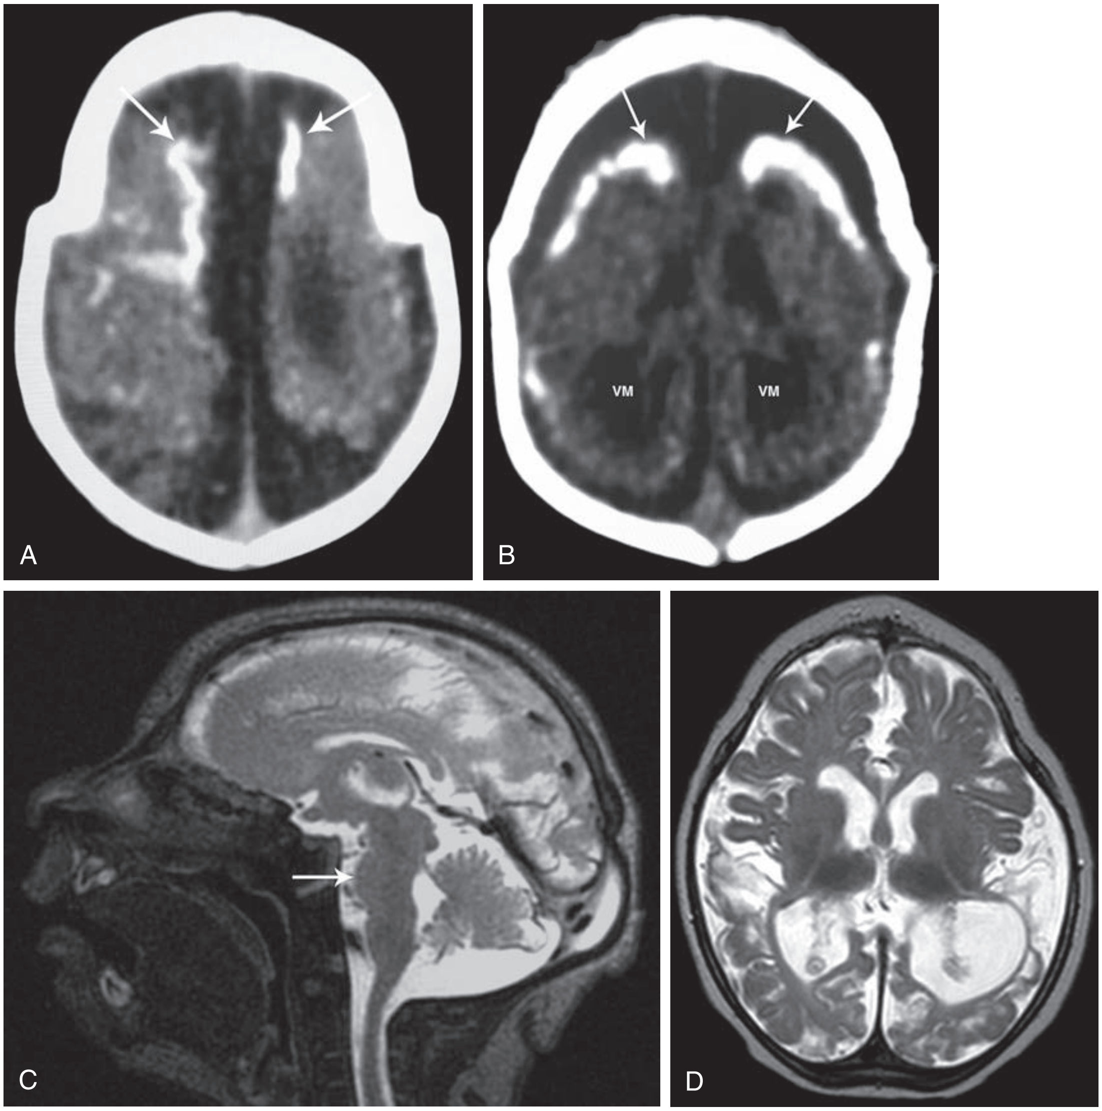

**Figure 34.35. Zika virus.** Neonate with known Zika virus exposure in utero. (A and B) Axial noncontrast CT, (C) sagittal T2-weighted, and (D) axial T2-weighted MR images show predominantly cortical-based calcifications (*arrows* in A and B). There is marked microcephaly and mild brainstem hypoplasia particularly at the level of the pons (*arrow* in C). There is bilateral ventriculomegaly *(VM)* and mild simplification of gyral pattern. *(Images provided by Henrique M. Lederman, MD, PhD, and Sergio Cavalheiro, MD, PhD, Sao Paulo, Brazil.)*

# Pediatric Brain Neoplasms

Sanjay P. Prabhu and Tina Young Poussaint

## OVERVIEW

Brain tumors are the most common solid pediatric tumors and are the leading cause of death in children from solid tumors.[1] The incidence rate of all childhood primary brain and central nervous system (CNS) tumors is estimated to be 5.47 cases per 100,000 person-years.[2] An estimated 4830 new cases of childhood primary malignant and nonmalignant brain and other CNS tumors are expected to be diagnosed in the United States in 2017.[2] The incidence of brain tumors is highest in infants (<1 year of age), followed by children ages 1 to 4 years.[3] The most common site of childhood brain tumors is the cerebellum (18.7%), followed by the frontal, temporal, parietal, and occipital lobes (15.7%).[3]

The most recent World Health Organization (WHO) classification of central nervous system tumors represents a major restructuring of the diffuse gliomas, medulloblastomas, and other embryonal tumors, and incorporates new entities defined by both histology and molecular features.[4] Of particular note, the embryonal tumors have also undergone substantial changes in their classification, most notably with removal of the term *primitive neuroectodermal tumor (PNET)* from the diagnostic lexicon. The following description tries to incorporate some of these more recent changes while acknowledging the previously accepted terminology that is still currently used in clinical discussions.

## ETIOLOGY

The etiology of pediatric brain tumors is an area of continuing research beyond the scope of this chapter, requiring understanding of genetic alterations, signaling systems, and molecular genetics and pathways. No specific risk factor explains more than a small proportion of childhood brain tumors. Known risk factors for childhood brain tumors include therapeutic doses of ionizing radiation to the head for brain tumors and radiation for leukemia,[5,6] and certain genetic syndromes. Some genetic inherited syndromes have an association with brain tumors including neurofibromatosis types 1 and 2, Gorlin syndrome (basal cell nevus syndrome), tuberous sclerosis, Turcot syndrome, von Hippel–Lindau syndrome, and Li–Fraumeni syndrome.[7]

## IMAGING

Wide availability of computed tomography (CT) has resulted in its use for diagnosis for patients with brain tumors presenting acutely. Its advantages include the ability to detect a mass, to identify lesion mass effect, to check for ventricular effacement and/or enlargement, lesional hemorrhage, calcification, and osseous involvement.

Magnetic resonance imaging (MRI) with contrast is the modality of choice at diagnosis to determine lesion size, location, and characterization due to its superior soft tissue resolution, multiplanar capability, and lack of ionizing radiation. Presence of contrast enhancement reflects disruption of the blood-brain barrier. The degree of contrast enhancement does not always correlate with tumor grade. For example, benign tumors such as choroid plexus papillomas and pilocytic astrocytomas can enhance avidly, whereas anaplastic astrocytomas may not enhance at all.[8]

The definition of lesion margins and accurate staging of the tumor by confirming the presence or absence of tumor spread through the neural axis are essential for treatment planning. In addition, diffusion tractography and functional MRI can be used to show the relationship of the tumor to eloquent brain and other vital structures to minimize treatment damage to these regions. Intraoperative MRI systems are being increasingly used to guide tumor resection and stereotactic and minimally invasive tumor resection.

MRI can be used to assess tumor response and progression and to monitor treatment effects. After surgical resection, MRI is used to determine the presence of residual tumor, to look for postoperative complications, and for routine follow-up. Advanced techniques (discussed later in this chapter) are used to complement structural imaging and provide insight into tumor physiology.[9]

## ROLE OF ADVANCED IMAGING TECHNIQUES IN IMAGING BRAIN TUMORS

### Diffusion-Weighted Imaging

Contrast on diffusion-weighted imaging (DWI) reflects the mean distance travelled by free water protons in tissue due to Brownian motion.[10,11] Diffusivity of tissues is indicated by the apparent diffusion coefficient (ADC), which is a scalar parameter with units of $mm^2$/sec. Diffusion occurs freely in the direction of tract orientation and is restricted in orthogonal planes.

Diffusion tensor imaging (DTI) is an adaptation of DWI, and is performed by acquiring diffusion data in six or more directions, enabling determination of the direction and magnitude of water diffusion. The degree of anisotropy is expressed by a variety of quantitative measures, the most common of which is fractional anisotropy (FA), which reflects the presence of myelinated white matter tracts and related processes such as axonal transport in tissues. Connecting the directions of diffusion in each voxel to those of neighboring voxels using a variety of mathematical algorithms enables creation of a three-dimensional white matter tract map, termed *tractography*.[12]

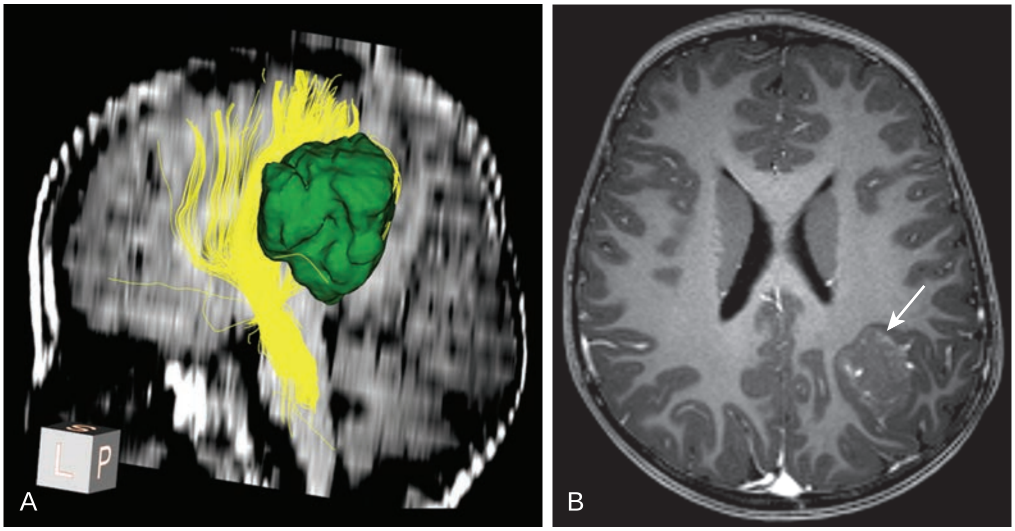
DWI can help assess cellularity of a lesion, as markedly decreased ADC usually correlates well with the histologic measures of tumor cellularity in brain neoplasms. The ADC value depends on the complexity of the cytoarchitecture and the rapid exchange of protons between different compartments. The cytoarchitecture of the tumor can inhibit random Brownian motion and thus causes water diffusion to deviate from strict Gaussian behavior.[9] Generally, highly cellular tumors have reduced diffusivity, whereas vasogenic edema and necrosis show increased diffusion.[8,13,14] However, overlap between tumor grades makes it imperative that the ADC values are interpreted in conjunction with the structural MRI sequences.[8,15]

DWI can be extremely useful in the postoperative period, when low ADC values at the surgical margins or within the resection cavity may be indicative of ischemia, residual cellular tumor, or abscess, and in conjunction with conventional MRI helps exclude artifact from hematoma.[16] ADC values can also be used to assess treatment response, detect tumor recurrence, and may help differentiate tumor recurrence from pseudoprogression.[17]

DTI can help identify the patterns of tumor interaction with white matter fiber tracts: deviation, edema, infiltration, and destruction.[18] DTI in conjunction with volumetric data can guide surgical resection and predict possible postoperative deficits resulting from white matter tract damage (e-Fig. 35.1). Reduction in FA has been

## Abstract:

Brain tumors are the most common solid pediatric tumors and are the leading cause of death in children from solid tumors. Radiologists play a very important role in the diagnosis and management of pediatric patients with brain tumors. The most recent World Health Organization (WHO) classification of central nervous system tumors represents a major restructuring of the diffuse gliomas, medulloblastomas, and other embryonal tumors, and incorporates new entities defined by both histology and molecular features. The following description incorporates some of these more recent changes while acknowledging the previously accepted terminology that is still currently used in clinical discussions. In addition to describing characteristic imaging features of the more commonly encountered pediatric brain tumors in practice, this chapter describes the role of advanced imaging techniques in the management of pediatric patients with brain tumors including functional MRI, MR spectroscopy and perfusion-weighted imaging is also discussed. Special emphasis is placed on some of the genetic alterations in tumors that have an important role in the management of these patients.



**e-Figure 35.1. Presurgical tractography.** (A) Tractography of the portion of the posterior limb of the internal capsule that forms the left corticospinal tract (shown in *yellow*) in a patient with a left parietal lobe tumor (segmented and shown in *green*). The tract is displaced medially by the solid tumor in the left parietal lobe, but still intact. (B) Axial postcontrast MPRAGE MRI shows the cortical-based enhancing tumor *(arrow).*

found in the white matter of medulloblastoma patients, even in the absence of abnormalities on structural sequences.[19] Deceased FA values correlate with the age at which radiation was administered and with worse school performance, and may be a biomarker of the effects of radiotherapy.[20]

Other applications include ADC histogram technique in diffuse midline tumors of the pons, which has demonstrated significant correlation between diffusion metrics and survival, with lower diffusion values (increased cellularity), and increased enhancement associated with shorter survival.[21] Functional diffusion mapping (fDM) has been suggested as a tool for early detection of tumor treatment efficacy, although interpretation requires careful correlation with structural sequences and the underlying biology of both tumor and healthy tissue.[22] Serial parametric response mapping of ADC, performed at multiple time points of therapy, has the potential to distinguish pseudoprogression from true progression of tumors.[23]

## Magnetic Resonance Spectroscopy

Magnetic resonance spectroscopy (MRS) enables detection and quantification of normal and abnormal metabolites in the brain. MRS can help identify tumor tissue, differentiate tumor types, and separate active tumor from radiation necrosis or scar formation. MRS can be performed on most standard MRI scanners, typically incorporating either the point resolved spin echo (PRESS) or stimulated echo acquisition mode (STEAM) techniques. Simultaneous acquisition of MRS from multiple voxels increases spatial resolution and is called chemical shift imaging (CSI) or magnetic resonance spectroscopic imaging (MRSI).[24]

Normal metabolites detected in the brain include N-acetylaspartate (NAA), a neuronal marker; choline (Cho), a membrane marker; and creatine (Cr), a marker of energy metabolism. Myoinositol (mI), a glial marker, can be better resolved with short echo-time MRS techniques. Concentrations of metabolites are usually expressed in the form of metabolite ratios.

Most brain tumors are characterized by the presence of increased Cho/Cr and decreased NAA/Cr ratios, indicating loss of neuroaxonal integrity and increased cell membrane turnover. Presence of lactate, an indicator of anaerobic metabolism, indicates impaired energy metabolism.[25]

Tumor characterization has been attempted using MRS. In general, high-grade tumors have higher Cho/Cr and lower NAA/Cr ratios than low-grade ones. One exception is juvenile pilocytic astrocytoma, in which the choline peak can be markedly elevated. Necrotic areas in rapidly growing malignant tumors such as medulloblastomas and atypical teratoid rhabdoid tumors may contain lipid resonances.[26] In adults, lactate is typically associated with high-grade gliomas. In children, lactate is frequently paradoxically elevated in pilocytic astrocytomas, a low-grade tumor.[23] The presence of specific metabolites such as alanine in meningiomas (an inverted doublet at 1.44 parts per million [ppm]), and taurine (peak at 3.3–3.4 ppm) in medulloblastoma may help in narrowing the differential diagnosis[27,28] (e-Fig. 35.2). Citrate has been described in pediatric brain tumors and can be particularly high in pontine gliomas[29] and in Grade 2 astrocytomas that have progressed.[30]

## Perfusion-Weighted Imaging

Perfusion-weighted imaging (PWI) measures cerebral hemodynamics at the microcirculation level (e-Fig. 35.3). Measured parameters include cerebral blood volume (CBV), cerebral blood flow (CBF), and mean transit time (MTT). CBV is defined as the volume of blood in an area of brain tissue expressed in mL/100 g, and is the most commonly used parameter in brain tumor evaluation.[31]

Three main techniques are available to measure perfusion within the brain: T2*-weighted dynamic susceptibility contrast (DSC) imaging, T1-weighted dynamic contrast-enhanced (DCE) perfusion, and arterial spin labeling (ASL).

DSC is the most widely available technique, and, consists of a rapid bolus of intravenous paramagnetic contrast agent administration, followed by a rapid acquisition of a series of echo-planar images during the first pass of contrast material through the capillary bed. The contrast medium in the blood passes through the tissues and results in a signal drop proportional to the blood volume.[32] Challenges to routine use in children include the need to use power injectors and large-bore intravenous catheter placement.[33]

DCE T1-weighted permeability perfusion pharmacokinetic parameters have been useful for discriminating low-grade and high-grade pediatric tumors.[34] In one study, the rate constant from the blood plasma into the extracellular extravascular space ($K^{trans}$), rate constant from extracellular extravascular space back into blood plasma ($K_{ep}$), and extracellular extravascular volume fraction ($V_e$) were all significantly correlated with tumor grade; high-grade tumors showed higher $K^{trans}$, higher $K_{ep}$, and lower $V_e$.

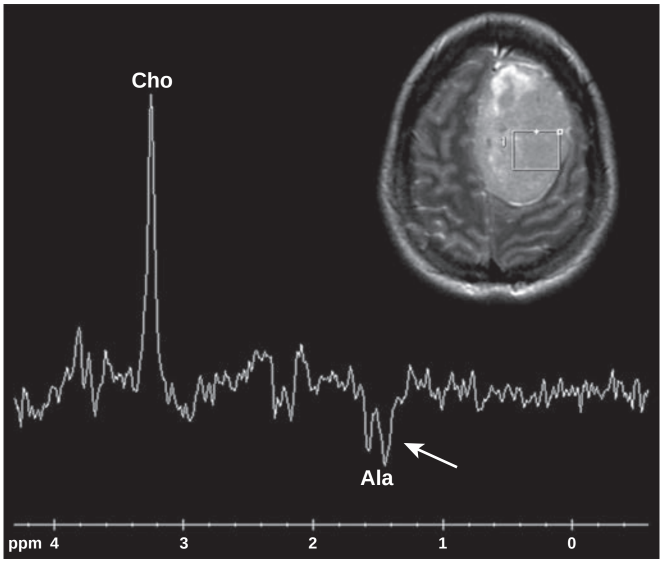
ASL uses endogenous blood as a tracer agent. Differences in signal intensity changes on ASL are smaller when compared with contrast-enhanced perfusion techniques and depend on other parameters such as the T1 relaxation time of blood and time delay between the tagging pulses and the readout time of the images.[33] ASL has shown promise for hemodynamic evaluation of brain tumors.[35-37] High-grade pediatric brain tumors display higher CBF compared with low-grade tumors, and CBF is correlated with tumor microvascular density.[38] Lower-grade astrocytomas have relatively lower regional blood volume (rCBV) than higher-grade tumors such as anaplastic astrocytomas and glioblastomas.[39] However, in pediatric patients, low-grade pilocytic astrocytomas can have a high relative blood volume.[32]

## Functional Magnetic Resonance Imaging

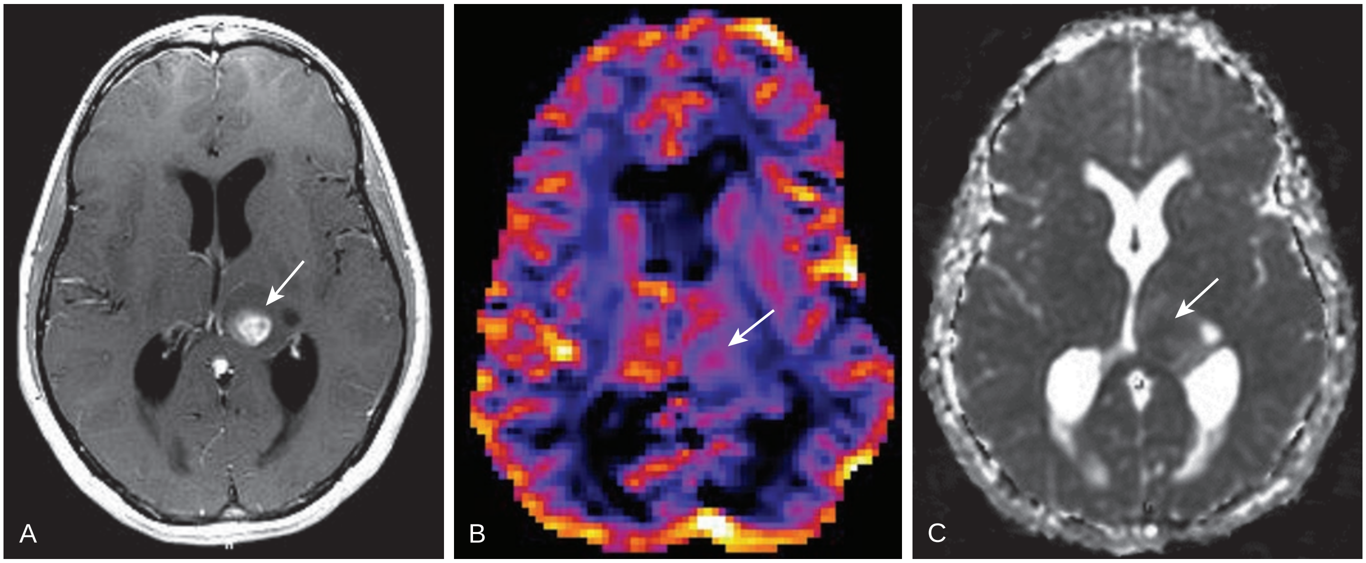
Functional MRI (fMRI) is a technique that relies on the fact that oxyhemoglobin is diamagnetic and deoxyhemoglobin is paramagnetic. Due to the relative increased blood flow and consequent increased utilization of oxygen within the activated portions of the brain, the magnetic resonance signal (called the blood oxygen level–dependent [BOLD] signal) is measurably different compared with other parts of the brain. Event-related paradigms (short bursts of stimuli followed by rest) or block design paradigms (alternating blocks of same type of stimuli) are described for use in presurgical planning.[40] fMRI has been successfully used in sedated younger pediatric patients.[41-43] The primary value of fMRI is in localizing eloquent areas in the brain controlling language, motor functions, and memory. This information helps guide therapeutic approaches to minimize damage to eloquent cortex.[44] The acceptance of fMRI and its capabilities has largely replaced the invasive Wada test in determining hemispheric dominance of memory and language functions.[45] It is important to note that changes in blood flow in and around hypervascular tumors can affect the regional reliability and accuracy of fMRI.[46]

## Single Positron Emission Computed Tomography and Positron Emission Tomography

Assessment of regional cerebral blood flow by single positron emission computed tomography (SPECT) has been largely replaced by magnetic resonance perfusion and functional MRI techniques. Positron emission tomography (PET) is an adjunct to MRI and CT brain tumor evaluation, used to determine metabolic activity at diagnosis, to determine response to therapy, and to distinguish between treatment effect and tumor recurrence. Fluorodeoxyglucose ($[^{18}F]$ FDG) is the most commonly used isotope for PET studies in children. Other labeled agents such as amino acid analogues, $[^{11}C]$ methionine and $[^{11}C]$ tyrosine, have shown promise in detecting low-grade tumors in adults, but their role in children is yet to be established.[47] These amino acid analogues are incorporated into tumor proteins, and degree of uptake reflects tumor



**e-Figure 35.2. Magnetic resonance spectroscopy.** Single-voxel MRS (TE 144 msec) over the extraaxial dural-based lesion in the left frontal lobe (see *inset* T2-weighted image) shows a prominent choline peak (Cho) and reduced creatine and NAA peaks. The inverted doublet centered at approximately 1.55 to 1.6 ppm is consistent with an alanine peak, reported in meningioma. Note the small inverted doublet peak centered at 2.3 ppm, which is of uncertain etiology.



**e-Figure 35.3. Perfusion-weighted imaging.** (A) Axial T1-weighted MRI shows a rounded central enhancing mass lesion in the left thalamus *(arrow).* (B) Axial perfusion image shows a focal area of increased perfusion corresponding to the enhancing solid portion of the tumor in the left thalamus *(arrow)* suggesting high-grade lesion and pathology was glioblastoma multiforme. (C) ADC map shows areas of decreased diffusion corresponding to the solid component of the left thalamic tumor *(arrow).*

protein synthesis.[48,49] Other agents being investigated include cell proliferation agents such as [$^{11}$C]-labeled fluorothymidine and cell hypoxia imaging agents such as fluoromisonidazole ([$^{18}$F] MISO) and Cu-diacetyl-bis (N4-methylthiosemicarbazone (Cu-ATSM).

## WORLD HEALTH ORGANIZATION CLASSIFICATION OF TUMORS

The new 2016 WHO Classification of Tumors of the Central Nervous System uses molecular parameters in addition to histology to define many tumor entities, formulating how CNS tumor diagnoses should be structured in the molecular era.[4] This classification presents major restructuring of the diffuse gliomas, medulloblastomas, and other embryonal tumors, and incorporates new entities that are defined by both histology and molecular features. Some of these tumors are relevant to pediatric practice and will be addressed below. It is hoped that this classification of tumors will further evolve and facilitate epidemiologic studies and improved treatments.

## CLASSIFICATION OF PEDIATRIC BRAIN TUMORS BY LOCATION

Classification of tumors by location helps limit the differential diagnosis in conjunction with the appearance of the lesion on conventional MRI and advanced imaging techniques (Box 35.1).

## TUMORS OF THE CEREBRAL HEMISPHERES

### Astrocytomas

The most recent WHO classification of brain tumors divides astrocytomas into two broad groups. The first group consists of diffuse astrocytic and oligodendroglial tumors, which includes diffuse and anaplastic astrocytoma and glioblastoma. Each of these types is further subdivided into three subtypes based on the presence or absence of isocitrate dehydrogenase (IDH) mutations.[4] For both grade II and III tumors, the great majority falls into the IDH-mutant category. The second group consists of other astrocytic tumors, which includes pilocytic astrocytomas (with pilomyxoid astrocytomas as subtype), subependymal giant cell astrocytomas, and pleomorphic xanthoastrocytoma (with and without anaplastic features).

### Pilocytic and Pilomyxoid Astrocytomas

Pilocytic astrocytomas (PA) are grade I WHO tumors that account for 20% to 30% of all childhood brain tumors.[50] They arise typically in the first two decades of life and there is no definite gender predominance. The most common locations are in the optic pathways, hypothalamus, thalamus, basal ganglia, cerebral hemispheres, cerebellum, and brainstem. Patients with neurofibromatosis type 1 (NF1) have an increased risk of developing pilocytic astrocytomas, including optic pathway tumors, which tend to have a better long-term prognosis than in patients without NF1.[51]

On CT and MRI, a pilocytic astrocytoma is usually a well-defined lesion that demonstrates contrast enhancement of its solid component (Fig. 35.4). Tumoral “cystic” components containing proteinaceous fluid are seen more often in cerebellar lesions. They often contain a contrast-enhancing mural nodule. Increased ADC values due to their low cellularity help to distinguish them from higher-grade astrocytomas. The enhancing components of pilocytic astrocytomas tend to have low perfusion with decreased rCBV, although nodules with increased perfusion may be seen.[52]

Rarely, pilocytic astrocytomas can present with diffuse leptomeningeal spread, most often seen in association with the diencephalic syndrome (discussed later) or with the pilomyxoid variant. These tumors have an indolent course, but their propensity for slow-growing persistent recurrences makes them difficult to treat.[53] Pilomyxoid astrocytoma (PMA) represents a variant of classical PA with more invasive growth and increased risk of recurrences and dissemination.

**BOX 35.1** Classification of Pediatric Brain Tumors Based on the Location of the Tumors

1) **TUMORS OF THE CEREBRAL HEMISPHERES**
    a) Astrocytomas (WHO grades I-IV)
    b) Supratentorial embryonal tumors
    c) Atypical teratoid rhabdoid tumor
    d) Supratentorial ependymoma
    e) Thalamic astrocytoma
    f) Dysembryoplastic neuroepithelial tumor (DNET)
    g) Meningioangiomatosis
    h) Germinoma
    i) Choroid plexus tumors—papilloma and carcinoma
    j) Neuronal and mixed neuronal-glial tumors (including desmoplastic infantile ganglioglioma [DIG])
2) **SELLAR AND SUPRASELLAR TUMORS**
    a) Craniopharyngioma
    b) Chiasmatic/hypothalamic glioma
    c) Hypothalamic hamartomas
    d) Pituitary adenoma
    e) Germ cell tumors
    f) LCH
    g) Rathke cleft cyst
    h) Arachnoid cysts
    i) Dermoid/epidermoid cysts
3) **POSTERIOR FOSSA TUMORS**
    **Intraaxial**
        a) Medulloblastoma
        b) Cerebellar astrocytoma
        c) Tectal glioma
        d) Brainstem neoplasms including diffuse midline gliomas
        e) Atypical teratoid rhabdoid tumors (ATRT)
        f) Ependymomas
        g) Teratoma
        h) Hemangioblastoma
    **Extraaxial**
        a) Dermoid
        b) Epidermoid
        c) Teratoma
        d) Schwannoma
        e) Meningioma
        f) Skull base neoplasms
4) **PARAMENINGEAL TUMORS**
    a) Osseous, chondroid, or myeloid origin
    b) Other mesenchymal origin tumors
    c) Tumors from notochordal elements
    d) Metastatic disease including leptomeningeal disease from dissemination of primary brain tumors
5) **PINEAL REGION TUMORS**
    a) Germ cell tumors
    b) Pineal parenchymal tumors
    c) Tumors of supporting tissues of the pineal gland or adjacent structures

Typically, pilocytic astrocytomas exhibit distinct histology with biphasic architecture of loose, microcystic and compact, fibrillary areas. However, some tumors display a heterogeneous histopathologic appearance that can mimic other glial neoplasms. Not infrequently, pilocytic astrocytomas exhibit atypical histologic features suggestive of anaplasia that can suggest a diffuse high-grade glioma. Genetic alterations resulting in aberrant signaling of the mitogen-activated protein kinase (MAPK) pathway have been implicated in the development of pilocytic astrocytomas. The presence of the most commonly identified BRAF-KIAA1549 fusion gene mutation may be associated with improved clinical outcomes.[54,55]

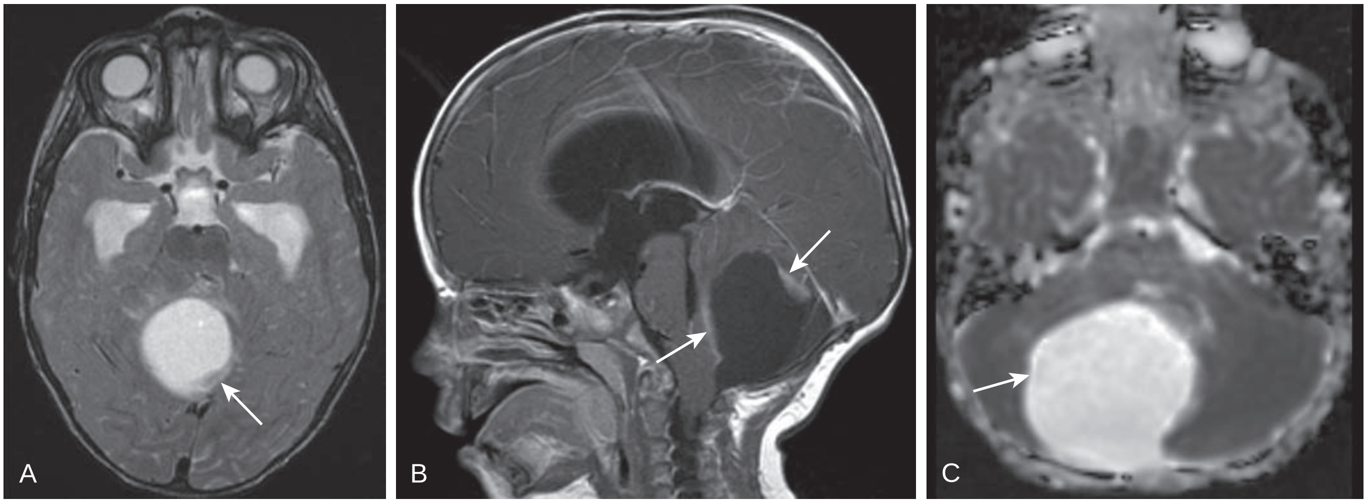


**Figure 35.4. Cerebellar astrocytoma.** (A) Axial T2-weighted MRI shows a large cystic mass centered in the right cerebellar hemisphere with small solid components along the posterior and anterior aspects *(arrow).* (B) Postcontrast sagittal MPRAGE MRI shows the solid components *(arrows)* along the anterior and posterior margins enhance after paramagnetic contrast administration. (C) ADC map shows increased diffusion within the lesion *(arrow)* consistent with the relatively low cellularity within the lesion.

Gross total resection is often curative, but micrometastases may occur. Recent treatment trials for unresectable recurrent disease have incorporated molecular *BRAF* status in low-grade glioma treatment with MEK inhibitor drugs. The role of Ras/MAPK alterations seems to be dominant in all pediatric low grade gliomas, but specifically in hemispheric tumors.[56]

## Diffuse Astrocytomas

Diffuse astrocytomas are low-grade tumors (WHO grade II) that are rare compared with pilocytic astrocytomas.[57] Around one-third arise in the frontal or parietal lobes, which represents the most common location.[57] On MRI, they have relatively ill-defined margins but they are uniformly hypointense on T1- and hyperintense on T2-weighted sequences. They do not enhance on postcontrast images and they do not show restricted diffusion.[58] Anaplastic transformation to a higher-grade tumor occurs in only about 10% of pediatric cases.[59] Diffuse astrocytomas do not show significantly increased rCBV and may show elevated myoinositol on MRS.[60,61]

## Anaplastic Astrocytoma

Anaplastic astrocytomas represent close to 2% of all CNS tumors in children.[62] They are poorly circumscribed infiltrative lesions with rapid growth rates.[58] They most commonly occur in the cerebral hemispheres, particularly the frontal and temporal lobes. They typically do not enhance on postcontrast images, and do not show evidence of hemorrhage or necrosis, which differentiate them from glioblastomas.[58,63] Anaplastic astrocytomas have lower ADC values and increased rCBV compared with lower-grade tumors.[61] On MRS, anaplastic astrocytomas show increased choline and decreased N-acetylaspartate, with decreased myoinositol compared with the spectra of lower-grade tumors.[60]

## Glioblastomas

Glioblastomas are rare in children, accounting for about 3% of primary brain tumors.[64] These tumors occur most commonly in the frontotemporal region but can affect other lobes or deep gray structures. They present typically as heterogeneously enhancing tumors with areas of necrosis with marked surrounding edema. The solid components show restricted diffusion, and increased perfusion and permeability parameters. These features may help differentiate them from lower-grade tumors and can help differentiate between tumor recurrence and treatment response. On MRS, in addition to elevated choline, reduced NAA, and reduced myoinositol, glioblastomas typically have elevated lactate due to anaerobic metabolism and elevated lipids resulting from tumor necrosis.[61] Prognosis is poor, but survival rates are better compared with adult glioblastomas.[65]

## Diffuse Gliomas

Under the new WHO classification, diffuse gliomas include the WHO grade II and grade III astrocytic tumors, the grade II and III oligodendrogliomas, the grade IV glioblastomas, and the related diffuse gliomas of childhood.[4] Astrocytomas that have a more circumscribed growth pattern, lack IDH gene alterations, and frequently have *BRAF* alterations (pilocytic astrocytoma, pleomorphic xanthoastrocytoma) or *TSC1/TSC2* mutations (subependymal giant cell astrocytoma) are considered distinct from the diffuse gliomas. The WHO grade II diffuse astrocytomas and WHO grade III anaplastic astrocytomas are now each divided into IDH-mutant, IDH-wildtype, and not otherwise specified (NOS) categories. Although prognostic differences between grade II diffuse astrocytomas and IDH-mutant WHO grade III anaplastic astrocytomas are not as marked, this has not been noted in all studies.[66,67] The current recommendation is that WHO grading is retained for both IDH-mutant and IDH-wildtype astrocytomas, although the prognosis of the IDH-mutant cases appears more favorable in both grades.

## High-Grade Gliomas

High-grade gliomas are relatively rare in children compared with adults. Supratentorial high-grade gliomas comprise a third of pediatric high-grade gliomas and occur most commonly in adolescents (Fig. 35.5). Most high-grade gliomas in children are purely astrocytic and classified as either anaplastic astrocytomas (WHO grade III) or glioblastomas (WHO grade IV); other mixed or non–astrocytic types are rare.[63]

# Supratentorial Embryonal Tumors

The term *primitive neuroectodermal tumor (PNET)* has been removed from the diagnostic lexicon in the most recent WHO classification.

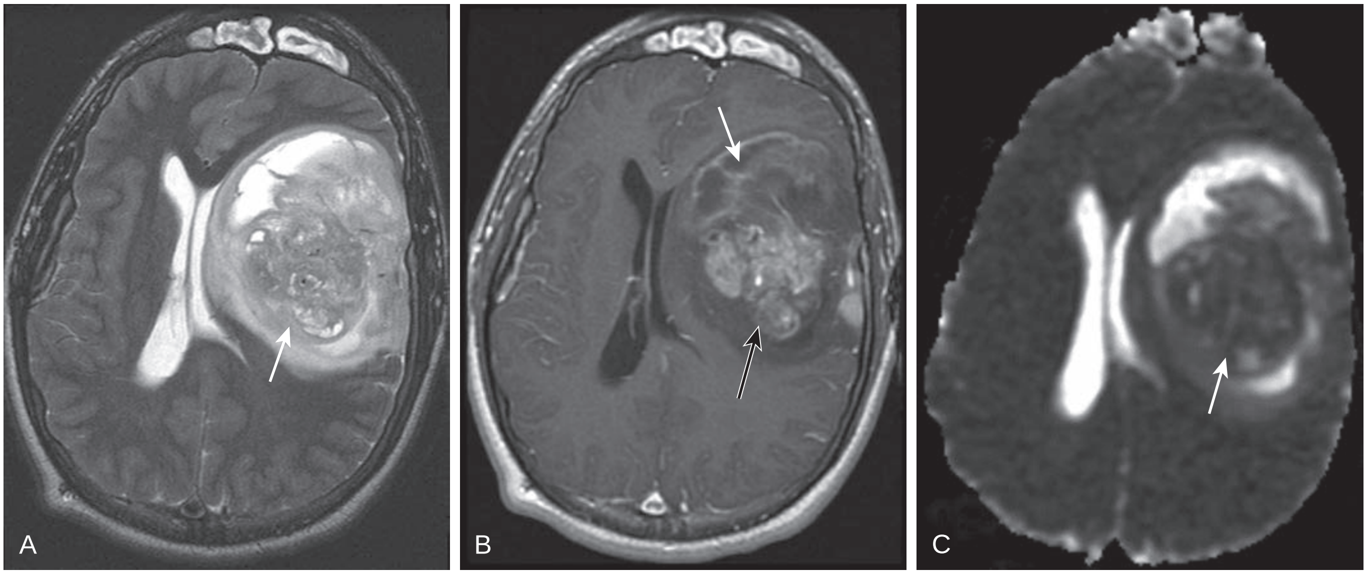

**Figure 35.5. Supratentorial high-grade glioma.** (A) Axial T2-weighted MRI shows a large heterogeneous mass *(arrow)* in the left frontal, temporal, and parietal lobes with marked mass effect, subfalcine herniation, surrounding edema, and rightward midline shift. (B) Postcontrast T1-weighted MRI shows heterogeneous enhancement of the solid components of the tumor *(black arrow)* and nonenhancing components anteriorly *(white arrow)* suggestive of necrosis. (C) ADC map reveals decreased diffusion within the solid component *(arrow)* indicating high cellularity.

This reclassification was driven by the recognition that many of these rare tumors display amplification of the C19MC region on chromosome 19 (19q13.42). C19MC-amplified tumors include the lesions previously known as ETANTR (embryonal tumors with abundant neuropil and true rosettes, but also referred to as embryonal tumors with multilayered rosettes), ependymoblastoma, and, in some cases, medulloepithelioma.[53] In the 2016 CNS WHO classification, the presence of C19MC amplification results in a diagnosis of embryonal tumor with multilayered rosettes (ETMR), C19MC-altered. In the absence of C19MC amplification, a tumor with histologic features conforming to ETANTR/ETMR should be diagnosed as embryonal tumor with multilayered rosettes, NOS, and a tumor with histologic features of medulloepithelioma should be diagnosed as medulloepithelioma (recognizing that some medulloepitheliomas do not have C19MC amplification). 2016 CNS WHO classification has created a probable additional category of CNS embryonal tumor, NOS that includes tumors previously designated as CNS PNET.

Although supratentorial embryonal tumors are relatively rare, they are more common in the first decade, with peak incidence from birth to 5 years of age.[68] They account for 5% of all supratentorial tumors in childhood. They are often large at presentation and are well-defined lesions, occurring either in the cerebral hemispheres or lateral ventricles. They may be solid and homogenous, or can be heterogeneous with cyst formation.[69] Calcification is often seen on CT. On MRI, solid areas have restricted diffusion and T2-hypointense areas, reflecting the high nuclear-to-cytoplasm ratio and increased cellularity, as well as increased CBV on perfusion imaging. Necrosis and hemorrhage can also occur. Heterogeneous enhancement is seen after contrast administration interspersed with variable hypodense foci of necrosis (Fig. 35.6). Leptomeningeal dissemination and drop metastases occur frequently, necessitating imaging of the entire neuraxis at presentation and on follow-up.

## Supratentorial Ependymoma

Ependymomas constitute approximately 10% of all intracranial tumors in children; 90% of ependymomas occur intracranially, with two-thirds located in the posterior fossa and one-third within the supratentorial compartment.[70,71] These tumors are thought to arise from embryonic rests of ependymal tissue trapped in the developing cerebral hemispheres.[72] They are isointense to hyperintense to gray matter on T2-weighted MRIs.[73] On MRI, there is usually avid enhancement of the soft tissue components of the tumor, intermixed with poorly enhancing or nonenhancing areas.[73] Calcification, necrosis, and hemorrhage may be seen within these lesions, accounting for their heterogeneous appearance.

A recent study defined nine molecular subgroups, three in each anatomic compartment of the CNS: the spine, posterior fossa, and supratentorial compartment.[74,75] Two supratentorial subgroups are characterized by prototypic fusion genes involving *RELA* and *YAP1*, respectively. Patients with supratentorial *RELA*-positive ependymoma have a dismal prognosis. Risk stratification by molecular subgrouping is superior to histologic grading and the classification proposed was suggested as a basis for the new WHO classification.

## Thalamic Astrocytomas

Thalamic tumors account for less than 5% of pediatric intracranial tumors.[76] Most thalamic tumors are unilateral and around half are low-grade astrocytomas. They can be either well-circumscribed pilocytic astrocytomas or infiltrating diffuse gliomas. Imaging characteristics of lower-grade tumors are similar to pilocytic astrocytomas elsewhere.

Diffuse infiltrating thalamic tumors are less common in children. They are classified as low-grade diffuse astrocytomas, anaplastic astrocytomas, and glioblastoma multiforme. The low-grade diffuse astrocytomas are T1-hypointense and of intermediate or high signal intensity on T2-weighted images, and demonstrate no or variable enhancement.

A specific type of thalamic tumor called bithalamic glioma has also been recognized. This is a large symmetric lesion in both thalami that may extend to the basal ganglia and midbrain. Their deep location makes them difficult to access for surgical resection, and radiation with or without chemotherapy is still the treatment of choice. Somatic mutations of genes encoding for histone H3

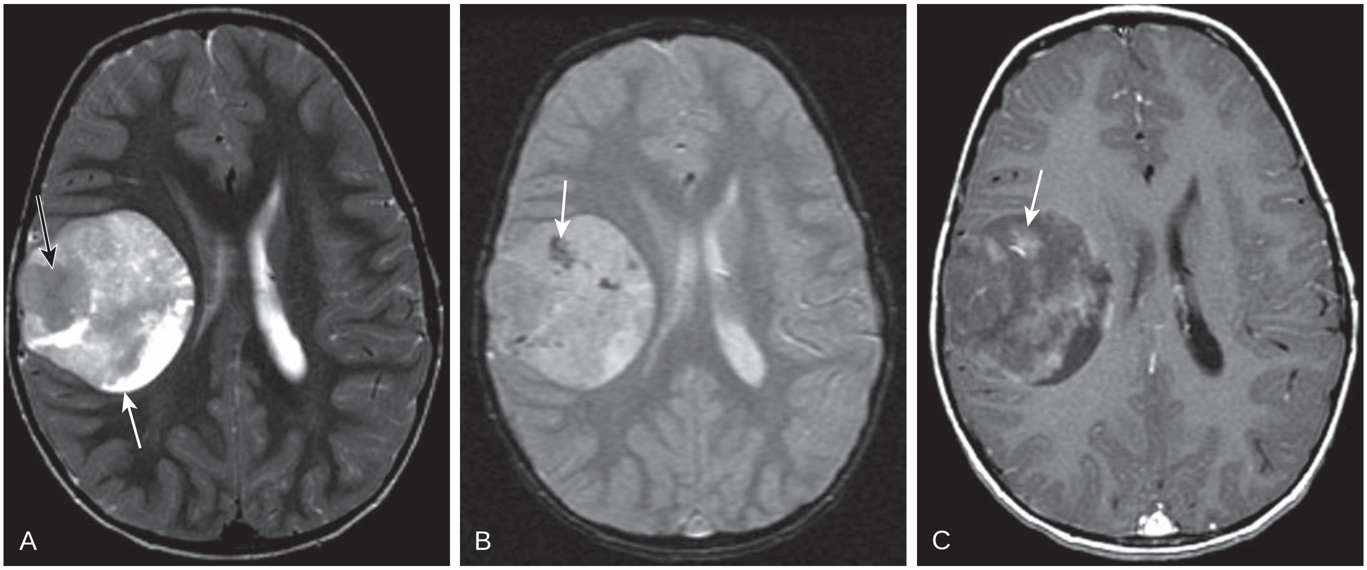

**Figure 35.6. Supratentorial CNS embryonal tumor (previously designated as primitive neuroectodermal tumor).** (A) Axial T2-weighted MRI shows a large well-defined heterogeneous mass lesion in the right cerebral hemisphere with a predominant solid T2-hypointense component *(black arrow)* and smaller areas of T2 prolongation *(white arrow).* (B) Axial gradient-recall echo MRI shows scattered foci of susceptibility *(arrow)* suggestive of calcification or blood products within the lesion. (C) Axial postcontrast T1-weighted MRI shows patchy heterogeneous enhancement within the lesion *(arrow).*

variants have been identified in a subgroup of high-grade gliomas arising in the thalamus, leading to inclusion of this subgroup into the group of tumors called diffuse midline gliomas.[77] However, the presence of the specific H3.3 K27M mutation results in poorer prognosis in brainstem gliomas compared with thalamic gliomas, although data currently exist only for adults.[78,79]

## Choroid Plexus Tumors

Choroid plexus tumors account for approximately 3% of pediatric brain tumors.[80] Of these, 10% to 20% arise in the first decade of life and 80% occur in the first 2 years of life, including a considerable number of tumors diagnosed in utero.[81] Choroid plexus papillomas account for most choroid plexus tumors (up to 85%) with the remainder being choroid plexus carcinomas.

These tumors typically occur in the trigone of the lateral ventricles in children, compared with adults where they occur in the fourth ventricle. On CT, they present typically as isodense to hypodense lobulated masses that enhance avidly and homogenously. They may contain punctate calcifications. On MRI, they present as homogenous intraventricular masses that are hypointense on T1-weighted images and predominantly hyperintense on T2-weighted images, with focal hypointense foci (Fig. 35.7).

Choroid plexus carcinomas may be hyperdense on CT reflecting increased cellularity. Carcinomas almost always invade the adjacent brain through the ventricular wall and cause vasogenic edema.[82] They are characterized by areas of heterogeneous signal intensity on both T1- and T2-weighted images because of hemorrhage and necrosis. Imaging differentiation between papillomas and carcinomas may be difficult. Extensive parenchymal invasion and peritumoral vasogenic edema are suggestive of malignancy.[82] MRS will demonstrate significantly higher mI levels in choroid plexus papillomas. Choroid plexus carcinomas, on the other hand, have significantly elevated levels of choline compared with choroid plexus papillomas.[83]

Spinal drop metastases can occur with both choroid plexus papilloma and carcinoma, although this is more frequent with carcinoma. Screening of the spine for possible metastasis should be part of the routine preoperative protocol.

## Neuronal and Neuronal-Glial Tumors

### Neurocytomas

Neurocytomas are rare tumors, accounting for less than 0.5% of all brain tumors.[84] They usually occur in adolescents and young adults. They arise in the lateral ventricles, close to the foramen of Monro and the third ventricle, and are called central neurocytomas. Extraventricular neurocytomas also occur, and are confined to the brain parenchyma.

On MRI, these tumors present as well-circumscribed lobulated masses in the anterior aspect of the lateral ventricles. They are isointense to slightly hypointense to gray matter on T1-weighted images and hyperintense on T2-weighted images, and may enhance after contrast administration. In a small subset of patients, MRS has demonstrated a glycine peak at 3.55 ppm in addition to a high choline peak and decreased NAA peak.[85]

### Desmoplastic Infantile Ganglioglioma/Astrocytoma

Desmoplastic infantile ganglioglioma/astrocytomas are rare supratentorial tumors that occur in young children less than 18 months of age with an incidence of around 1.25%. These tumors typically involve the cerebral surface and overlying dura.[86,87] They are often large at presentation and are predominantly cystic with a solid peripheral component, and most commonly occur in the frontal and parietal lobes. On CT, the cystic component is similar to cerebrospinal fluid, and the superficial solid component is isodense or slightly hyperdense and enhances postcontrast.[86] On MRI, T1-weighted images characteristically show a hypointense cystic mass with a peripheral solid component that enhances intensely after gadolinium administration.[86,88] Extension of the enhancement to the leptomeninges is characteristic and correlates with the dural attachment of the solid component. The solid portion is heterogeneous on T2-weighted images. Meningeal thickening and enhancement adjacent to the solid tumor component, calcifications, and osseous thinning are common associated features. The prognosis is often good if surgical resection can be carried out without damage to adjacent structures.

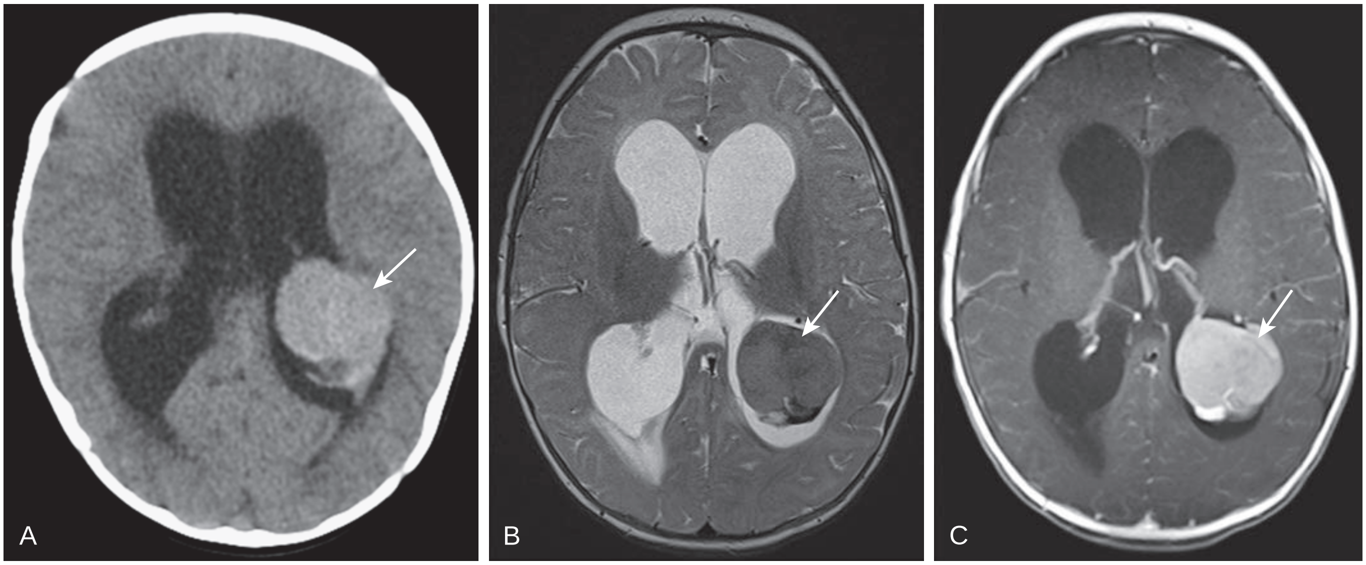

**Figure 35.7. Choroid plexus papilloma.** (A) Axial noncontrast CT shows a lobulated hyperdense mass in the left lateral ventricle *(arrow)*. (B) Axial T2-weighted MRI shows the mass in the left lateral ventricle is hypointense compared with the brain parenchyma *(arrow)*. (C) Axial postcontrast T1-weighted MRI shows homogenous enhancement of the lesion *(arrow)* after contrast administration.

## SELLAR AND PARASELLAR TUMORS

### Craniopharyngiomas

Craniopharyngiomas are slow-growing, benign, nonglial tumors arising in the sellar and parasellar region that comprise between 3% and 10% of all pediatric brain tumors.[70] They are classified as WHO grade I tumors and arise from ectodermal remnants of the Rathke's pouch. They have a bimodal incidence with peak incidence in the first and fifth decades. The adamantinous variant occurs more often in children, whereas the squamous-papillary variant tends to occur in adults.[70] Although histologically benign, they can invade surrounding structures eliciting a gliotic response making resection challenging.

Imaging reflects the mixed cystic and solid nature of these tumors with 90% having calcification and cyst formation. On MRI, high signal intensity on both T1- and T2-weighted images is seen within areas of the lesions with high protein content or as result of subacute hemorrhage (Fig. 35.8). Hypointensity seen on T1-weighted images reflects presence of keratin in some of the cystic areas. CT can demonstrate calcification, which is important for diagnosis and surgical planning. Calcification, vascular encasement, and tumor recurrence are more common in the adamantinous type. Heterogeneous enhancement is seen in the solid components of the tumor.

Surgical treatment remains the mainstay, with radiotherapy having a role in cases that are not amenable to gross total resection. Recurrence-free 5-year survival is close to 87%, but falls to less than 50% with subtotal resection.[89] Follow-up imaging must be directed toward identifying recurrence, second tumors, and associations with moyamoya syndrome.

### Chiasmatic/Optic Pathway/Hypothalamic Gliomas

Optic pathway gliomas are low-grade pilocytic astrocytomas (WHO grade I), which represent 15% of supratentorial tumors.[90] Although sporadic lesions are not uncommon, there is a strong association of optic nerve gliomas with NF1 and bilateral optic nerve tumors are virtually pathognomonic of this diagnosis.[91] From 20% to 50% of optic gliomas occur in patients with NF1, whereas the prevalence of optic pathway gliomas in the NF1 population is between 1.5% and 19%.[91] The tumors may involve the optic nerves, optic chiasm, optic tract, lateral geniculate bodies, and optic radiations. Tumors in children with NF1 are less aggressive than those in children without NF1.[92]

Optic pathway gliomas are usually isointense to the cortex and hypointense to white matter on T1-weighted images. On T2-weighted images, lesions demonstrate mixed signal intensity, predominantly isointense to hyperintense relative to white matter and the cortex (Fig. 35.9). After contrast administration, intense enhancement is common. Use of coronal and axial fat-suppressed thin-section postcontrast T1-weighted images and inversion recovery or T2-weighted images with fat saturation enables optimal visualization of the optic pathways.[93] T2-hyperintensity extends along the optic radiations, although rarely beyond the lateral geniculate bodies. In these cases, it is difficult to differentiate between nonenhancing tumor and edema.

Diencephalic syndrome may be seen in a proportion of patients with hypothalamic/chiasmatic astrocytomas. These children are severely emaciated, although they have normal linear growth. Tumors associated with this syndrome are often larger, occur at a younger age, and are more aggressive. Further, these tumors may seed throughout the CSF pathways.[94] Chemotherapeutic treatment of optic pathway gliomas is started in younger patients, patients with progressive symptoms, and those with extensive CNS involvement.[92]

## POSTERIOR FOSSA TUMORS

### Medulloblastoma

Medulloblastoma (MB) is the most common posterior fossa tumor in childhood, representing up to 38% of posterior fossa tumors and approximately 15% to 20% of all pediatric brain tumors. It is an embryonal neural tumor, histologically classified in five groups by the WHO in its most recent classification: classic MB, anaplastic MB, large cell MB, desmoplastic-nodular MB, and MB with extensive nodularity. A simpler, more practical classification into three groups is used: classic MB (the most common), desmoplastic-nodular MB, and large cell-anaplastic (LCA) MB, the most malignant. This classification correlates relatively well with structural MRI.

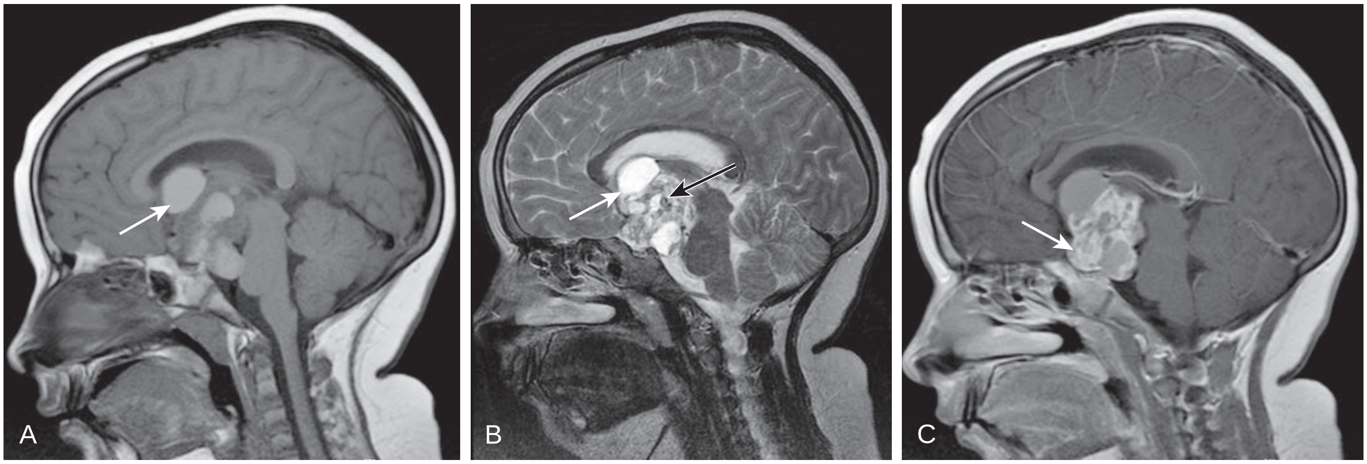

**Figure 35.8. Craniopharyngioma.** (A) Sagittal T1-weighted MRI shows a large suprasellar lesion containing solid and cystic components, with T1-shortening within the cystic components *(arrow)* consistent with proteinaceous content. (B) Sagittal T2-weighted MRI shows T2 hyperintensity within the cystic components *(white arrow)* and scattered hypointensity consistent with foci of calcification *(black arrow).* (C) Sagittal postcontrast T1-weighted MRI shows avid enhancement of the solid component *(arrow).*

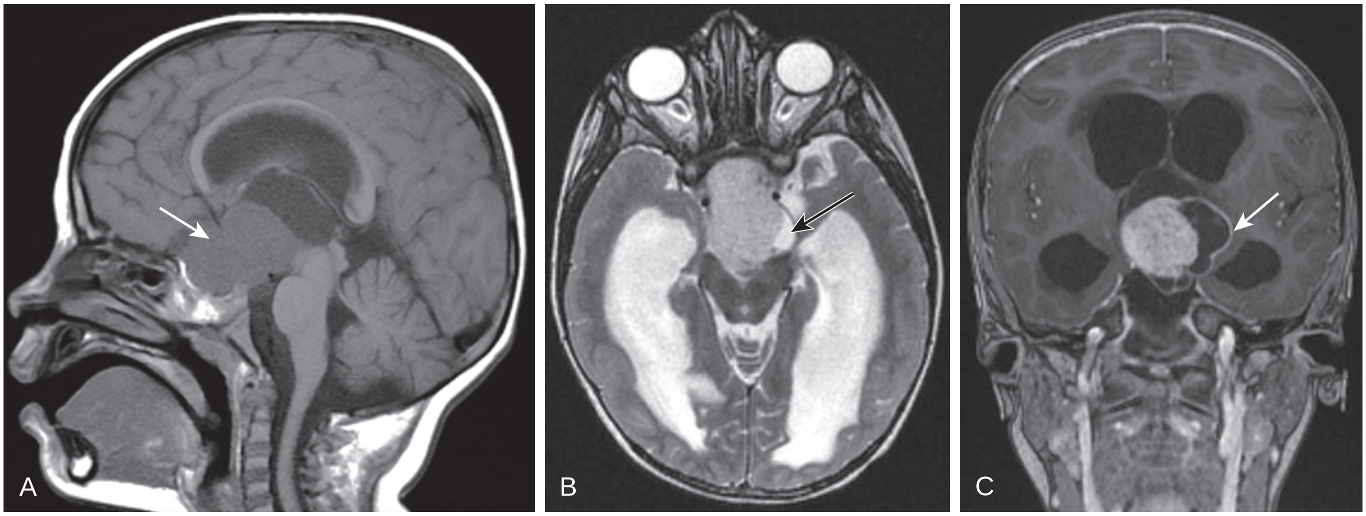

**Figure 35.9. Chiasmatic/hypothalamic glioma.** (A) Sagittal T1-weighted MRI shows a large lobulated suprasellar mass *(arrow)* in the region of the optic chiasm with superior extension into the third ventricle and pontine cistern. (B) Axial T2-weighted MRI shows the lesion is hyperintense compared with brain parenchyma and there is a more hyperintense cystic component along its superior and right aspects *(black arrow).* (C) Coronal T1-postcontrast image shows marked enhancement of the central solid component and peripheral enhancement of the cystic components *(arrow).*

Classic MB presents as a homogenous, compact and well-circumscribed central posterior fossa mass filling the fourth ventricle and causing hydrocephalus. The mass is moderately hypointense on T1, minimally hyperintense to hypointense on T2-weighted images (mildly hyperattenuating on CT), moderately bright on FLAIR, and shows markedly restricted diffusion (Fig. 35.10). This reflects the high cellularity of the tumor and its high nuclear to cytoplasmic ratio. Focal hemorrhage or cystic necrosis may be seen. Enhancement is variable; most tumors enhance in a diffuse, patchy, or ringlike manner, but some do not, although prominent vascular signal voids may be seen within the lesion. Macroscopic intracranial and/or spinal leptomeningeal dissemination may be demonstrated, but not commonly at presentation.

Desmoplastic nodular MB is located within the cerebellar hemispheres away from the midline. They are well circumscribed, compact, somewhat multinodular, and have markedly restricted diffusion. They avidly enhance in a multinodular manner. Large cell anaplastic MB is the most malignant. It has low T1, slightly elevated T2 and FLAIR signal, demonstrates markedly restricted diffusion, and usually enhances diffusely. The most typical (although not most common) presentation is a small tumor in the fourth ventricle, often without hydrocephalus, but already associated with early leptomeningeal dissemination. However, they most often present with a nonspecific pattern on MRI.

As molecular expression may relate to different anatomic origins, anatomically oriented MRI may correlate well with the molecular classification. Currently, four subgroups are identified: WNT subgroup, sonic hedgehog (SHH) subgroup, group 3, and group 4 (these last two subgroups lack specific molecular markers, but the tumors in each group cluster together). WNT MB is characterized by a good long-term prognosis. It presents mostly with the classic histology, affects girls and boys equally, but is uncommon in infants.

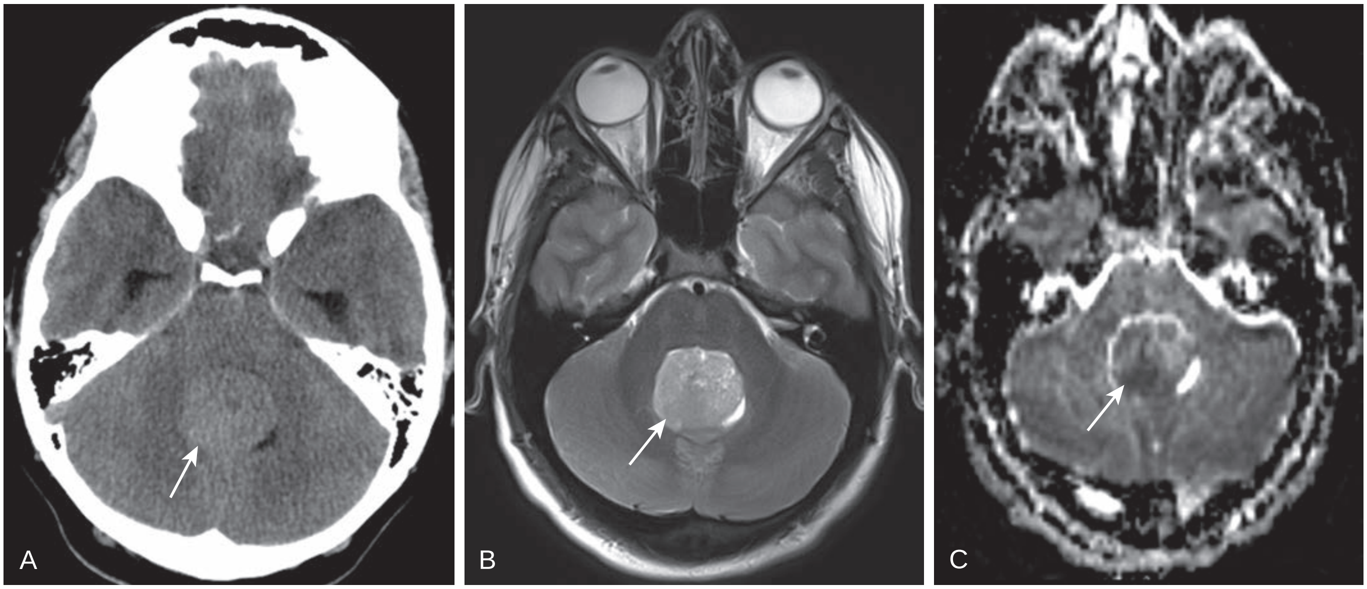

**Figure 35.10. Medulloblastoma.** (A) Axial T2-weighted MRI shows a solid T2-hypointense mass centered in the midline within the cerebellum *(arrow).* (B) Postcontrast axial T1-weighted MRI shows heterogeneous enhancement of the lesion. (C) Apparent diffusion coefficient map shows restricted diffusion in parts of the mass *(arrow),* indicating high cellularity.

It often seems to develop from the lower rhombic lip, which has a strong Wnt expression and therefore 75% of WNT tumors occur along the cerebellopontine angle or cerebellar peduncle.[95] SHH signaling modulates the development of the external granular layer and the production of granule cells; accordingly, tumors of the SHH MB subgroup arise from the cerebellar hemispheres.[95] Tumors of both *group 3* and *group 4* develop in the midline in the immediate vicinity of the fourth ventricle, and may be histologically classic or LCA, with metastatic dissemination.[95,96] Group 3 is found mostly in infants, is associated with *MYC* amplifications, and has the worst prognosis. Group 4 corresponds to the typical MB, with an intermediate prognosis. A notable MRI feature of group 4 lesions is the absence of enhancement after contrast administration, implying a specific "preservation" of the tumoral blood-brain barrier. At recurrence, SHH MB recurs most frequently locally in the resection cavity, whereas group 3 and group 4 recur almost exclusively with leptomeningeal dissemination.[96]

As a practical summary, medulloblastomas should be considered high in the list of differential diagnoses of a posterior fossa tumor that has a vermian location, signs of increased cellularity, restricted diffusion, and intratumoral hemorrhage. MRI of the spine should be obtained at presentation, as the overall incidence of CSF dissemination at diagnosis is between 20% and 30%.[97]

Treatment of medulloblastoma is multimodal, consisting of surgery, radiation therapy, and chemotherapy. e-Table 35.1 summarizes the correlation between the genetic profile, histology, and clinical prognosis.

## Cerebellar Astrocytomas

Features of cerebellar astrocytomas are similar to astrocytomas elsewhere in the brain as discussed in detail previously.

## Tectal Gliomas

Patients with tectal gliomas present with symptoms of obstructive hydrocephalus, caused by growth located adjacent to the aqueduct of Sylvius. Tectal plate lesions can be diagnosed based on imaging findings alone. Imaging appearance is similar to pilocytic astrocytomas elsewhere. Most tectal gliomas do not enhance after contrast enhancement (Fig. 35.11). They may require CSF diversion procedures to relieve hydrocephalus, but do not usually require biopsy or resection. Careful observation suffices for slowly progressing asymptomatic tumors. Rarely, tumors greater than 10 cm may require surgical debulking and/or chemotherapy.[98,99]

## Brainstem Gliomas

Brainstem tumors account for up to 12% of all brain tumors in children.[3] Based on MRI, four types are described: focal, dorsal exophytic, cervicomedullary, and diffuse midline glioma.

### Diffuse Intrinsic Pontine Glioma (Diffuse Midline Glioma)

These tumors are typically centered in the pons. Tumors previously referred to as diffuse intrinsic pontine gliomas are now classified under a newly defined entity called diffuse midline gliomas characterized by K27M mutation in the histone H3 gene *H3F3A* or less commonly in the *HIST1H3B/C* histones.[4] The peak incidence is from ages 6 to 8 years, coinciding with an expansion of a neural precursor–like cell population in the ventral pons, proposed as the possible cell-of-origin.[100]

On CT, pontine gliomas are hypodense or isodense. Calcification or hemorrhage is rare. On MRI, these tumors are isointense to hypointense on T1-weighted images and hyperintense on T2-weighted images. Typically, they partially surround the basilar artery. Enhancement is minimal or absent at presentation in most patients, but in the later stages of tumor progression, diffuse enhancement and necrosis may be present (Fig. 35.12).

These tumors have increased ADC values and reduced FA at presentation with reduction in ADC after initiation of radiotherapy.[101-103] Increased ADC values are thought to be secondary to a larger extracellular volume, possibly arising from a combination of vasogenic edema and a lower number of tumor cells.[104] Volumetric ADC histogram metrics demonstrate significant correlations between diffusion metrics and survival, with lower diffusion values (increased cellularity), increased skewness, and enhancement associated with shorter survival.[21,103] DTI suggests that the tracts are initially infiltrated[105] but not fully disrupted, with better visualization of white matter tracts after radiation.

**e-TABLE 35.1** Medulloblastomas: Summary of Genetic Profile, Histology, and Clinical Prognosis

| Genetic Profile | Histology | Prognosis |
|---|---|---|
| **Medulloblastoma, WNT-activated** | Classic | Low-risk tumors—classic morphology is a feature of almost all WNT-activated tumors |
| | Large cell/anaplastic (rare) | Clinicopathologic significance uncertain |
| **Medulloblastoma, SHH-activated, TP53-mutant** | Classic | Uncommon high-risk tumor |
| | Large cell/anaplastic | High-risk tumor; prevalent in children ages 7-17 years |
| | Desmoplastic/nodular (rare) | Clinicopathologic significance uncertain |
| **Medulloblastoma, SHH-activated, TP53-wildtype** | Classic | Standard-risk tumor |
| | Large cell/anaplastic | Clinicopathologic significance uncertain |
| | Desmoplastic/nodular | Low-risk tumor that occurs in infants, prevalent in infants and adults |
| | Extensive nodularity | Low-risk tumor that occurs in young infants |
| **Medulloblastoma, non-WNT/non-SHH, Group 3** | Classic | Standard-risk tumor |
| | Large cell/anaplastic | High-risk tumor |
| **Medulloblastoma, non-WNT/non-SHH, Group 4** | Classic | Standard-risk tumor, classic morphology seen in most group 4 tumors |
| | Large cell/anaplastic | Clinicopathologic significance uncertain |

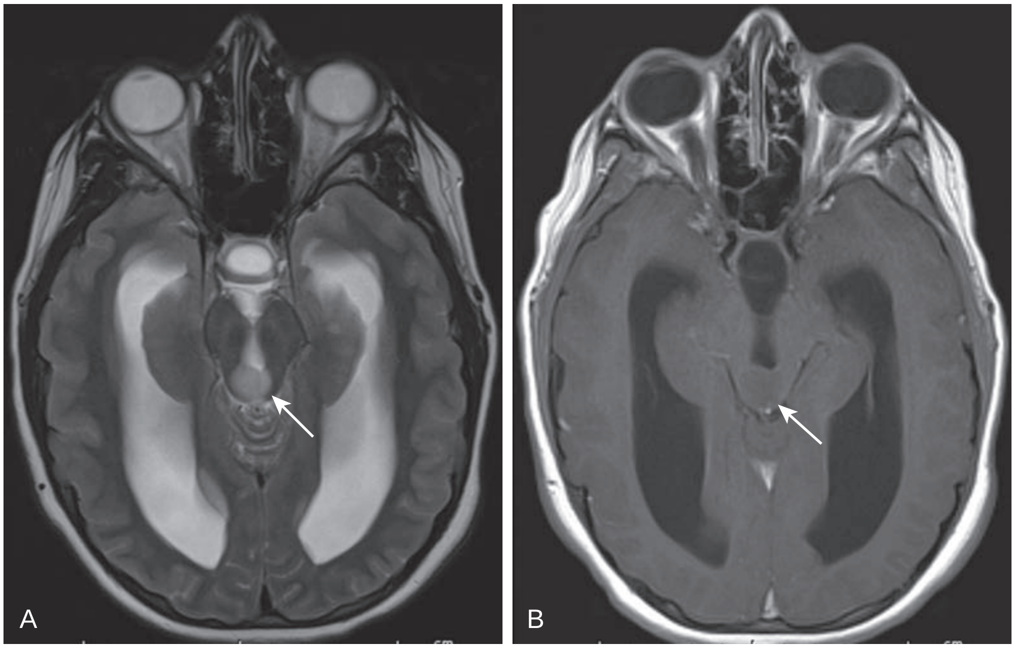

**Figure 35.11. Tectal plate glioma.** (A) Axial T2-weighted MRI shows a hyperintense lesion *(arrow)* involving the tectum causing obstruction of the aqueduct. (B) Axial postcontrast T1-weighted MRI shows the mass is T1-isointense to brain parenchyma *(arrow)* and does not enhance after contrast administration.

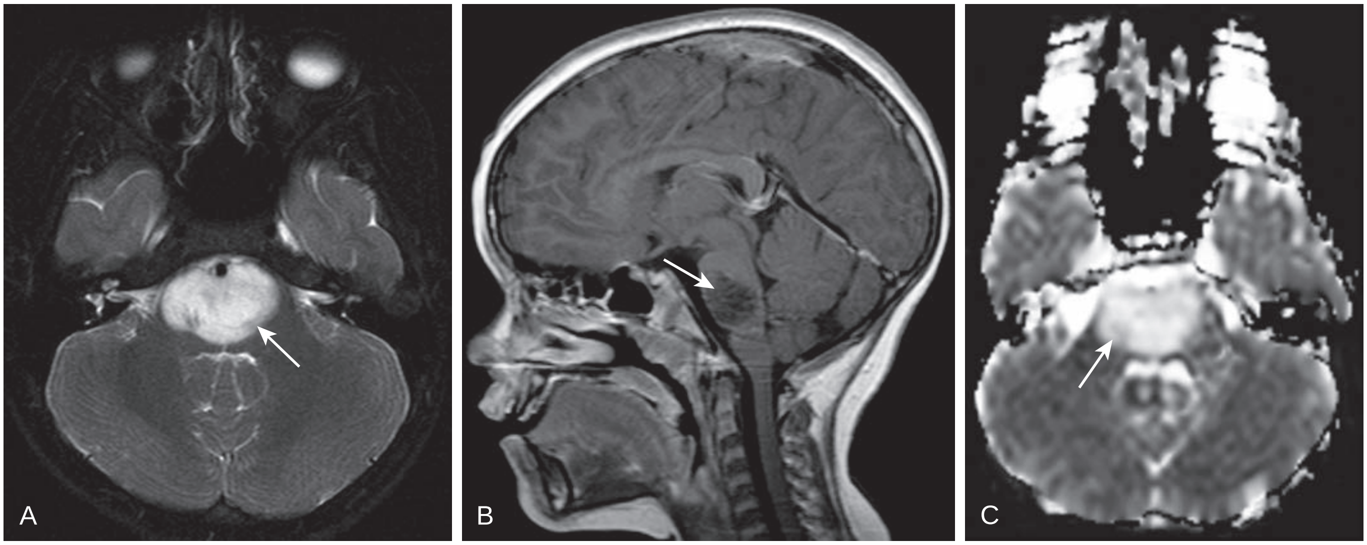

**Figure 35.12. Diffuse midline glioma of the pons.** (A) Axial T2-weighted MRI shows a rounded, hyperintense mass centered in the pons *(arrow)* surrounding the basilar artery and narrowing the pontine cistern. (B) Postcontrast sagittal T1 MRI shows that the lesion does not enhance *(arrow)* after contrast administration. (C) ADC map shows increased diffusion within the lesion *(arrow),* a typical finding at initial presentation.

Tumor progression then results in complete loss of anisotropy possibly due to tract infiltration and disruption.[21,101]

These tumors have a poor long-term survival and were previously considered inoperable. Biopsy of some of these lesions is now being performed allowing the development of new molecular analyses using very small amounts of tissue.[106-108] These tumors usually respond initially to radiation therapy, which has improved the median overall survival from weeks to months.[109] Adjuvant therapies such as radiation sensitizers, differentiation agents, cytotoxic drugs, molecularly targeted drugs, and immunotherapy have been tried. Although they have shown preliminary evidence of immunologic and clinical response, outcomes for patients have not changed significantly.[107,109-111]

### Low-Grade Brainstem Astrocytomas

Low-grade brainstem tumors are usually pilocytic astrocytomas. These are focal tumors that arise in the brainstem and typically extend in an exophytic fashion from its dorsal margin.[112] Imaging features are similar to pilocytic astrocytomas elsewhere.

## Atypical Teratoid Rhabdoid Tumors

Atypical teratoid/rhabdoid tumors (AT/RT) are highly malignant tumors seen in young children, with a peak incidence between birth and 3 years.[113] They are the most common malignant CNS tumor in children below 1 year of age.[3] These tumors account for almost 10% of CNS tumors in children and approximately 1% to 2% of all pediatric brain tumors.[114] Almost 60% of these tumors are seen in the posterior fossa at the cerebellopontine angle. However, supratentorial AT/RTs are also frequently seen in the pineal region, spine, and suprasellar region.[115]

AT/RT has been identified as pathologically distinct entities from medulloblastoma and other embryonal tumors. In the recent WHO classification, AT/RT is now defined by alterations of either the *INI1* or, very rarely, *BRG1 genes*. If a tumor has histologic features of AT/RT but does not harbor either of the diagnostic genetic alterations, only a descriptive diagnosis of CNS embryonal tumor with rhabdoid features is available; in other words, the diagnosis of AT/RT requires confirmation of the characteristic molecular defect.[4,116]

Imaging appearances are similar to medulloblastoma: isointense on T1-weighted images and hypointense signal intensity on T2-weighted images (e-Fig. 35.13). Cystic areas are common. Due to their highly cellular nature, T2 hypointensity is often seen in the solid areas, associated with restricted diffusion. Hemorrhage and calcification is not uncommon.[117] Subarachnoid spread throughout the CNS with spinal drop metastases is common, with frequency ranging between 25% and 46%.[118,119]

Survival rates for patients with AT/RT are generally poor but have improved in recent years with aggressive multimodality therapies and development of trials specifically designed for this entity.[120] Although some older studies quoted 2-year survival rates as low as 18%, more recent studies have reported improved 2-year survival rates up to 60% for patients with gross total resection of the primary tumor.[120,121] Survival rates are higher in children older than 3 years of age. Poor prognosis is related to the young age of the affected patients, as well as the high propensity for CSF tumor dissemination. Distant metastases to the lungs and abdomen also may be seen.

### Infratentorial Ependymomas

Infratentorial ependymomas constitute 8% to 15% of posterior fossa tumors in children. The molecular features were previously discussed. They arise from the ventricular ependymal lining and grow out of the fourth ventricle via the foramina of Luschka and Magendie into the cerebellopontine angles and cisternal spaces around the brainstem and cervicomedullary junction. These tumors are T1 hypointense and isointense to gray matter on T2-weighted images, and demonstrate heterogeneous enhancement (Fig. 35.14). Up to 50% contain foci of calcification. Disseminated disease is present in 7% to 15% of patients at diagnosis.[122] Posterior fossa ependymomas demonstrate significantly higher ADC values than medulloblastomas and lower ADC values than astrocytomas,[123] which may help in preoperative tumor differentiation.

Extent of surgical resection is the most important prognostic factor. Complete surgical resection followed by other treatments has a more than 80% 3-year disease-free survival rate.[124,125] Older age and favorable histologic grading indicate a better prognosis.[126]

## PINEAL REGION TUMORS

Pineal tumors comprise between 3% and 8% of all pediatric brain tumors.[127] Pineal region tumors can be divided into four categories: germ cell tumors, pineal cysts, pineal parenchymal tumors, and tumors of the supporting tissues of the pineal gland or adjacent structures (such as pineal gliomas, dermoids, and epidermoids).

The most common pineal region tumors are germ cell tumors, of which 65% are pure germinomas.[128] Other variants such as nongerminomatous germ cell tumors (NGGCTs), mixed germ cell tumors, teratomas, embryonal cell carcinoma, yolk sac tumor, and choriocarcinoma constitute the remainder.

### Germ Cell Tumors

Germinomas are hyperdense on CT and enhance homogenously. The typical appearance on CT is a calcified pineal gland surrounded by noncalcified tumor. On MRI, these lesions have homogenous signal isointense to gray matter on all sequences with intense contrast enhancement. These tumors grow anteriorly into the floor of the third ventricle and may infiltrate the thalami and midbrain (Fig. 35.15). Spinal dissemination is seen in up to 36% of cases.[129]

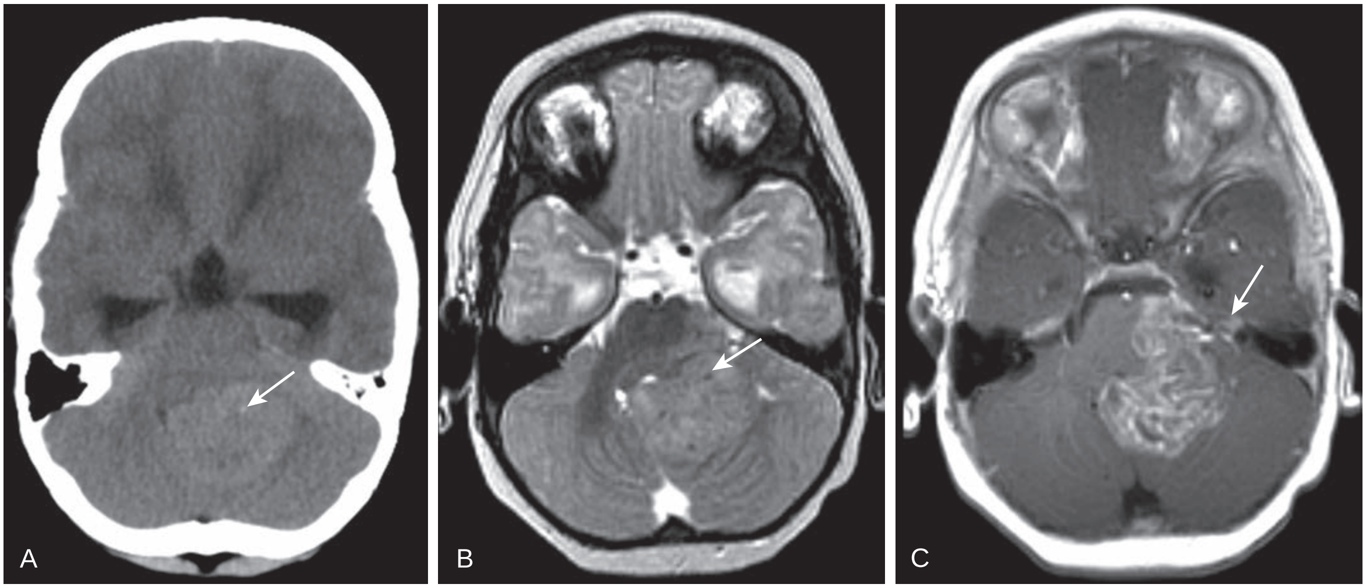

**Figure 35.14. Ependymoma.** (A) Axial noncontrast CT shows a hyperdense mass lesion occupying the fourth ventricle and extending through the left foramen of Luschka. Note several tiny punctate areas of calcification *(arrow).* (B) Axial T2-weighted MRI shows the lesion *(arrow)* is isointense compared with gray matter. (C) Axial postcontrast MPRAGE MRI shows heterogeneous enhancement of the lesion and its extension toward the left foramen of Luschka *(arrow).*

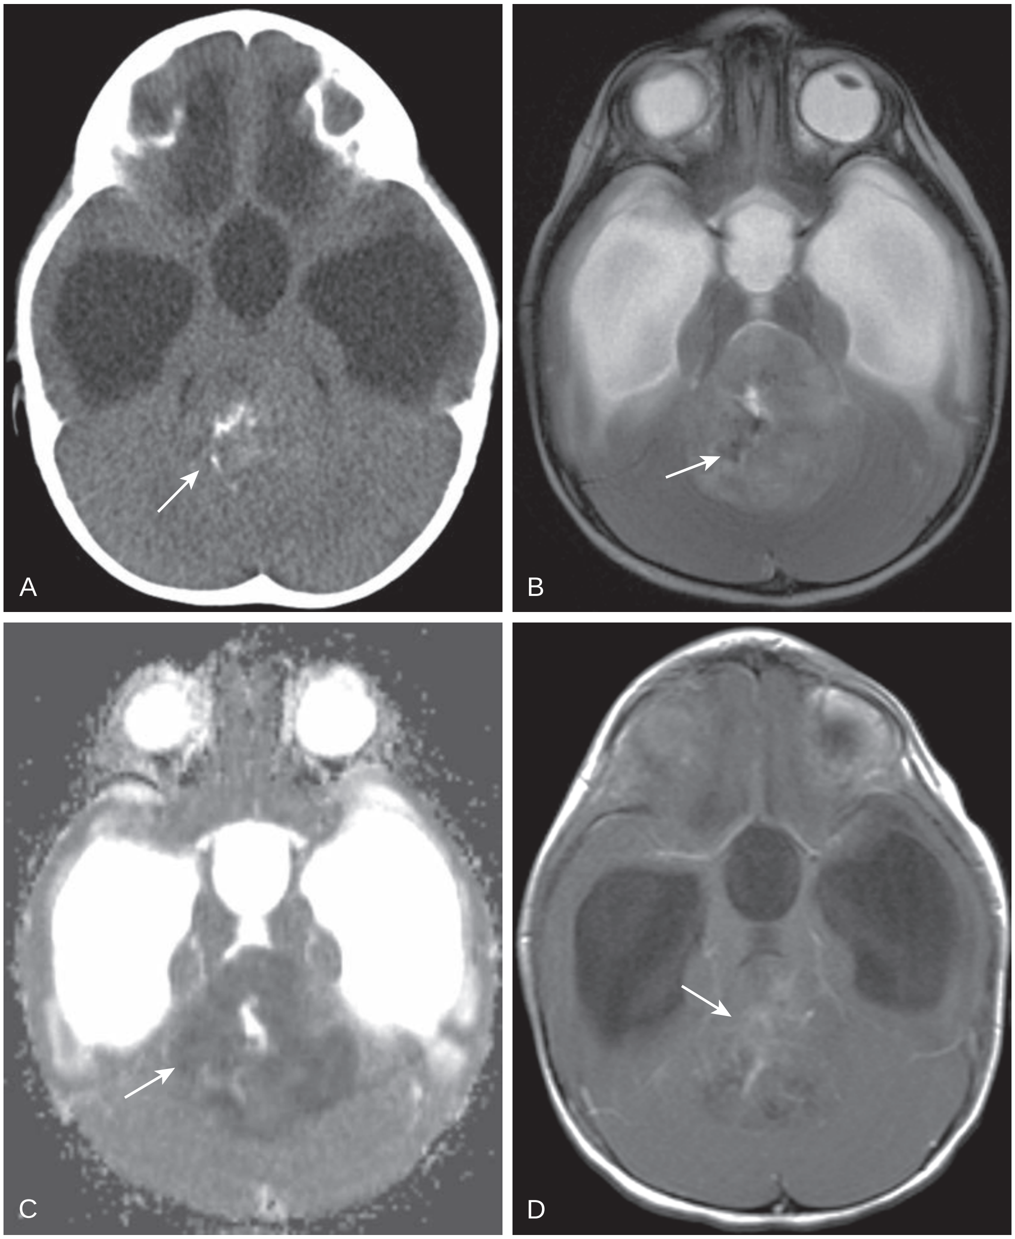

**e-Figure 35.13. Infratentorial atypical teratoid/rhabdoid tumor.** (A) Axial non contrast CT head shows a large posterior fossa mass with areas of calcification *(arrow)*. (B) The axial T2-weighted image, the predominant solid component is hypointense compared with gray matter. Foci of even lower signal intensity *(arrow)* correspond to the foci of calcification seen on the CT. (C) Apparent diffusion coefficient (ADC) map shows restricted diffusion within the mass reflecting the hypercellularity within the tumor *(arrow)*. (D) Axial post-contrast T1-weighted MRI shows patchy enhancement of the mass *(arrow)*.

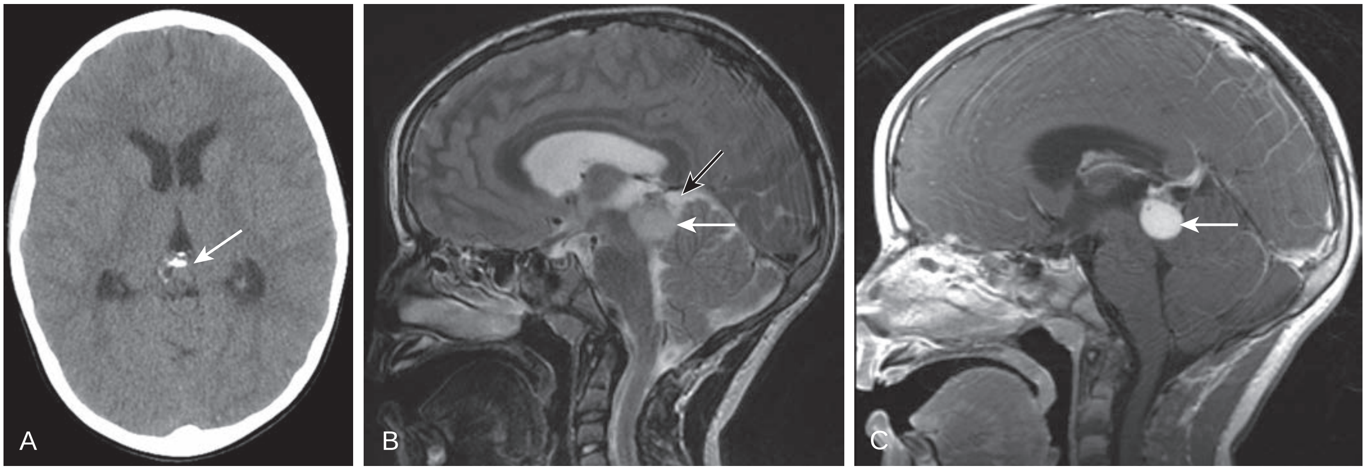

**Figure 35.15. Pineal germinoma.** (A) Axial unenhanced CT shows a partially calcified lesion *(arrow)* in the pineal region. Note presence of hydrocephalus resulting from third ventricular obstruction. (B) Sagittal T2-weighted MRI shows a rounded mass *(white arrow)* hyperintense to gray matter centered in the pineal region. Note the presence of cystic T2-hyperintense component along the superior aspect *(black arrow).* (C) Postcontrast T1-weighted MRI shows homogenous enhancement of the solid component *(arrow)* of the lesion.

Imaging appearances of NGGCTs are nonspecific, with intratumoral cysts and calcifications being a relatively common finding. For example, teratomas are heterogeneous and contain cysts and calcification and demonstrate variable enhancement. The presence of fat is a specific feature. The presence of hemorrhage is more suggestive of a choriocarcinoma.

## Pineal Parenchymal Tumors

Pineocytomas are well-differentiated tumors that retain morphologic features of the pineal parenchymal cells. They are slow-growing, circumscribed, but noncapsulated tumors. They are more commonly solid tumors, although cystic variants have been described. Solid tumors are either hypointense or isointense to gray matter and T2-hyperintense. Enhancement is homogenous and calcification is common. Cystic variants are often indistinguishable from pineal cysts.[130]

Pineoblastomas are malignant, unencapsulated tumors that resemble embryonal tumors NOS, but are distinct from such tumors in other locations due to their photosensory differentiation.[131] On MRI, these lesions are hypointense to isointense on T1-weighted images and variable low, high, or mixed signal on T2-weighted images. They have lobulated contours and enhance homogenously (e-Fig. 35.16). They calcify less often then pineocytomas. The "exploded pattern" of calcification with peripheral displacement of pineal gland calcification is considered more typical of pineal parenchymal tumors, differentiating them from germ cell tumors.[132] Pineoblastomas are resected surgically with adjuvant craniospinal radiation and multiagent chemotherapy. Prognosis is relatively poor.[133]

## CONCLUSION

Advances in neuroimaging coupled with advances in molecular biology and neurosurgery over the past decade have improved our ability to detect, diagnose, characterize, and treat pediatric CNS tumors. It is important to recognize the typical features of each of these tumors on imaging studies, as this forms the basis for further management. Accurate characterization and reporting of a tumor at presentation and its relation to eloquent areas can help plan immediate and, in some cases, long-term management (e-Box 35.2). In the future, it is hoped that imaging studies will become further refined to enable rapid and more accurate diagnoses, helping design treatment regimens tailored to the needs of an individual patient, and enable improved assessment of treatment response and early detection of recurrence.

### KEY POINTS

1. MRI with contrast is the imaging modality of choice for the diagnosis of pediatric brain tumors.
2. Advanced imaging techniques can help understand tumor physiology and map out the surgical plan by defining relationship of tumors to eloquent areas.
3. The latest WHO classification emphasizes molecular parameters in addition to histological features in the classification of brain tumors, which relate increasingly to the management and outcome.
4. In addition to providing a complete description of imaging features of a new tumor, the radiologist's report should include information that can help inform surgical planning and other treatment measures.
5. Increasing use and availability of minimally invasive techniques and intraoperative imaging calls for greater radiologist involvement in planning surgical management of pediatric brain tumors.

(B) Postcontrast sagittal T1-weighted MRI shows heterogeneous enhancement of the mass *(white arrow)* with a small focus of nonenhancement in its posterior aspect *(black arrow).* (C) Sagittal T1-postcontrast MRI through the cervical and upper thoracic spine shows linear and nodular enhancement *(arrows)* along the surface of the cervical and upper thoracic spinal cord consistent with leptomeningeal seeding of the tumor.

### **e-BOX 35.2** Key Points to Include in the Report When a New Tumor Is Identified

- Signal characteristics, including enhancement characteristics, presence of calcification and/or hemorrhage
- Intraaxial or extraaxial location
- Lesion extent
- Surrounding edema or white matter infiltration
- Relationship to adjacent structures (e.g., optic chiasm, pituitary gland, and eloquent cortical areas)
- Relationship and effect on arterial and venous structures
- Mass effect, midline shift, and subfalcine, transtentorial, or uncal herniation
- Presence of leptomeningeal enhancement and craniospinal dissemination
- Osseous involvement in cases of extraaxial tumors
- Reduced or increased diffusivity
- Perfusion characteristics
- Magnetic resonance spectroscopy

# 36 Cerebrovascular Disorders

Jordan Smith, Ross Holwerda, and Lisa H. Hutchison

Stroke is defined as a neurologic deficit persisting for more than 24 hours and may be caused by cerebral ischemia or intracranial hemorrhage. The annual incidence of stroke in children ranges from 2 to 13 cases per 100,000 patients and is among the top 10 causes of death in childhood.[1] Among children diagnosed with stroke, more than 40% will have major neurologic sequelae and more than 75% will have perceptible residual neurologic deficits.[2]

The clinical presentation of stroke in children is sometimes heralded by the abrupt onset of focal neurologic deficits; however, the symptoms are often nonspecific, resulting in delayed diagnosis.

The most common predisposing conditions in children include cerebrovascular arteriopathy, vascular anomalies, aneurysms, congenital heart disease, sickle cell disease, and hematologic abnormalities.[1] Over half of all strokes in children are ischemic caused by intrinsic vasculopathy or embolic phenomenon, and vascular malformations, aneurysms, and venous sinus thrombosis are the most common causes of hemorrhagic stroke.[2] This chapter focuses on pediatric vascular abnormalities as causes of ischemic and hemorrhagic stroke.

## ARTERIOPATHY

Ischemic stroke in children has an annual incidence of between 2 and 3 per 100,000 children in the United States.[3] Identifiable causes of ischemic stroke occur in approximately 70% of cases, including arterial dissection, moyamoya disease, sickle cell disease, vasculitis/angiitis of the central nervous system, and coagulopathy. The remaining cases are often idiopathic in origin. Twenty-five percent of children with ischemic stroke have coexistent cardiac disease, suggesting a component of embolic etiology.[2]

The most common symptoms of ischemic stroke in children are hemiplegia, seizures, fever, dysphagia, headache, and altered level of consciousness. Headache and seizures are especially common in chronic ischemic conditions such as moyamoya disease.[4]

***Imaging.*** The imaging features of ischemic stroke in children are variable and depend on the underlying cause. In acute arterial dissection, large vessel arterial distribution infarction is often present on computed tomography (CT) or magnetic resonance imaging (MRI). By contrast, in proximal, chronic steno-occlusive disease such as moyamoya disease (Fig. 36.1), infarctions may be absent, conform to an arterial territory, or lie within the watershed zones between the major vascular territories.

Noninvasive vascular imaging such as computed tomographic angiography (CTA) or magnetic resonance angiography (MRA) may show dissection as an abrupt vascular cutoff intracranially or as tapering stenosis, commonly seen with involvement of the neck vasculature. In moyamoya disease, stenosis or occlusion of the supraclinoid segment of the internal carotid artery and/or proximal middle and anterior cerebral arteries is usually present, with collateral vessel formation in the basal ganglia and along the pial surfaces.[5] Vasculitis causes irregular narrowing of medium or small vessels and is inconsistently demonstrated on CTA or MRA.[6] Catheter angiography remains the gold standard for the imaging diagnosis of cerebrovascular disease in children and should be considered whenever a small vessel vasculitis is suspected or when surgical treatment is contemplated.

## VASCULAR ANOMALIES

Vascular anomalies are disorders of vascular development. Although congenital, they may only become symptomatic many months or years after birth. Intracranial vascular malformations are classified according to the vascular channels involved and the hemodynamics of the lesion (high-flow vs. low-flow).[7]

### High-Flow Vascular Anomalies

High-flow vascular anomalies occur when there is an abnormal connection between an artery and a vein that bypasses the normal arteriolar-capillary network. In arteriovenous fistula (AVF), the supplying artery communicates directly with the draining vein through a macroscopic fistula. In arteriovenous malformation (AVM), the supplying artery connects with the draining vein through a plexiform network of abnormal vessels, termed the *nidus*. Both AVF and AVM can be further subdivided, on the basis of anatomic location, as dural, subarachnoid (vein of Galen malformation), pial, or parenchymal (Figs. 36.2, 36.3, and 36.5; e-Fig. 36.4).[7,8]

High-flow vascular malformations may produce clinical manifestations by different methods.[7,9,10] The presence of a direct channel between a supplying artery and a draining vein allows for potentially rapid blood flow. In the absence of venous outflow obstruction, the malformation may cause high-output cardiac failure. Additionally, the lower resistance through the malformation may result in diversion of blood away from the normal brain parenchyma ("steal" phenomenon), producing cerebral ischemia. High-flow malformations also expose the draining veins to arterial pressure, which may cause progressive stenosis of the vein (termed *high-flow venopathy*) or the development of a varix or venous aneurysm that predisposes to hemorrhage. High-flow venopathy may be a cause of seizures or cerebral atrophy due to impaired tissue perfusion from venous hypertension. Hydrocephalus can develop from increased venous pressures that result in impaired resorption of cerebrospinal fluid (see Fig. 36.3A).

### Dural High-Flow Anomalies

Dural AV fistulas in the pediatric population are most frequently congenital, as opposed to acquired AV fistulas in the adult population. The malformation is formed by an abnormal connection between the meningeal arterial supply from the external carotid vasculature with a dural venous sinus (see Fig. 36.2).[7,10,11] The abnormal connections are frequently located in the vicinity of the torcular herophili, and may be associated with high-output heart failure.

### Vein of Galen Malformations

Vein of Galen malformation (VOGM) is a fistulous connection with arterial supply from the deep choroidal arteries and venous drainage through a persistent dilated embryonic median prosencephalic vein, one of the embryologic precursors of the vein of Galen (see Fig. 36.3).[7,11,12] The symptoms, signs, and age at presentation associated with VOGMs depend on the angioarchitecture of the anomaly and the degree of venous outflow obstruction. In the absence of venous outflow obstruction, VOGMs may produce

## Abstract:

Cerebrovascular disorders in the pediatric population can have devastating, long lasting effects resulting from complications such as ischemic or hemorrhagic stroke. The most common predisposing conditions for stroke in children include cerebrovascular arteriopathy, vascular anomalies, aneurysms, congenital heart disease, sickle cell disease, and hematologic abnormalities. Over half of all strokes in children are ischemic caused by intrinsic vasculopathy or embolic phenomenon. Vascular malformations, aneurysms, and venous sinus thrombosis are the most common causes of hemorrhagic stroke. Among children with stroke, more than 40% will have major neurologic sequelae and more than 75% will have perceptible residual neurologic deficits. In this chapter, cerebrovascular disorders are broadly categorized into arteriopathy, high and low flow vascular anomalies, and aneurysms highlighting important clinical and imaging findings that point to a specific diagnosis. Case examples are provided to familiarize the reader with expected imaging manifestations of both common and uncommon cerebrovascular disorders. Knowledge and early recognition of cerebrovascular disorders is imperative as they often predispose patients to ischemic or hemorrhagic stroke. Understanding the variable clinical presentations as well as imaging manifestations of these vascular phenomena is necessary to make a timely diagnosis and initiate prompt treatment when necessary.

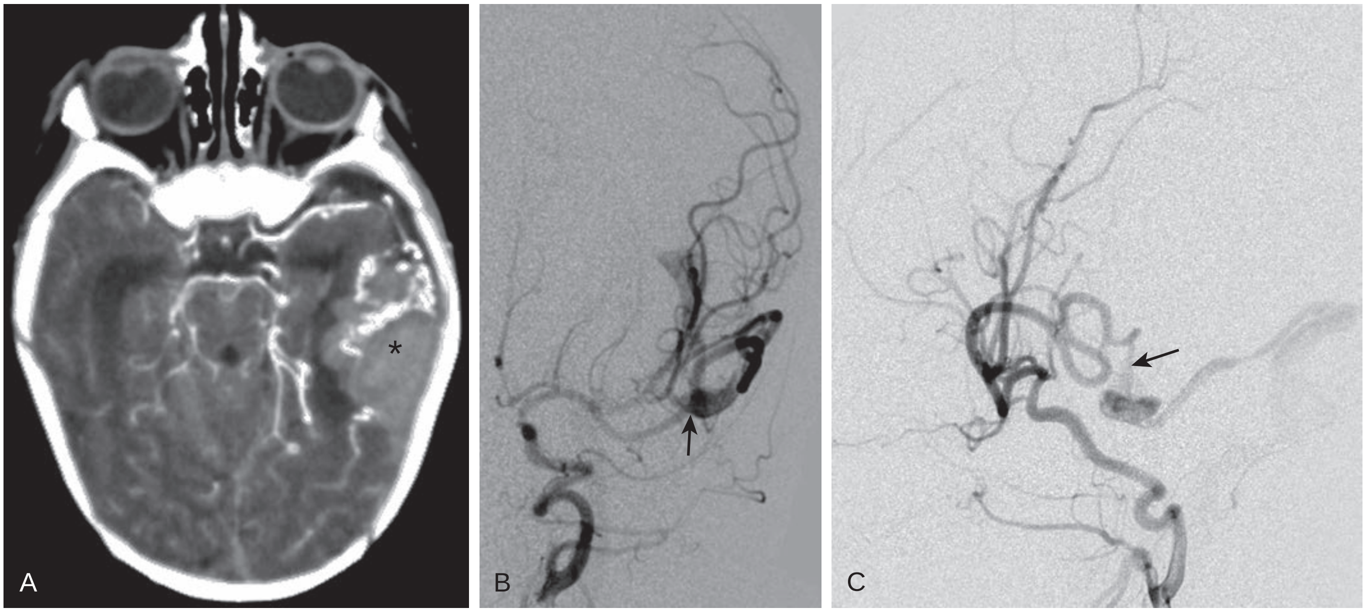
Stroke
Vascular anomalies
Vascular malformations
Aneurysm
Arteriopathy
Telangiectasia



**e-Figure 36.4. Pial arteriovenous fistula and left temporal hemorrhage in an 18-day-old child presenting with irritability, poor feeding, and vomiting.** (A) Contrast-enhanced CT image shows hemorrhage *(asterisk)* in the left temporal lobe associated with enlarged vessels. (B) Frontal digital subtraction angiogram shows a pial arteriovenous fistula *(arrow)* supplied by the left middle cerebral artery. (C) The lateral angiogram demonstrates a fistula *(arrow)* between the middle cerebral artery and the dilated cortical vein.

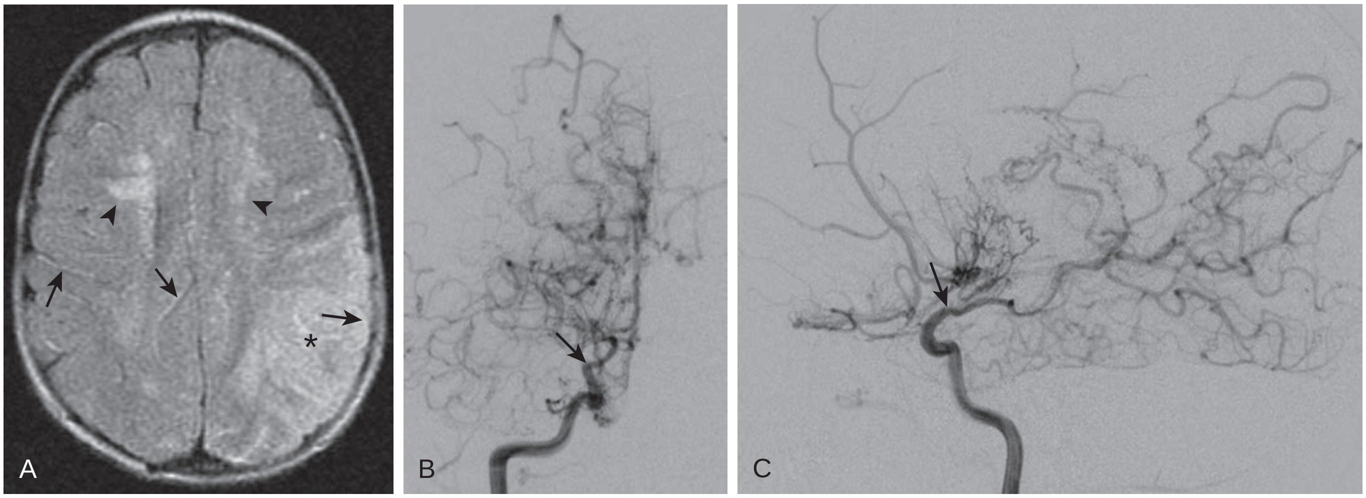


**Figure 36.1. Moyamoya disease in a 2-year-old child presenting with new-onset right-sided hemiplegia.** (A) Axial fluid-attenuated inversion recovery MRI shows a subacute infarct involving the left middle cerebral artery–posterior cerebral artery watershed territory *(asterisk).* There is periventricular white matter T2 prolongation due to chronic ischemic change *(arrowheads).* Linear sulcal signal abnormality is demonstrated bilaterally, consistent with slow flow *(arrows)* in leptomeningeal vessels. (B) Frontal projection from digital subtraction angiogram shows severe steno-occlusive changes involving the distal right internal carotid artery *(arrow),* with occlusion of the middle and anterior cerebral arteries and multiple basal collaterals. (C) Lateral projection again shows the distal tapering and occlusion of the supraclinoid internal carotid artery *(arrow),* multiple basal collaterals, and anterior shift of the posterior cerebral territory through pial collaterals to supply the posterior portions of the middle and anterior cerebral territories.

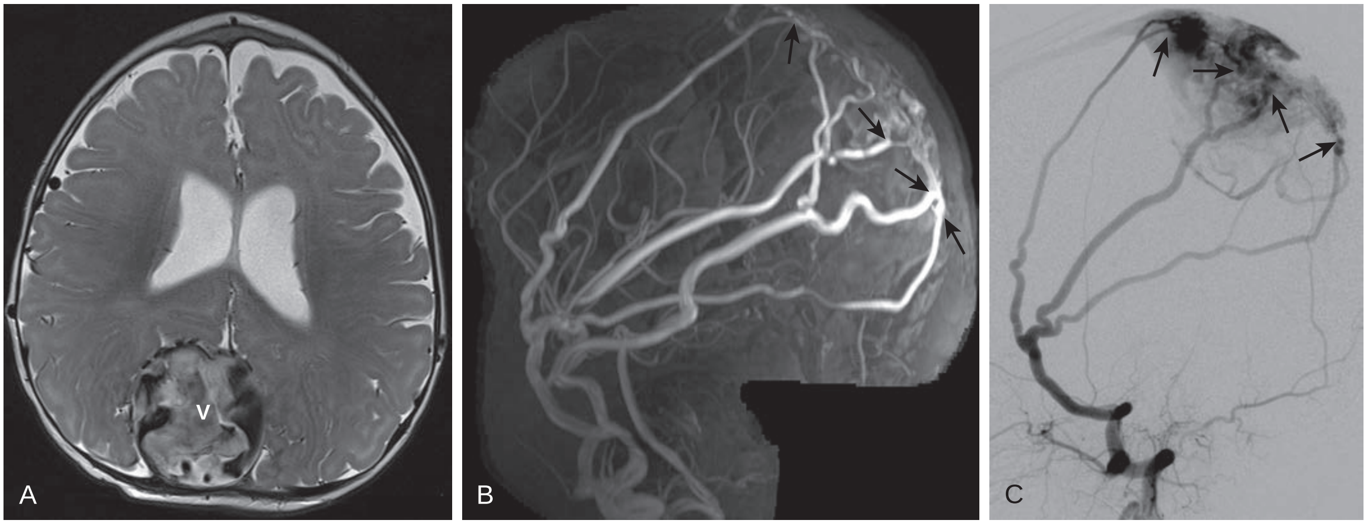

**Figure 36.2. Dural arteriovenous fistula in a 5-month-old girl presenting with vomiting, lethargy, macrocephaly, and distended pulsating scalp veins.** (A) Axial T2-weighted MRI shows an enlarged, partially thrombosed superior sagittal sinus *(V).* Also noted are prominent middle meningeal arterial branches along the dural surface bilaterally. (B) Coronal maximum intensity projection reconstruction of a magnetic resonance venogram shows bilaterally enlarged middle meningeal arteries with fistulae *(arrows)* to the dilated, partially thrombosed superior sagittal sinus. (C) Lateral digital subtraction angiogram demonstrates the dural arteriovenous fistulae with the markedly enlarged middle meningeal artery branches directly communicating through several fistulae *(arrows)* with the superior sagittal sinus near the torcular herophili.

congestive heart failure in the fetus or neonate due to the shunting of blood through the malformation. Additionally, intracranial hemorrhage can occur from rupture of the varix. VOGMs with fewer arteriovenous connections often present later in infancy or childhood with hydrocephalus or brain atrophy caused by progressive venous hypertension and impaired parenchymal perfusion (see Fig. 36.3).

## Pial High-Flow Anomalies

Pial AVM comprise a pial arterial supply with cortical venous drainage (see e-Fig. 36.4).[7] Pial AVMs are rarely detected in the neonate and usually come to medical attention in late infancy or early childhood. The fistulous connections occur along the surface of the brain, resulting in dilation of the superficial cortical draining

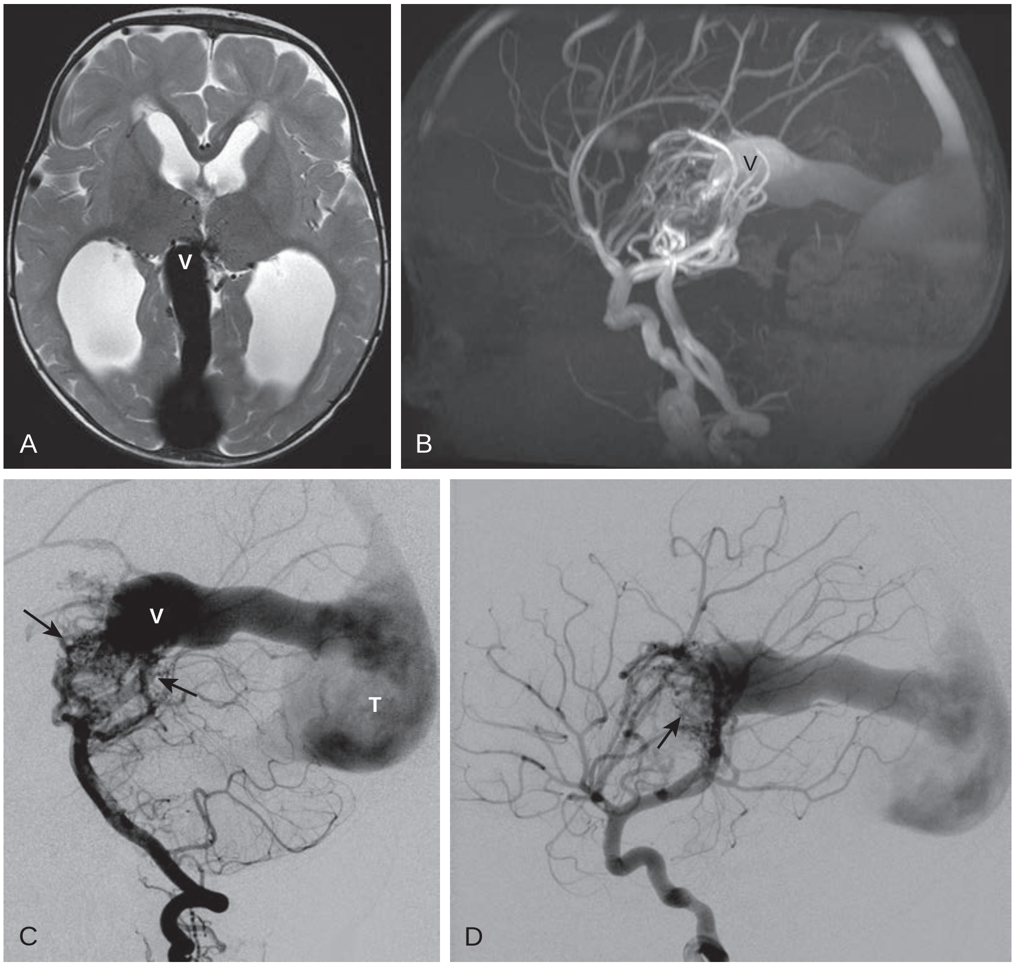

**Figure 36.3. Vein of Galen malformation in a 12-month-old child presenting with macrocephaly and developmental delay.** (A) Axial T2-weighted MRI shows a dilated median vein of the prosencephalon *(V).* The straight sinus and torcular herophili are enlarged. Multiple small serpiginous signal voids are present medially between the thalami from enlarged branches of a primitive arterial arcade. Hydrocephalus is present from venous hypertension. (B) Sagittal maximum intensity MRA confirms a high-flow arteriovenous connection with marked flow related enhancement in the varix and draining sinuses. (C) Lateral digital subtraction angiogram of the left vertebral artery injection shows enlarged left vertebral, basilar, and posterior cerebral arteries supplying a primitive arterial arcade with a vascular nidus of abnormal vessels draining into the enlarged prosencephalic vein. (D) Lateral right internal carotid artery injection demonstrates additional anterior circulation supply to the malformation *(arrow).*

veins. Pial AVM may be asymptomatic for long periods, being discovered only incidentally on imaging performed for other reasons, or the high-flow anomaly may be a cause of catastrophic intracranial hemorrhage.

## Parenchymal High-Flow Anomalies

Intraparenchymal AVMs, like pial anomalies, derive their arterial supply from either the anterior or posterior cerebral circulation (see Fig. 36.5). Parenchymal AVMs usually present after infancy, most often as a cause of intracranial hemorrhage.[7,9,10] Intranidal aneurysms and varices occur commonly; however, aneurysmal dilation of the supplying arteries is much less frequent than in adults.

***Imaging.*** Imaging in high-flow vascular malformations is directed toward delineation of the vascular anomaly and demonstration of complications. Dural AVF and VOGM may be diagnosed in utero on either obstetrical sonography or fetal MRI.[7,8,11] Fetal ultrasound (US) or MRI of dural AVF shows an off-midline vascular mass with enlarged meningeal arteries. Fetal US or MRI of VOGM demonstrates a midline vascular mass, with increased flow in the supplying arteries and draining veins on color Doppler examination. In dural AVF, as well as VOGM, fetal cardiomegaly and congestive heart failure with hydrops may be present. In addition to showing the vascular mass, fetal and postnatal MRI scans may show T1 shortening in the white matter, indicating chronic ischemic brain injury. Postnatal CT is now used less frequently but may show chronic ischemic brain injury with loss of gray/white matter contrast and parenchymal calcification, in addition to the vascular anomaly.

Treatment of dural malformations and VOGMs is typically performed via an endovascular approach.[9,10,13] Successful treatment of the anomaly requires occlusion of the arteriovenous connection. AVFs may be treated by placement of coils across the lesion, whereas closure of AVMs requires obliteration of the nidus and is best accomplished by using a liquid embolic agent.[10,13] Pial and parenchymal malformations are often treated with endovascular embolization, surgical resection, or combined preoperative embolization followed by surgical resection.[9,10,13] Malformations

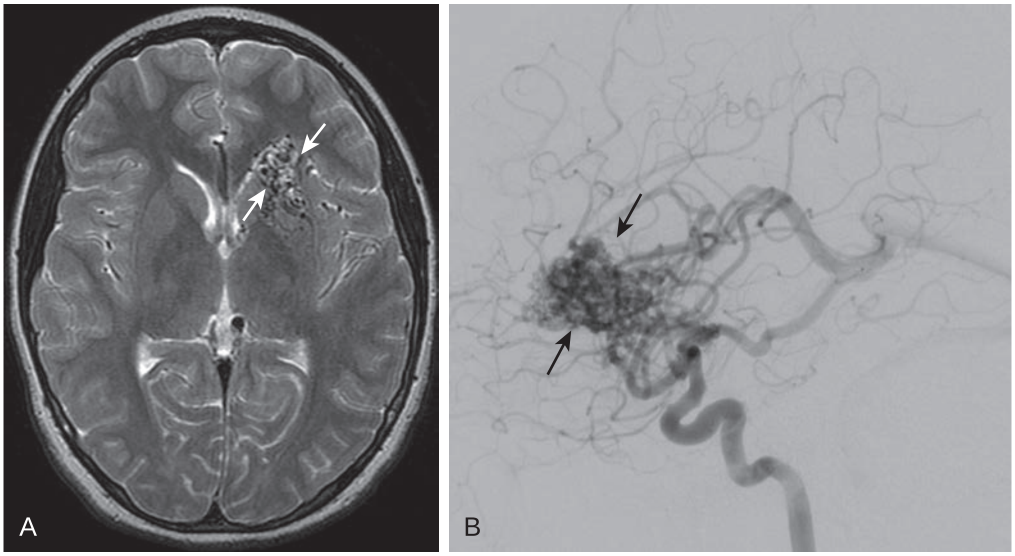

**Figure 36.5. Frontal arteriovenous malformation and intraventricular hemorrhage in an 11-year-old girl presenting with severe headache, vomiting, and left leg weakness.** (A) Axial T2-weighted MRI shows multiple signal voids in the left inferior frontal lobe involving the caudate head and basal ganglia. (B) Lateral cerebral angiogram demonstrates the large vascular nidus *(arrows)* with early opacification of the internal cerebral veins and straight sinus.

that are not surgically accessible may be treated by using endovascular techniques or focused radiation therapy, including proton beam treatment.[14,15]

## Low-Flow Vascular Anomalies

Low-flow vascular anomalies include capillary telangiectasias, cavernous malformations, and developmental venous anomalies (DVAs).[16-21] Each of these entities consists of a malformed, endothelial-lined, blood-filled vascular structure.

### Capillary Telangiectasia

Capillary telangiectasias are composed of dilated capillaries and are found most frequently within the pontine tegmentum.[16-18] Capillary telangiectasias are usually clinically silent and are noted incidentally on imaging performed for other reasons. Rare cases of pontine hemorrhage in which no cause is determined may be caused by capillary telangiectasia.

***Imaging.*** Capillary telangiectasias are typically not apparent on noncontrast imaging and appear as a faint focus of T2 prolongation without an associated mass effect (e-Fig. 36.6). After the administration of contrast, subtle enhancement is seen.

### Cavernous Malformation (Cavernoma)

Cavernous malformations are localized collections of venous blood.[18-21] They can occur in isolation but may also occur very close to DVAs, which suggests a venous origin. Cavernous malformations may be single or multiple; when multiple, they may be familial, or they may develop in response to radiation therapy for treatment of neuro-oncologic disease.[8,21] Cavernous malformations may be discovered incidentally on imaging or may produce symptomatic intracranial hemorrhage or symptoms due to mass effect. Pediatric cavernous malformations behave more aggressively compared with their adult counterparts and are two to three times more likely to hemorrhage.[21]

***Imaging.*** On imaging, small cavernous malformations are typically occult or very subtle on spin-echo imaging but appear as foci of signal loss on long echo, gradient echo, or susceptibility-weighted imaging because of the presence of the magnetic susceptibility effects from associated blood products (Fig. 36.7).[8] Larger lesions are centrally hyperintense on T1-weighed and T2-weighted imaging, with a hypointense rim from the deposition of hemosiderin around the margin of the lesion. Cavernous malformations are usually found within the brain parenchyma but are occasionally superficial and exophytic, simulating an extra-axial mass. Faint post contrast enhancement is also a common feature.

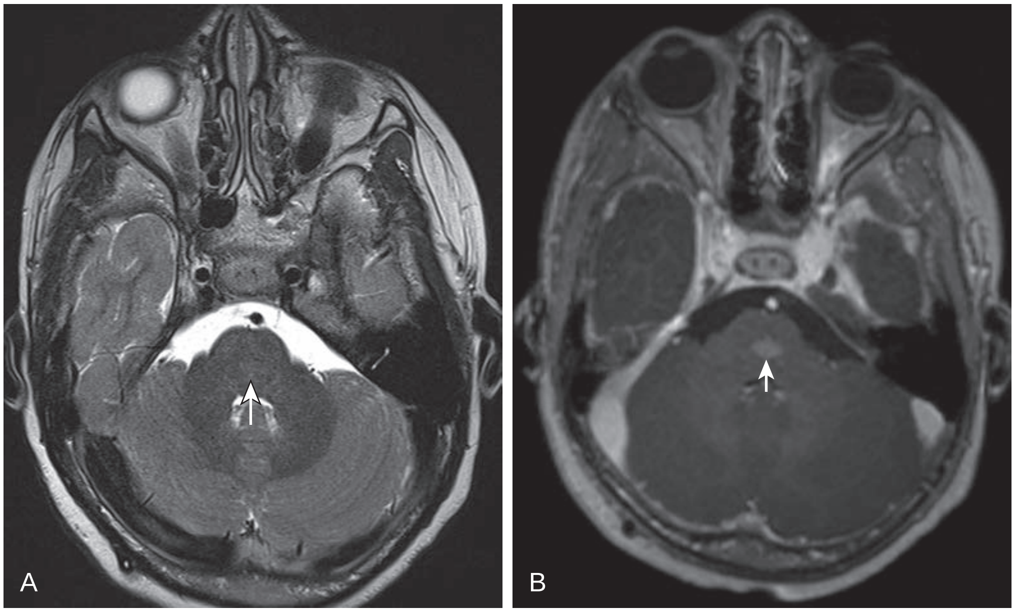
### Developmental Venous Anomaly

DVAs are abnormal veins typically draining normal brain parenchyma. The usual appearance of a DVA is of a cluster of medullary veins radially arranged around the end of an abnormally dilated collecting vein.[19,22] DVAs may be small or provide the entire venous drainage for a cerebral lobe or hemisphere. DVAs are usually asymptomatic and discovered incidentally but are occasionally associated with intracranial hemorrhage, especially when associated with a cavernous malformation. Intracranial DVAs may be seen in association with venous malformation or other vascular anomalies of the scalp and face.[22] DVAs are occasionally identified in association with cortical malformations in the evaluation of seizures.[23]

***Imaging.*** On contrast-enhanced CT or MRI, DVAs are seen as multiple enhancing medullary veins draining into a single collecting vein, an appearance often referred to as the *caput medusa* (Fig. 36.8). DVAs are also visible on catheter angiography and should opacify with contrast at the same time as normal intracerebral veins.[19,22]

## ANEURYSMS

Intracranial aneurysms in children differ in many respects from aneurysms in adults.[24-26] Pediatric aneurysms account for less than 5% of all aneurysms and are rare in the first year of life.[25,27,28] Intracranial aneurysms in children are more likely to be fusiform, involve the posterior circulation, and be larger at the time of presentation than in adults.[25] Symptoms of mass effect are at least as common as those from subarachnoid hemorrhage. Aneurysms



**e-Figure 36.6. Pontine capillary telangiectasia in a 5-year-old with optic pathway glioma.** (A) Axial T2-weighted MRI demonstrates nearly imperceptible T2 prolongation in the pontine tegmentum *(arrow).* (B) Postcontrast axial T1-weighted image shows a blush of enhancement without mass effect typical of capillary telangiectasia.

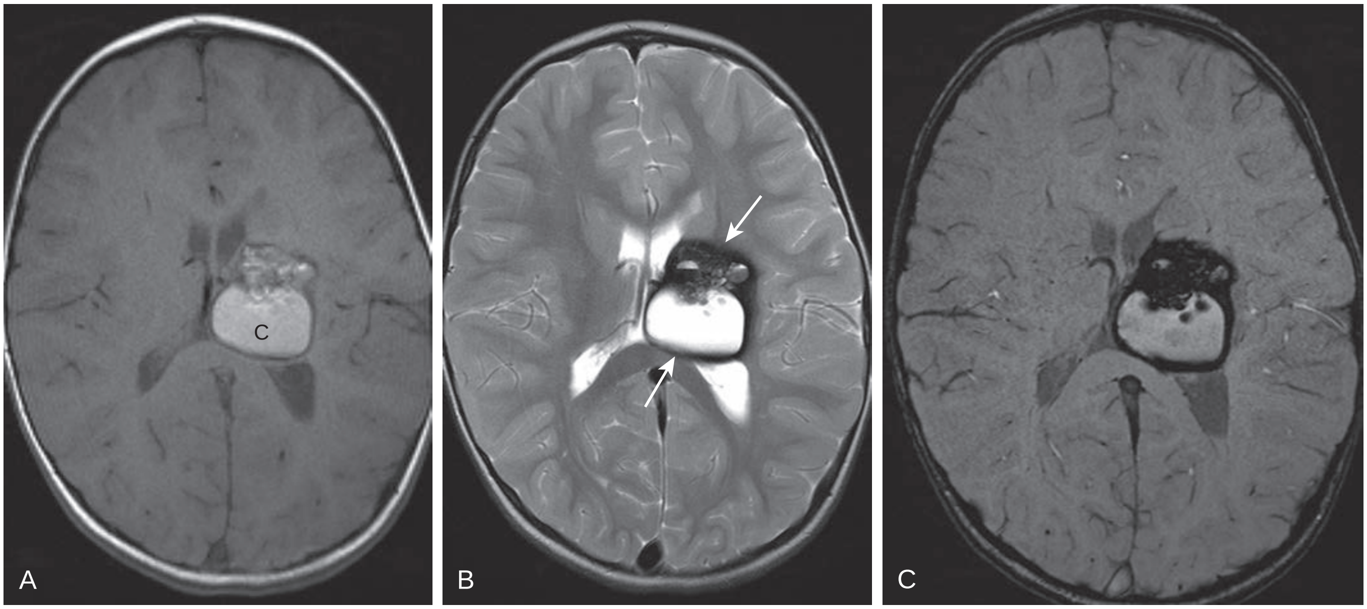


**Figure 36.7. Cavernous malformation involving the left basal ganglia and the thalamus in a 3-year-old presenting with early left hand preference and speech delay.** (A) Axial T1-weighted MRI reveals a large heterogeneous lesion with areas of T1 shortening suggestive of blood products. (B) Axial T2-weighted image demonstrates a low signal intensity rim of hemosiderin *(arrows)* surrounding the lesion. (C) Susceptibility-weighted sequence demonstrates "blooming" of the susceptibility artifact from hemosiderin.

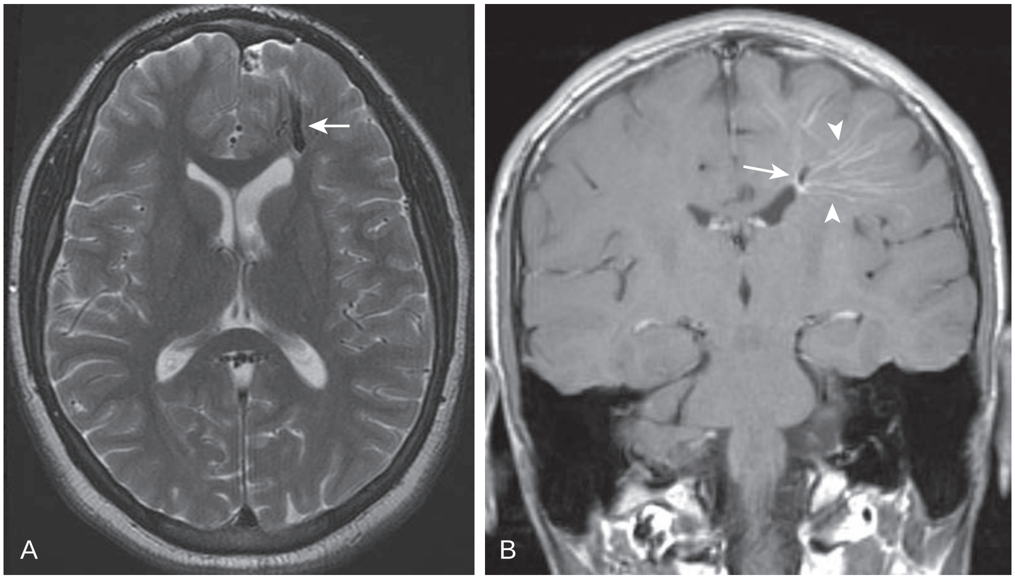

**Figure 36.8. Developmental venous anomaly in a 15-year-old with remote history of trauma presenting with increasing headaches.** (A) Axial T2-weighted MRI shows a prominent intraparenchymal dilated vein in the anterior left frontal lobe *(arrow).* (B) Postcontrast coronal T1-weighted images show the cluster of radially arranged medullary veins *(arrowheads),* the "caput medusa," associated with the abnormally dilated collecting vein *(arrow)* of a developmental venous anomaly.

in children, especially those that are giant or fusiform, may also be discovered incidentally on neuroimaging performed for unrelated reasons. Unlike in adults, in whom aneurysms show a female predominance, in children, boys are more likely to be affected than girls.[25] Comorbidities such as collagen vascular disease, polycystic kidney disease, dwarfism, moyamoya disease, and infections are present with roughly 25% of intracranial aneurysms in children.[25,29]

Saccular aneurysms, the most common form in adults, tend to occur at vessel bifurcations and are believed to be caused by chronic hemodynamic stress on the vessel wall (Fig. 36.9).[25] However, because of the time required for vascular stresses to have an effect, saccular aneurysms are much less common in children. Saccular aneurysms tend to occur most frequently at the origin of the posterior communicating artery but are also found at the origin of the anterior communicating artery and basilar artery bifurcation in children.

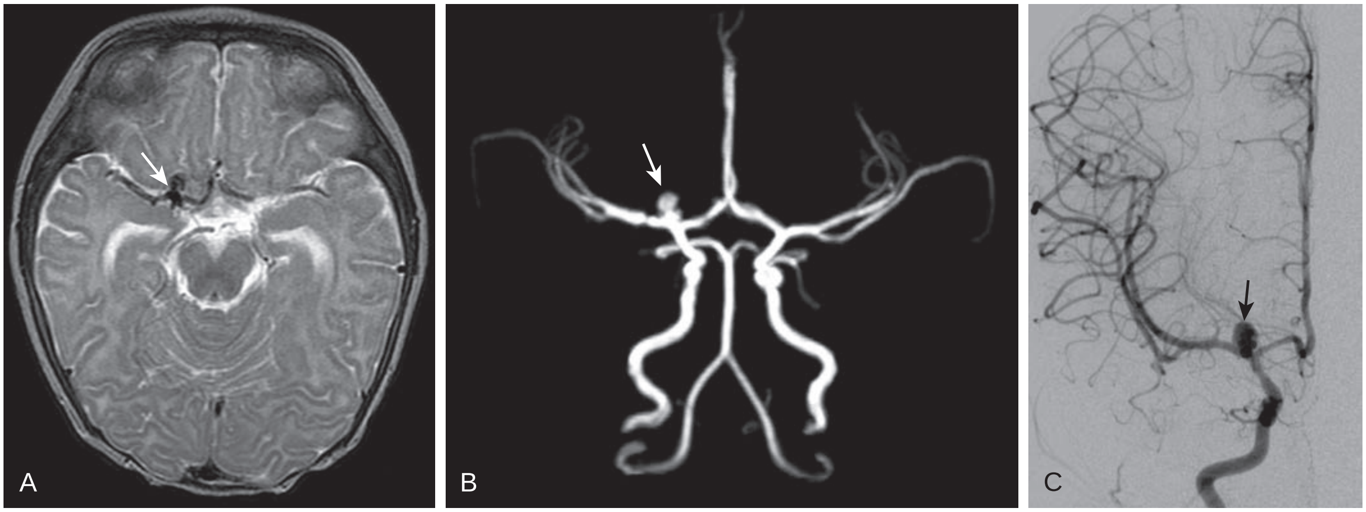

**Figure 36.9. Aneurysmal subarachnoid hemorrhage in a 5-month-old girl with new-onset seizure.** (A) Axial T2-weighted MRI demonstrates a region of signal void *(arrow)* near the right internal carotid artery–middle cerebral artery bifurcation. (B) Time-of-flight MRA demonstrates flow-related enhancement in a lobulated saccular aneurysm *(arrow)* involving the proximal M1 segment of the right middle cerebral artery. (C) The saccular aneurysm *(arrow)* is confirmed on the frontal view from a right internal carotid artery catheter angiogram.

Fusiform aneurysms can be congenital or caused by vessel dissection.[25,30] Common sites of involvement in children include the supraclinoid internal carotid artery, the proximal middle cerebral artery, and the basilar artery. Fusiform aneurysms are more likely to result in symptoms due to mass effect (e-Fig. 36.10) but can also result in subarachnoid hemorrhage, particularly when vessel dissection is the underlying cause.

Mycotic aneurysms tend to occur along distal vascular segments.[24,25] Aneurysms caused by infections are likely to lead to subarachnoid hemorrhage and may rapidly increase in size or number. Posttraumatic aneurysms may also occur in distal vascular segments.

***Imaging.*** CT is often the first study performed when an intracranial aneurysm is suspected. Subarachnoid, intraventricular, or parenchymal hemorrhage may be seen on non–contrast-enhanced CT. In giant aneurysms, a hyperdense mass in proximity to the parent artery is typically evident.[8] CTA may be used to delineate the relationship of the aneurysm to the parent vessel, the size of the aneurysm neck, intraaneurysmal thrombus, and potential collateral vessels, all factors important in treatment planning.

On MRI, an aneurysm may appear as a localized signal void, adjacent to an intracranial vessel or as a fusiform expansion of the vascular signal void. Giant aneurysms may have a lamellated appearance, with alternating areas of T1 shortening and signal void because of the presence of both thrombus and intraaneurysmal flow. Adjacent artifacts from vascular pulsation may be present in the phase encode direction of the images (see e-Fig. 36.10A). MRA can visualize aneurysm features relevant to endovascular or surgical treatment planning. Although MRA avoids radiation and can be performed without contrast, it is often limited by flow artifacts in high-flow lesions.

Catheter angiography remains the gold standard for the evaluation of intracranial aneurysms and is often performed with the intent of endovascular treatment during the procedure.[22,26] Catheter angiography, especially when combined with rotational imaging, shows the anatomic features of the aneurysm and provides information on aneurysm hemodynamics.

## KEY POINTS

- Pediatric stroke can be caused by either cerebral ischemia or intracranial hemorrhage.
- The presenting symptoms of stroke in children are frequently nonspecific, which often results in delay in diagnosis and initiation of therapy.
- The majority of children with stroke will have a persistent neurologic deficit on follow-up.
- Ischemic infarctions may be in an arterial territory or in a vascular watershed zone distribution, depending on the nature of the underlying vasculopathy.
- Vascular anomalies are classified on the basis of hemodynamics, angioarchitecture, and anatomic location.
- Aneurysms are less common in children than in adults and may come to clinical attention because of either subarachnoid hemorrhage or symptoms of local mass effect.

# 37 Pediatric Stroke

*Susan Sotardi, Michael Rivkin, Katyucia De Macedo Rodrigues, and P. Ellen Grant*

Stroke is a leading cause of disability and death in children. Three distinct time periods can be used to categorize stroke in the pediatric population: fetal (14 weeks of gestation until the onset of labor), perinatal/neonatal (between late third trimester and the first month of life), and childhood (beyond the first month of life until adulthood). The true incidence of fetal stroke is unknown, particularly because the causes of fetal demise are often uncertain, and neurologic deficits in a surviving fetus are largely undetectable until birth. The incidence of stroke observed in the perinatal/neonatal period is between 1 per 1,600 and 1 per 5,000 live births.[1] Therefore neonates constitute the second most common age group, after adults, in which stroke occurs. In children, ages 30 days to 19 years, the overall incidence is approximately 2 per 100,000.[2] Among children who survive the neurologic insult, more than 50% will develop permanent neurologic or cognitive sequelae,[3] frequently resulting in a large economic burden to the family and society.

Detection rates of stroke across fetal, neonatal, and childhood populations are rising due to improved imaging techniques, as well as higher awareness of pediatric stroke among medical professionals. However, despite improved diagnostic modalities, the cause of the stroke often cannot be determined with certainty; delays in diagnosis along with multiple, overlapping risk factors frequently complicate the clinical picture. The causes of stroke in the pediatric population are shown in Box 37.1. These etiologies can be categorized by both patient age and the vessel of origin: arterial versus venous. In the United States, the epidemiology of pediatric stroke has shifted from infectious etiologies, still common in the developing world, to congenital and genetic disorders, such as congenital heart disease, sickle cell anemia, extracranial carotid dissection, and thrombophilia.

Delayed recognition of pediatric stroke is common and leads to important delays in treatment. Clinical presentation of pediatric stroke differs by age and etiology, which frequently confounds early diagnosis. In a study of perinatal stroke, clinical presentations included seizures (72%), diffuse neurologic signs (63%), abnormal tone (38%), or encephalopathy (39%).[4] In children presenting to emergency rooms, several symptoms independently associated with stroke include: being well the week before presentation, face weakness, arm weakness, and inability to walk.[5] In children presenting with venous thrombosis, 58% of the children had seizures, 76% had diffuse neurologic signs, and 42% had focal neurologic signs.[6] Because the presentation, causes, diagnosis, treatment, and outcomes of pediatric stroke differ significantly from adults, approaches to adult stroke are not necessarily applicable to the pediatric population. While treatment guidelines have been established for adults, the hyperacute management of pediatric stroke continues to emerge.[7] Tissue plasminogen activator is now being administered in several pediatric stroke centers to children over the age of 2 years with stroke of less than 4.5 hours duration, and the use of endovascular thrombectomy, while nascent, is emerging in children over the age of 2 years with a somewhat longer timeframe.[8]

## FETAL STROKE

Fetal stroke is defined as occurring between 14 weeks of gestation until the onset of labor. Although diagnosis may be made by prenatal ultrasound, it has a low sensitivity for identifying fetal infarcts, and strokes identified by antenatal ultrasound screening are typically large.[3] Detection of fetal stroke is often delayed until the neonatal period or even later in life, when deficits become clinically perceptible and the child is diagnosed with presumed perinatal stroke. These poor detection rates limit the assessment of fetal stroke incidence rates.

### Risk Factors

Fetal stroke has different risk factors, clinical presentation, and outcomes compared with perinatal or childhood strokes. In more than 50% of cases of fetal stroke, no obvious cause is determined.[3] Maternal conditions associated with fetal stroke include: diabetic ketoacidosis, immune thrombocytopenic purpura, warfarin use, trauma, maternal fever with gastroenteritis, and antiepileptic medications.[3] Pregnancy-related factors include: fetal alloimmune thrombocytopenia, placental hemorrhage/thrombosis, abruptio placenta, multiple gestations, and twin-twin transfusion syndrome. Fetal conditions include: pyruvate decarboxylase deficiency, cytomegalovirus infection, non-A/non-B hepatitis, von Willebrand disease, and protein C deficiency.[3]

### Imaging Findings

Prenatal ultrasound is the most common screening tool for fetal brain abnormalities but is limited for the evaluation of stroke. Ultrasound detection rates are low for small and acute infarcts, and imaging findings are often not specific to stroke.[3] Injury location and suggestion of a vascular distribution may raise concern for infarction; however, ultrasound cannot provide a definitive diagnosis.

Detection of a brain abnormality on prenatal ultrasound is often further evaluated with fetal magnetic resonance imaging (MRI).[9] Fetal MRI has improved detection for ischemia and is the imaging modality of choice for confirming and assessing the extent of fetal ischemic brain injury (e-Fig. 37.1). Single-shot turbo (fast) spin echo T2-weighted sequences are most frequently utilized to minimize motion artifacts. It is also possible to obtain T1-weighted images, T2*-weighted images, T2/T1-weighted images, diffusion-weighted imaging (DWI), and spectroscopic data. Importantly, unlike in older children and adults, fetal diffusion-weighted MRI sequences may not be reliable in predicting the approximate onset of an ischemic event.[10]

The most common findings associated with fetal stroke are intraparenchymal hemorrhage (91%), ventriculomegaly (59%), porencephaly (13%), and hydrocephalus.[3] The pattern of parenchymal injury can suggest a venous or arterial origin of the stroke. Arterial ischemic strokes (AIS) in the prenatal period usually involve the major arterial territories, most commonly the middle cerebral artery (MCA). Venous strokes frequently result in hemorrhage, and hemorrhagic infarct should raise concern for venous thrombosis.

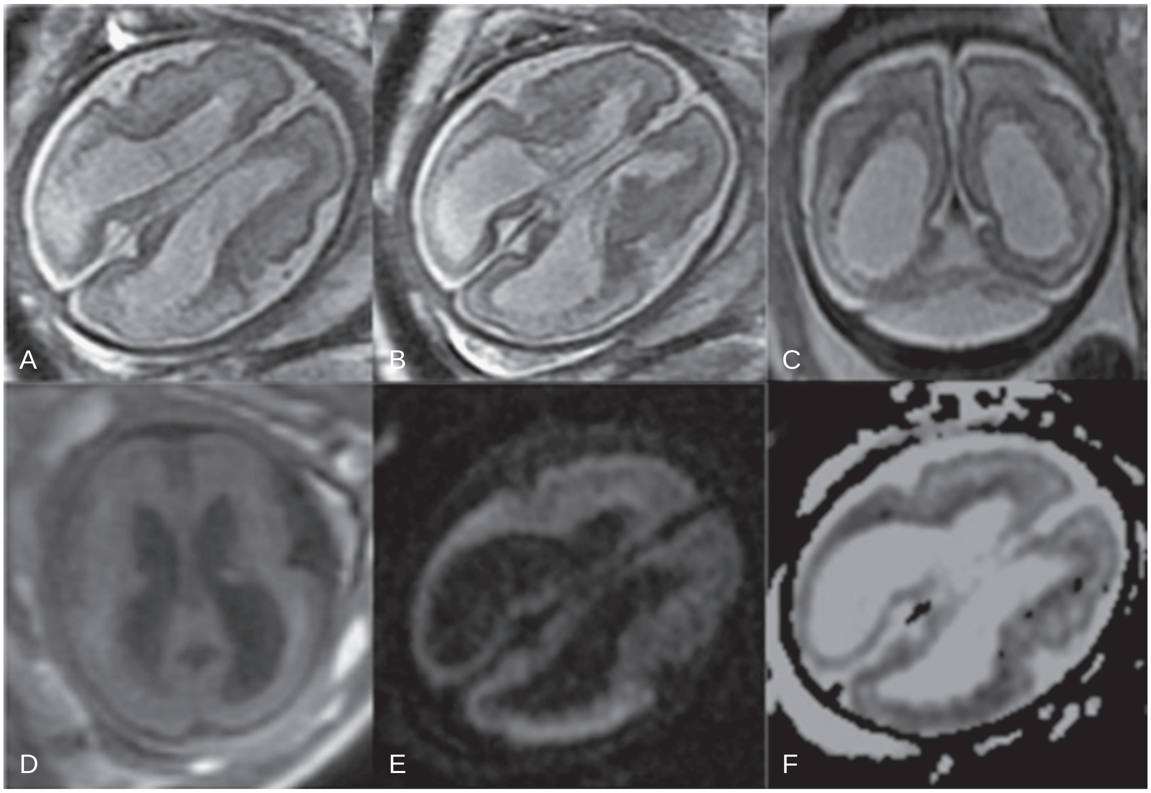
The age of the fetus at the time of infarct can contribute to the subsequent pathology and pattern of injury.[11] As early as 12 weeks' gestation, supratentorial hydranencephaly can be seen as the result of bilateral internal carotid artery infarcts. If an ischemic

## Abstract:

Stroke is a leading and under-recognized cause of disability in the pediatric population. Limited data on the detection of pediatric infarcts, as well as the causative etiology, contributes to a lack of understanding about stroke in children. Fetal stroke is defined as occurring between 14 weeks of gestation until the onset of labor and differs significantly in its clinical risk factors, presentation, imaging features and outcomes, when compared with perinatal or childhood infarcts. Perinatal stroke occurs between late third trimester and the first month of life. Arterial ischemic, venous and hemorrhagic strokes in the neonatal/perinatal period are separate entities with differing risk profiles and imaging characteristics. Childhood stroke occurs between 30 days and 18 years of age. Childhood stroke is distinct from neonatal and fetal stroke, with independent risk factors including vasculopathies/vasculitis, hypercoagulable states and genetic disorders. While imaging features of pediatric stroke may overlap, important patterns which help to distinguish these entities are presented in this chapter.

## Keywords:

Fetal infarct
Neonatal infarct
Pediatric infarct
Ischemic event
Stroke



**e-Figure 37.1. Fetal infarct.** A 30-year-old female underwent MRI scan after fetal ventriculomegaly was found on routine prenatal ultrasound at 29 weeks' gestational age. (A–C) T2-weighted MR images show dilatation of the lateral ventricles associated with mixed decreased and increased T2 signal, and thinning and irregularity of the periatrial white matter. (D) T1-weighted MR image shows that the regions of decreased T2 signal are associated with increased T1 signal consistent with evolving hemorrhage. (E) DWI and (F) ADC map also demonstrate decreased diffusion within the periventricular white matter, suggesting associated ischemic necrosis.

### BOX 37.1 Causes of Pediatric Stroke

**ARTERIAL ISCHEMIC STROKE**

**Cardiac**

Congenital heart disease
Valvular heart disease
Neoplasm, myxomas
Cardiac surgery
Myocarditis, cardiomyopathy

**Cerebral Vasculopathy**

Infection (e.g., meningitis)
Collagen vascular disease (e.g., systemic lupus erythematosus, giant cell arteritis, Takayasu arteritis, Kawasaki arteritis)
Primary angiitis of the central nervous system
Viral infection (e.g., varicella)
Trauma, dissection

**Disorders of Coagulation**

Protein C or S deficiency
Antithrombin III deficiency
Anticardiolipin antibodies
Lupus anticoagulant
Dysfibrinogenemia
Polycythemia and hyperviscosity

**Moyamoya**

Idiopathic/familial (Japanese)
Secondary (e.g., sickle cell disease)
Neurofibromatosis 1
Radiation vasculopathy

**Inborn Errors of Metabolism**

Fabry disease
Hyperhomocysteinemia
Ehlers-Danlos syndrome (type IV)

**SINOVENOUS THROMBOSIS**

Infection of the head and neck
Dehydration
Hypercoagulable states
Chemotherapeutic agents
Iatrogenic

event occurs during neuronal migration, particularly between 22 to 24 weeks' gestational age, the injury may result in cortical disorganization and polymicrogyria.[12,13] Before approximately 27 weeks' gestational age, the fetal brain lacks a glial response to injury; after 27 weeks, the fetal brain can demonstrate a glial response, which is typically seen as T2 hyperintense signal at the periphery of the infarct.[14] Schizencephaly occurs at less than 24 weeks of gestation and is thought to be due to destruction and defective development of a segment of the immature prosencephalic cortical mantle, potentially a consequence of ischemic etiologies.[11] Porencephaly resulting from cystic degeneration, without gliosis, can be seen before 27 weeks' gestation. The transmantle variant of porencephaly that follows prenatal AIS results from insults greater than 24 weeks' gestation.[11]

## Outcomes

There is minimal data available regarding outcomes in fetal stroke. In one study, 78% (35/45) of in utero strokes resulted in either death or adverse neurodevelopmental outcome at ages 3 months to 6 years.[3] Survivors may have developmental delay, cerebral palsy, and seizures.[3] In another small study, those with resulting cystic encephalomalacia plus atrophy had worse cognitive outcomes than children with atrophy or gliosis alone.[15] However, generalization of these data to individual fetuses is difficult due to the small numbers of cases as well as variability in infarct location and size.

# PERINATAL/NEONATAL STROKE

Perinatal stroke occurs between late third trimester and the first month of life, usually defined between 28 weeks' gestational age to 28 days old.[3] The incidence of AIS in newborns is reported as 1 in 2,300 to 5,000 deliveries,[16] and the yearly incidence of cerebral sinovenous thrombosis (SVT) in term newborns is reported as 1.4 to 12 per 100,000.[17] In this age group, the differentiation of ischemic stroke from hypoxic-ischemic injury may be challenging, particularly due to significant overlap in imaging findings, as well as coexisting pathophysiology. However, accurate interpretation is important given the differences in management and prognosis.

## Risk Factors

Risk factors differ by arterial and venous etiologies, as well as by hemorrhagic infarct. Risk factors for perinatal stroke in term infants can be categorized by maternal, fetal and placental factors. However, the cause of perinatal stroke is not identified in over half of patients.

In AIS, maternal factors include: thrombophilia, infertility, prolonged rupture of membranes, preeclampsia/hypertension, gestational diabetes, abnormal maternal gestational bleeding, smoking, illegal drug use, intrauterine growth retardation, infection, and maternal fever. Fetal conditions include: thrombophilia, congenital heart disease, arteriopathy, hypoglycemia, perinatal asphyxia, infection, need of resuscitation, and Apgar score of less than 7 at 5 minutes. Placental factors include: chorioamnionitis, placental infarcts, and placenta weighing less than tenth percentile.[16,18–20]

In SVT, maternal risk factors include: preeclampsia/HELLP syndrome, diabetes, maternal shock, maternal surgery, and history of clotting disorder. Perinatal risk factors include: complicated delivery, perinatal asphyxia, and fetomaternal transfusion. Neonatal risk factors include: sepsis or meningitis, dehydration, congenital heart defect, and extracorporeal membrane oxygenation (ECMO). Prothrombotic risk factors include: antithrombin level, protein C and S levels, factor V Leiden, prothrombin factor II, and other abnormalities.[17] Independent risk factors for idiopathic hemorrhagic stroke are lower maternal age, primiparity, prior spontaneous abortion, difficult fetal transition (bradycardia and low Apgar scores), and being small for gestational age.[21]

## Imaging Findings

### Arterial Ischemic Stroke

Causes of neonatal AIS are shown in Box 37.1. Perinatal AIS leads to focal ischemic necrosis in an arterial distribution, most commonly in the MCA territory.[22] Regions of AIS can evolve into focal volume loss, glial scarring, or cystic encephalomalacia, depending on the severity of the injury.

Computed tomography (CT) can detect hemorrhage and areas of advanced infarction; however, CT can be falsely negative in small acute infarcts, particularly in the context of some low-dose techniques. MR is the preferred modality for detection and evaluation of acute neonatal AIS (Fig. 37.2). Areas of acute infarct are easily identified as regions of bright signal on DWI and decreased signal on apparent diffusion coefficient (ADC) maps, typically in a vascular territory. The reduction in ADC can persist for up to 2 weeks and is more conspicuous during the first 4 days.[23] Subtle loss of gray-white matter differentiation may be identified on T2-weighted images; however, T2 signal changes may be imperceptible within the first hours after the ischemic event. MR angiography (MRA) may be helpful in evaluating the occlusion of a major intracranial artery but is frequently limited by the type

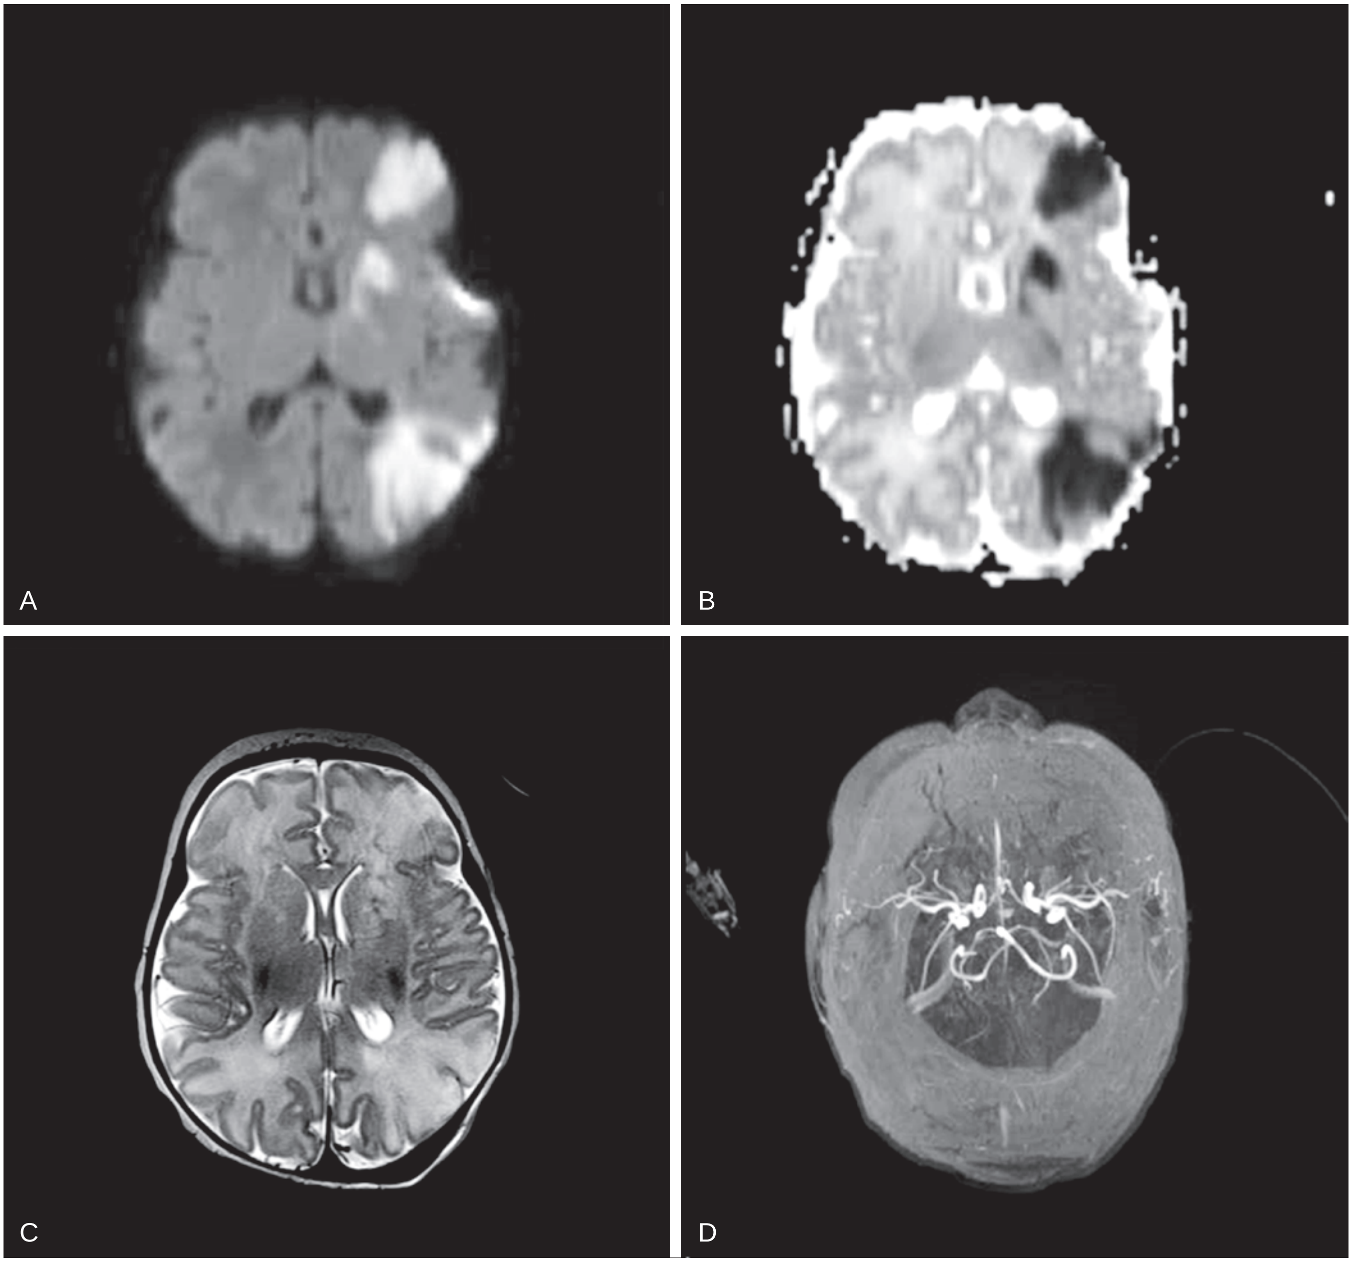


**Figure 37.2. Neonatal arterial ischemic strokes.** A 1-day-old full-term neonate with focal right-sided seizures and lip smacking. This neonate was found to have renal vein thrombosis, along with a PFO and VSD as well as the risk factor of maternal type 1 diabetes. (A) DWI and (B) ADC map demonstrate multiple acute/subacute arterial ischemic infarcts, throughout the left hemisphere in an MCA distribution, likely embolic in etiology. (C) Axial FSE T2-weighted MR image shows loss of gray-white differentiation and edema in involved regions. (D) TOF MRA image shows no evidence of luminal thrombus. *ADC,* Apparent diffusion coefficient; *DWI,* diffusion weighted images; *MCA,* middle cerebral artery; *PFO,* patent foramen ovale; *TOF MRA,* time of flight magnetic resonance angiogram; *VSD,* ventricular septal defect.

of MRA acquisition. With time-of-flight MRA sequences, turbulent or fast flow can result in the loss of normal flow-related signal, which may be mistaken for partially occlusive thrombus. Several sequences, such as arterial spin labeling (ASL)[24] and MR perfusion, may assist in determining cerebral perfusion. ASL can be used to obtain cerebral blood flow measurements and is particularly useful in determining the presence of reperfusion in areas of abnormal ADC.[25] ASL has shown hyperperfusion in the infarct core in 73% of neonatal arterial ischemic infarcts, frequently without a penumbra.[26]

Ultrasound has a high false negative rate and has limited utility in the evaluation of acute infarct,[22] but combined with color and pulsed Doppler, it remains a useful technique to evaluate the circle of Willis. It may be helpful for confirming or disproving areas of concern seen on MRA. If an intraluminal clot is identified, bedside Doppler can be used to monitor for recanalization.

## Venous Stroke

Venous strokes occur as a result of venous outflow obstruction. This may result from occlusion of a vein or venous sinus by thrombus, or by venous hypertension. Determining the exact mechanism is often complicated by the fact that venous thrombus is often not visualized and may have been resorbed before imaging.[27]

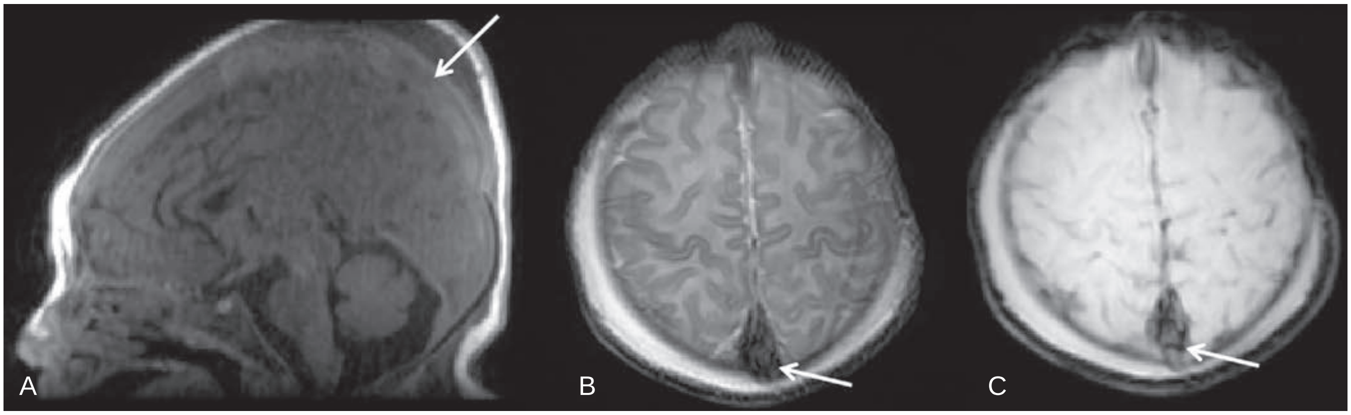

**Figure 37.3. Cerebral sinovenous thrombosis.** Neonate with Apgars of 5 and 9, presenting at 1 day of life with focal seizures. Mother had known Factor V Leiden heterozygosity. (A) Sagittal T1-weighted MR image demonstrates T1 hyperintense signal within the superior sagittal sinus *(arrow)*, consistent with SVT. (B) Axial T2-weighted and (C) gradient echo T2 MR images demonstrate hypointense signal within the superior sagittal sinus *(arrow)*, consistent with thrombus.

The common associated imaging findings of recent venous infarcts are: venous congestion, hemorrhage, and/or parenchymal ischemic injury, which may be cortical, subcortical, white matter-based, or involve deep gray matter.[28] Prior periventricular venous infarcts are assumed when unilateral parenchymal injury is identified with at least four of the following conditions: focal periventricular encephalomalacia, internal capsule T2 prolongation, cortical sparing, basal ganglia sparing, or remote hemorrhage.[29]

Preterm and term neonates show different patterns of brain lesions associated with SVT. Extensive white matter damage is predominant in preterm neonates, whereas, intraventricular and thalamic hemorrhage with punctate white matter lesions are more often seen in term infants.[30] However, intraventricular hemorrhage is common in both groups.[28] Over time, the affected brain parenchyma may show encephalomalacia or gliosis; however, some infarcts may demonstrate apparent resolution on follow-up imaging.

As with AIS, ultrasound has limited sensitivity in detecting SVT, especially peripheral cortical infarction.[22] Ultrasound may visualize an echogenic clot and lesions associated with a thrombosis (such as thalamic hemorrhage), and can monitor infarct evolution and screen for complications (such as hydrocephalus secondary to intraventricular hemorrhage). There is a high incidence of SVT (4.4%) in preterm infants with a gestational age of less than 29 weeks, and a recent report suggests that serial head ultrasound may have utility in this population.[31]

Noncontrast CT is helpful for the evaluation of intracranial hemorrhage and may rarely show hyperdense clot in the involved vein or venous sinus. Contrast-enhanced CT may demonstrate filling defects within the venous structures. However, MRI is the preferred modality for confirming the diagnosis and determining the extent of associated parenchymal injury (Figs. 37.3 and 37.4). MR venography (MRV) is helpful for evaluation of thrombosis and can be performed without contrast. However, all forms of MRV, particularly the most common time-of-flight acquisition, are prone to artifacts, which may simulate clot. Correlation with gradient-echo (GRE) or susceptibility-weighted images (SWI) can confirm venous thrombosis, which "blooms" on these sequences. GRE and SWI are also useful in detecting subtle intraparenchymal hemorrhage. High-resolution, contrast-enhanced T1-weighted images are more reliable for delineation of filling defects in the venous system and may be confirmatory for suspected findings on MRV.[32] However, given the unknown risks of gadolinium exposure,[33,34] contrast should only be given if MRV and GRE/SWI results are equivocal and confirmation of an intraluminal clot would alter management.

### Neonatal Hemorrhagic Stroke

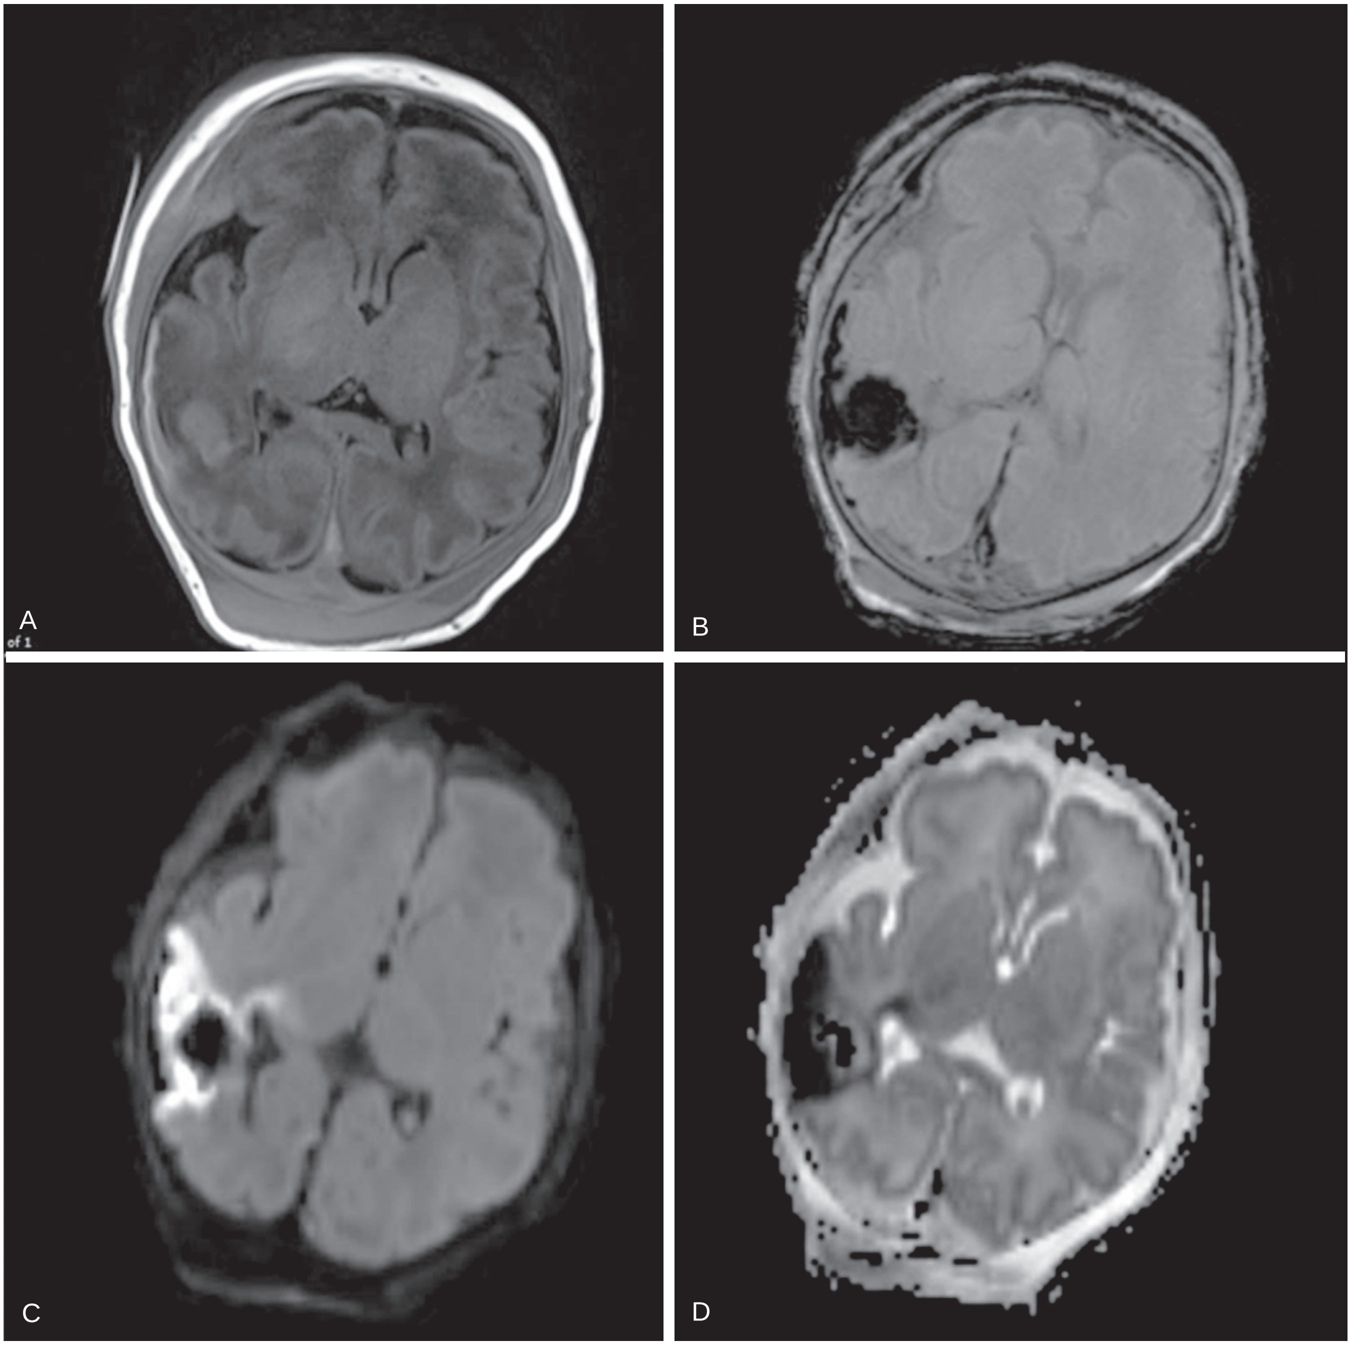
Although hemorrhagic stroke is most often the result of SVT and less often AIS, a significant proportion of cases are idiopathic and some have suggested the process constitutes a separate disease entity. Neonatal hemorrhagic stroke occurs with a reported incidence of 1 in 6,300 live births.[21] Cole et al. demonstrated that 63% of neonatal hemorrhagic strokes were idiopathic and 37% were hemorrhagic transformation of primary ischemic injuries.[21] The primary etiologies included: cerebral SVT, AIS, hypoxic ischemic encephalopathy, and presumed perinatal hemorrhagic stroke. Additional underlying abnormalities included trauma, coagulopathies, and vascular abnormalities (such as arteriovenous malformation, cavernous malformations, and aneurysm). The imaging findings of hemorrhage may be identified on ultrasound, CT, and/or MR depending on the size of the hemorrhage. MR GRE and SWI sequences are the most sensitive modalities for detecting intracranial hemorrhage (e-Fig. 37.5). Underlying structural abnormalities that may have been a source of hemorrhage usually cannot be evaluated in the acute period, so follow-up imaging is recommended to assess the underlying parenchyma once the size of hematoma has decreased or resolved.

### Outcomes

Outcomes after neonatal stroke depend on numerous factors, such as etiology, extent, and location of infarct. Perinatal stroke may result in cerebral palsy, cognitive impairments, epilepsy, and sensory impairments. Large infarctions, bilateral infarctions, and seizures tend to be associated with worse outcomes but are not definitely predictive.[35] Imaging findings of injury to specific brain regions may assist in the prediction of clinical outcomes.[36]

## CHILDHOOD STROKE

Childhood stroke can be defined as occurring after perinatal/neonatal stroke, between ages 30 days to 18 years. Based on imaging findings, the annual incidence of childhood stroke are estimated to be 2.4 cases per 100,000 patient population, higher than previously thought.[37] Recurrence of stroke in childhood also presents a significant challenge; in a recent study, 16% (56/355) of children with AIS experienced a recurrent ischemic event (stroke or transient ischemic attack [TIA]) during a follow-up period of at least 1 year.[38]



**e-Figure 37.5. Neonatal hemorrhagic infarct.** A 3-day-old female with unexplained anoxia and shoulder dystocia status after vacuum-assisted delivery. (A) Axial T1-weighted MR images demonstrate hyperintense signal consistent with hemorrhage in the right temporal lobe with overlying subpial hemorrhage. (B) SWI image confirms the right temporal lobe hemorrhage with subpial involvement. (C) High signal on DWI and (D) low signal on ADC map surrounds the hemorrhage confirming associated ischemic injury. Vessel imaging was unremarkable *(not shown)*.

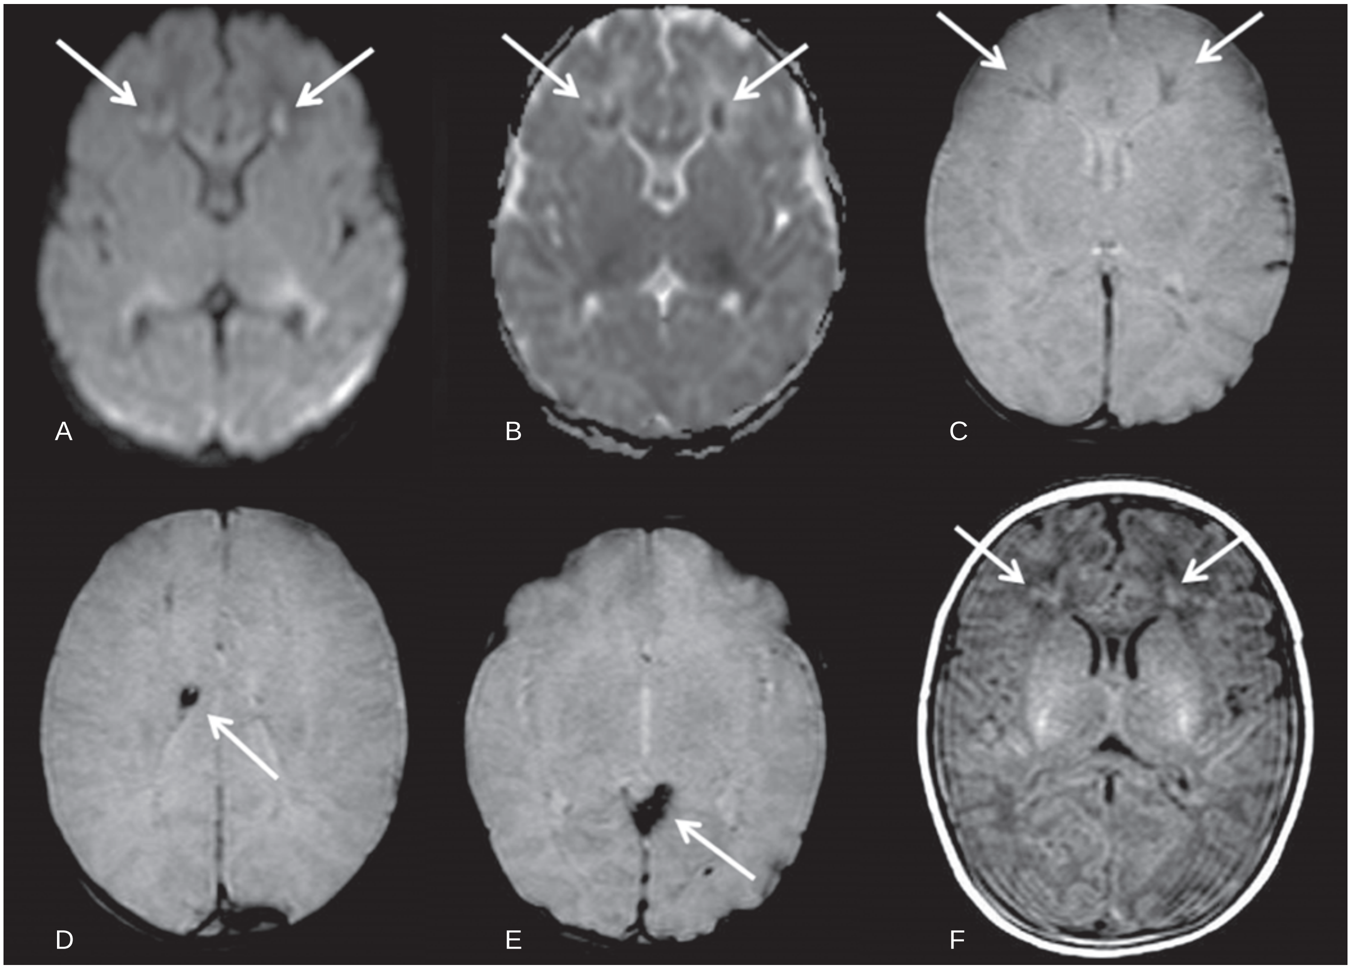


**Figure 37.4. Neonatal venous infarcts.** A 1-day-old full-term neonate with normal Apgars with multiple episodes of rhythmic jerking of the extremities in the first 24 hours of life, consistent with seizures. No known maternal risk factors. Pregnancy was complicated by small placental separation at 15 to 25 weeks. Tight nuchal cord was noted at delivery. (A) DWI and (B) ADC map demonstrate decreased diffusion in the frontal periventricular regions, in a medullary venous distribution *(arrows)*. (C–E) Axial gradient echo T2-weighted MR images demonstrate foci of blooming consistent with microhemorrhage and thrombus within the deep periventricular veins *(arrows)*. (F) Axial T1-weighted MR image demonstrates hyperintense signal in the frontal white matter in same region as blooming, likely hemorrhage *(arrows)*.

## Risk Factors

Childhood stroke is a distinct entity from neonatal and fetal stroke, with independent risk factors. The most common risk factors for stroke in children include: vasculopathies, cerebral vasculitis, primary and secondary hypercoagulable states, and genetic disorders.[39] SVT in children has been associated with numerous etiologies such as: dehydration, hypoxic-ischemic injury, postlumbar puncture, infections, medications, and multiple systemic conditions.[28]

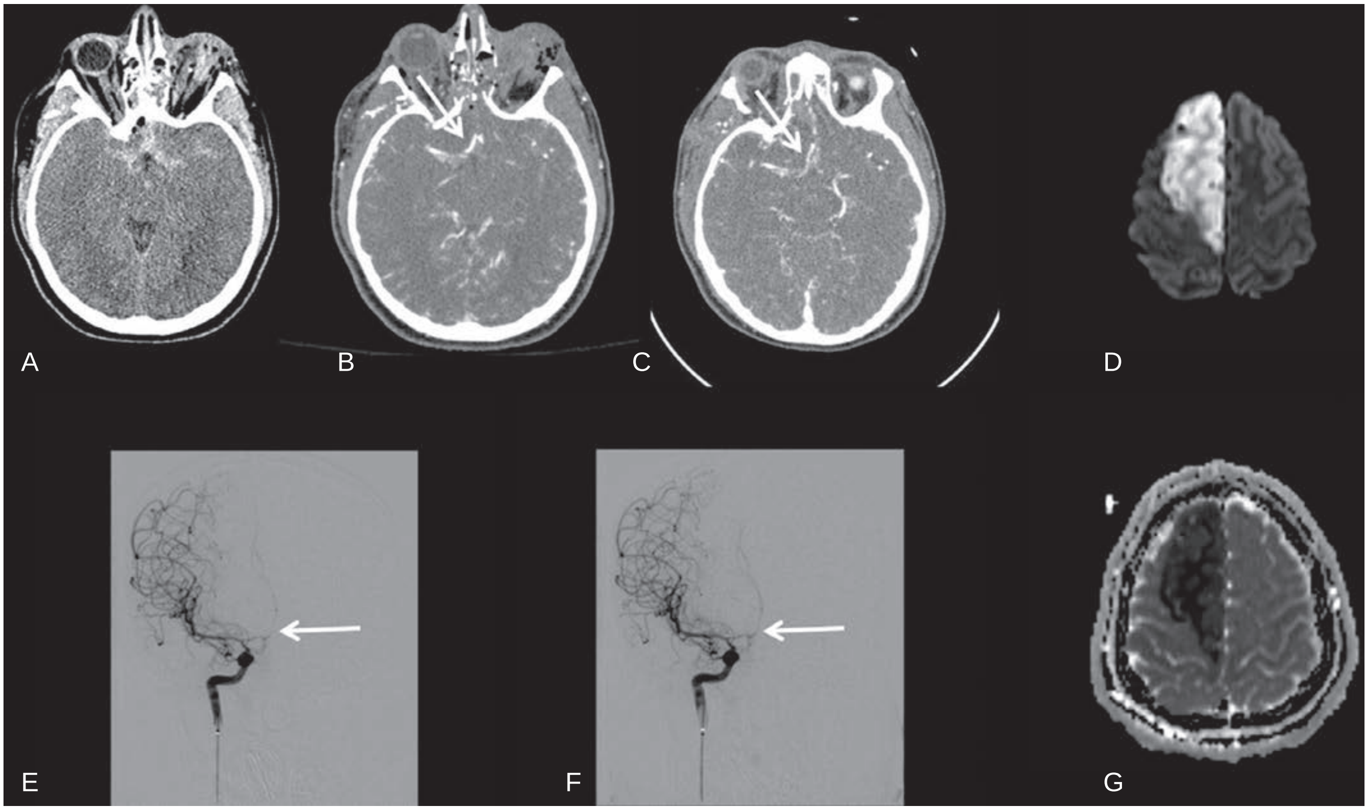
## Imaging Findings

Boxes 37.2 and 37.3 demonstrate general guidelines for the time-course of findings of stroke seen in CT and MR, respectively.

### Arterial Ischemic Stroke

Numerous etiologies are associated with childhood AIS, as seen in Box 37.1. In approximately one-third of childhood AIS, the cause of stroke is undetermined.[40] The major sources of childhood AIS are arteriopathy, hypercoagulable states, and thromboembolism.[41,42] Arteriopathies have numerous underlying etiologies, including transient cerebral arteriopathy, trauma-related vascular injury such as arterial dissection (Fig. 37.6) or vasospasm after subarachnoid hemorrhage (e-Fig. 37.7), postinfectious vasculitis (Fig. 37.8), immune-related arteritides, and sickle cell disease arteriopathy. Hypercoagulable states, such as protein C or S deficiency, antithrombin III, or factor V Leiden mutation, are also known causes of AIS. Thromboembolism may originate from intracranial or extracranial vessels, as well as cardiac disorders such as congenital or acquired heart disease, intracardiac shunts, and procedures.[41,42]

Arteriopathies are responsible for up to two-thirds of first-time stroke in previously healthy children.[43,44] The most common arteriopathy, known as transient cerebral arteriopathy (TCA), presents as a unilateral arteriopathy involving the anterior circulation, such as the distal internal carotid, proximal middle cerebral, or proximal anterior cerebral arteries.[45] Differentiating TCA from arterial dissection can be challenging, given that both are unilateral. However, the time course of the diseases differs significantly. In TCA, the stenosis increases over a period of 3 months and then stabilizes beyond 6 months, whereas arterial dissection usually improves over the initial 3 months.[45]



**e-Figure 37.7. Traumatic subarachnoid hemorrhage with vasospasm and infarct.** A 15-year-old male who suffered a gunshot wound to the face, globe trauma, with intracranial subarachnoid and intraparenchymal hemorrhage. Five days later, the patient developed right anterior cerebral artery territory infarct, consistent with vasospasm associated with traumatic subarachnoid hemorrhage. (A) CT shows subarachnoid hemorrhage seen in the suprasellar cistern. (B) At admission, the proximal right anterior cerebral artery (ACA) demonstrates normal caliber *(arrow)*. (C) Five days later, the proximal right ACA demonstrates irregular narrowing, consistent with vasospasm *(arrow)*. (D) DWI and (G) ADC map show acute infarct in the right ACA territory. (E) Digital subtraction angiogram demonstrates vasospasm of the right ACA *(arrow)* (F) with slight improvement *(arrow)* on postverapamil angiogram.

### BOX 37.2 Cerebral Infarction: Computed Tomographic Findings

**HYPERACUTE INFARCT (<12 HR)**

Normal (50%–60%)
Hyperdense artery (25%–50%)

**ACUTE (12–24 HR)**

Low-density basal ganglia
Loss of gray–white interfaces (insular ribbon sign, obstruction of cortex–medullary white matter border)
Sulcal effacement

**1–3 DAYS**

Increasing mass effect
Wedge-shaped low-density area that involves both gray and white matter
Hemorrhagic transformation may occur (basal ganglia and cortex are common sites)

**4–7 DAYS**

Gyral enhancement
Mass effect and edema persist

**1–8 WEEKS**

Contrast enhancement persists
Mass effect resolves
Transient calcification can occur (pediatric strokes)

**MONTHS TO YEARS**

Encephalomalacic change, volume loss
Calcification rare

*Data from Osborn AG.* Diagnostic neuroradiology: A text atlas, *St. Louis: Mosby-Year Book; 1994.*

### BOX 37.3 Cerebral Infarction: Magnetic Resonance Imaging Findings

**IMMEDIATE**

Absence of normal flow void
Intravascular contrast enhancement
Low apparent diffusion coefficient
Perfusion alterations

**<12 HOURS**

Anatomic alterations on T1-weighted image (T1WI)
Sulcal effacement
Gyral edema
Loss of gray–white interface

**12–24 HOURS**

Hyperintensity develops on T2-weighted image (T2WI)
Meningeal enhancement adjacent to infarct
Mass effect

**1–3 DAYS**

Intravascular and meningeal enhancement begins decreasing
Early parenchymal contrast enhancement
Signal abnormalities striking on T1WI, T2WI
Hemorrhagic transformation may become evident

**4–7 DAYS**

Striking parenchymal contrast enhancement
Hemorrhage apparent in 25%
Mass effect and edema begin to diminish
Intravascular and meningeal enhancement disappear

**1–8 WEEKS**

Contrast enhancement often persists
Mass effect resolves
Decrease in abnormal signal on T2WI sometimes noted (fogging effect)
Hemorrhagic changes evolve, become chronic

**MONTHS TO YEARS**

Encephalomalacic changes, volume loss in affected vascular distribution
Hemorrhagic residua (hemosiderin/ferritin)

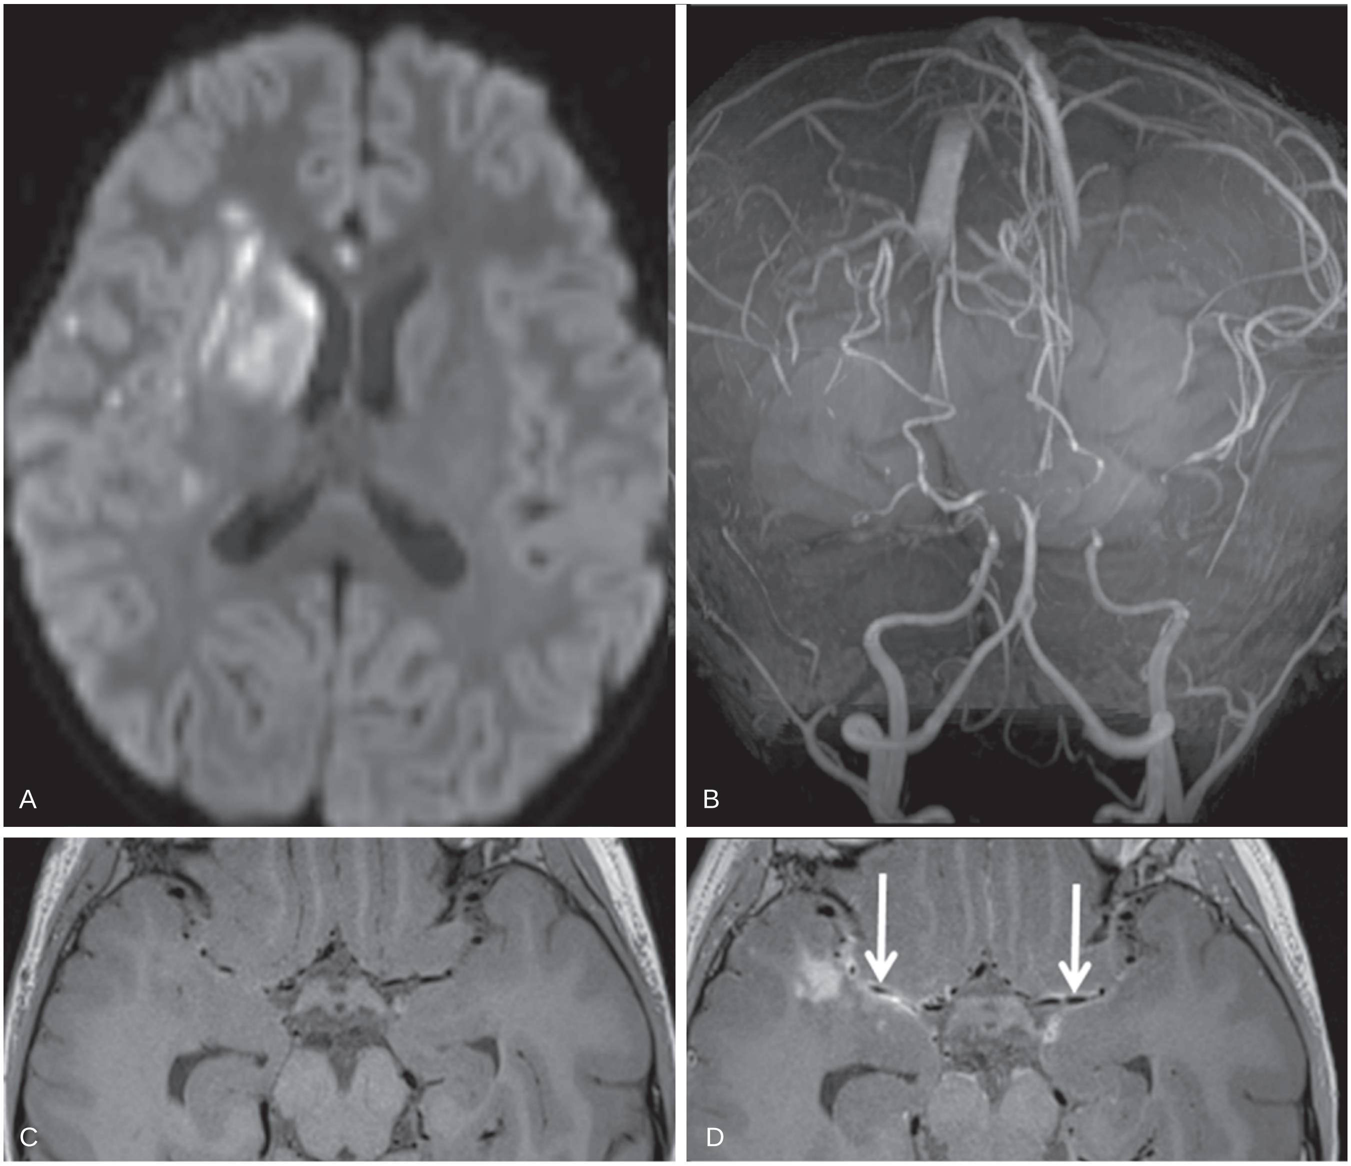
*Data from Osborn AG.* Diagnostic neuroradiology: A text atlas, *St. Louis: Mosby-Year Book; 1994.*

Arterial dissection may occur spontaneously or after trauma. The mechanism of infarct is formation of an intramural thrombus that can result in occlusion of the vessel or distal emboli. MRI with MRA is the initial diagnostic modality of choice (see Fig. 37.6). If noncontrast MRA sequences are degraded by flow-related artifacts, CTA may be helpful in confirming the lumen diameter. Imaging findings suggestive of dissection are: abrupt segmental narrowing with an intimal flap, a beaded appearance of the vessel, or pseudoaneurysm formation.[46] T1-weighted fat-saturated MR sequences can occasionally demonstrate eccentric hyperintense signal from the intramural hematoma of the dissection.

There are two classes of immunologic arteritides causing pediatric stroke: those associated with a systemic disease such as lupus, scleroderma, or polyarteritis nodosum, and primary central nervous system (CNS) arteritides.[44] Childhood primary angiitis of the CNS (cPACNS) is an increasingly recognized vasculitic inflammatory brain disease in previously healthy children. Three types of cPACNS have been described: nonprogressive angiography-positive large-medium vessel, progressive angiography-positive large-medium vessel, and angiography-negative small vessel disease.[44] For large vessel cPACNS, MRI and MRA with contrast should be performed. MRI most commonly shows unilateral ischemic lesions in large vessel territories;[47] however, bilateral involvement may occur. MRA of the affected vessel segment may reveal wall thickening and enhancement due to inflammation, as well as unilateral or bilateral stenosis, with beading and irregularity (e-Fig. 37.9). Children with small vessel, angiography-negative cPACNS have normal MRA and conventional angiography studies; meningeal contrast enhancement is relatively specific but infrequently seen.[44] Brain biopsy is often required for diagnosis.

Moyamoya syndrome is an arteriopathy associated with sickle cell disease, neurofibromatosis type 1, and trisomy 21[48]; if the cause remains undetermined, the findings are referred to as moyamoya disease. The annual risk of stroke in moyamoya disease is 3.2%,[49] and the risk of stroke in moyamoya syndrome depends on the etiology. In both moyamoya syndrome and disease, progressive vasculopathy results in stenosis of the intracranial arteries, with predilection for terminal portions of the internal carotid arteries. Thin, irregular collateral vessels, classically from the lenticulostriate arteries, lead to a classic "puff-of-smoke" appearance on angiography. MRI may demonstrate loss of the normal flow void in the distal carotid branches on T2-weighted images, as well as development of abnormally large and irregular collateral vessels (Fig. 37.10). FLAIR images often show increased signal in distal vessels, as a result of slow flow. Carotid stenosis may be seen on MRA, but is frequently overestimated in severity.[50] Postcontrast MRA and CTA can improve assessment of the vasculature. DWI is both sensitive and specific for the evaluation of acute infarct. Perfusion-weighted and ASL sequences may be helpful for assessing alterations in cerebral flow.

Sickle cell disease carries a significantly increased risk of stroke in children.[51,52] The rigid, sickle-shaped red blood cells lead to vascular occlusion, and chronic vessel wall damage results in stenotic vessels. The proximal MCA or distal internal carotid artery (ICA)



**e-Figure 37.9. Large vessel arteritis.** Bilateral progressive large vessel cerebral arteritis in a 6-year-old female presenting with a stuttering course of progressive motor deficits. Evaluation of blood and CSF was negative for infection or malignancy and did not reveal evidence of a systemic inflammatory disorder. This patient improved with treatment with high dose steroids. (A) Axial DWI shows decreased diffusion in a multifocal distribution. (B) TOF MRA shows loss of flow related enhancement in both intracranial internal carotid arteries beginning proximal to bifurcation, and the proximal bilateral MCAs and PCAs. (C) Axial T1-weighted 3D fast spin echo MR image at the level of the circle of Willis shows bilateral MCA beading and irregularity. (D) Axial postcontrast T1-weighted 3D fast spin echo MR image (vessel wall imaging) shows bilateral MCA enhancement *(arrows)* consistent with vasculitis.

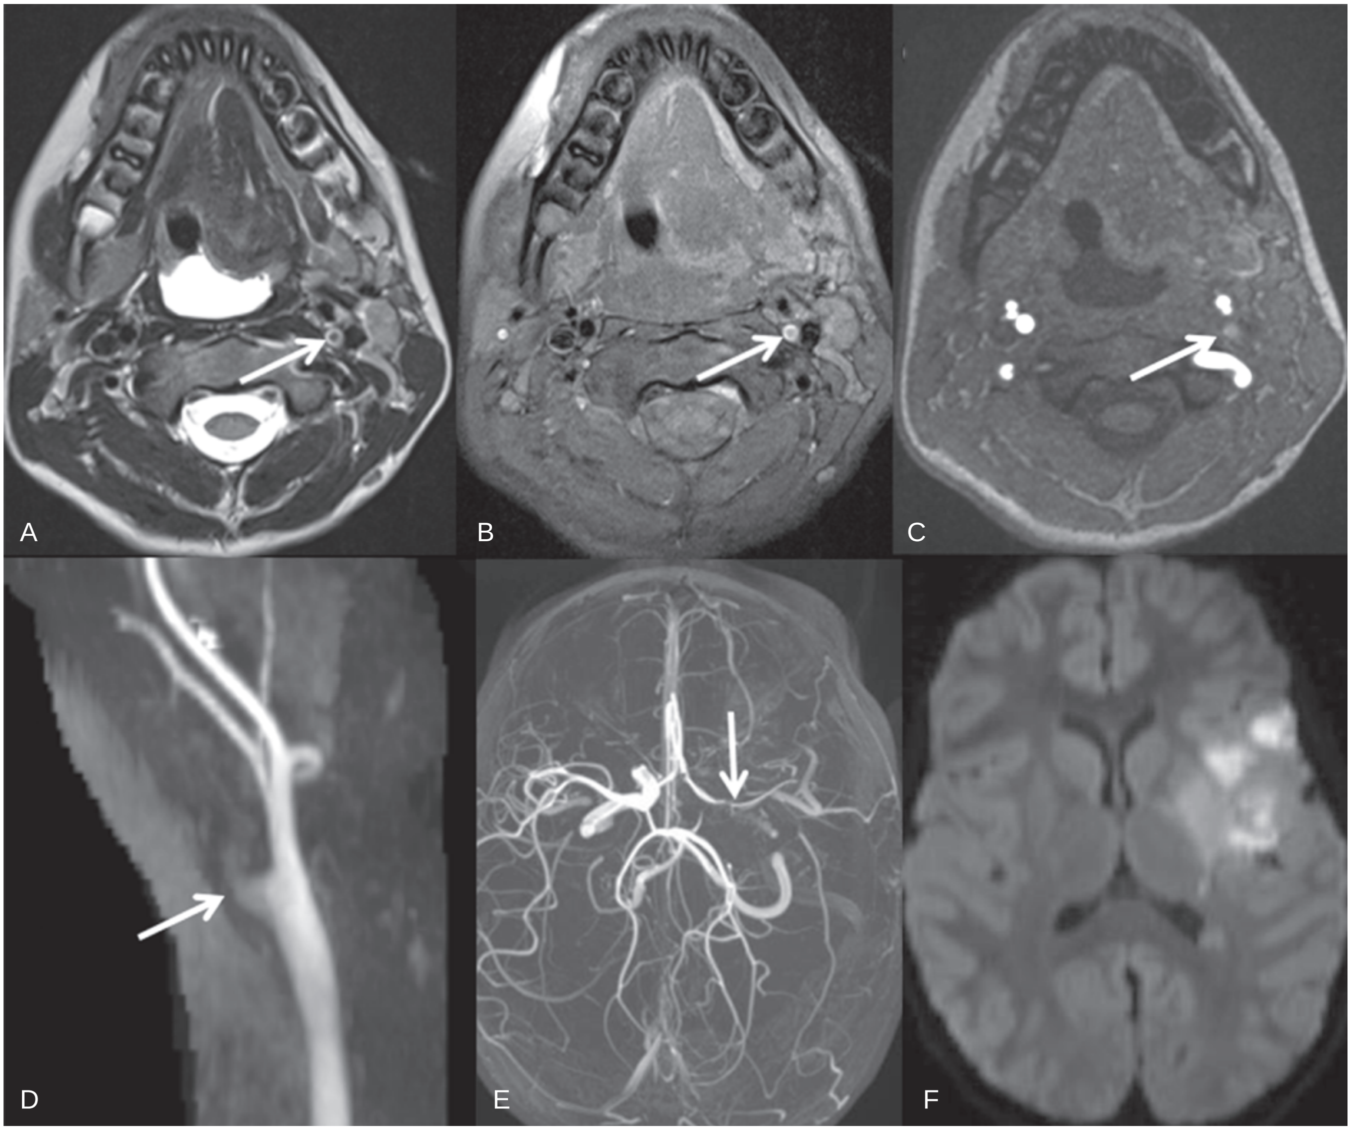


**Figure 37.6. Carotid dissection with acute infarction.** An 8-year-old female who presented with an episode of decreased responsiveness, right-sided weakness, and left eye deviation after emerging from a swimming pool without clear history of trauma. (A) Axial FSE T2-weighted MR image demonstrates T2 hyperintense signal circumferentially in the left carotid *(arrow)*, suggesting subintimal hematoma/dissection. (B) Fat-saturated T1-weighted MR image also shows the circumferential hyperintense signal *(arrow)* confirming intramural hematoma/dissection. (C) TOF MRA of the neck shows loss of normal flow related enhancement in the same region *(arrow)*. (D) MIP from the same TOF MRA of the neck and (E) MIP from the 3D TOF brain demonstrates loss of flow-related signal in the left internal carotid artery from just distal to the bifurcation to its bifurcation with decreased flow-related enhancement in the left MCA *(arrow)*. (F) DWI demonstrating associated left MCA infarction. *FSE,* Fast spin echo; *MIP,* maximum intensity projection; *TOF MRA,* time of flight magnetic resonance angiogram; *MCA,* middle cerebral artery.

branches are the most commonly involved vessels. Biannual screening with transcranial Doppler (TCD) imaging is routinely performed, and abnormally elevated velocities from stenotic arteries necessitates blood transfusion to prevent stroke.[53] Prior to TCD screening, stroke occurred in 5% to 10% of children.[51] Brain MRI is usually performed to evaluate children with sickle cell anemia presenting with acute onset of symptoms such as seizures, or motor or sensory deficits. Acute infarcts may be superimposed on a diseased brain with atrophy and chronic changes. In the setting of moyamoya syndrome, MRA commonly shows irregular stenotic arteries involving the anterior circulation with leptomeningeal collaterals. CTA has restricted use in the evaluation of patients with sickle cell disease, as iodinated contrast predisposes to sickling. Low osmolar agents should be used, along with transfusion and hydration to reduce the risk of complications.

## Venous Stroke

In children, SVT is the primary cause of venous stroke, with incidence of approximately 0.67 case per 100,000 children per year.[6] Risk factors include head and neck disorders (29%), acute systemic illnesses (54%), chronic systemic diseases (36%), and prothrombotic states (41%).[6] Dehydration, complicated otitis media, and sinusitis are the major risk factors in older children. Without treatment, 30% of SVT patients will have propagation of the thrombus, which are associated with new venous infarcts in 40% of children.[54]

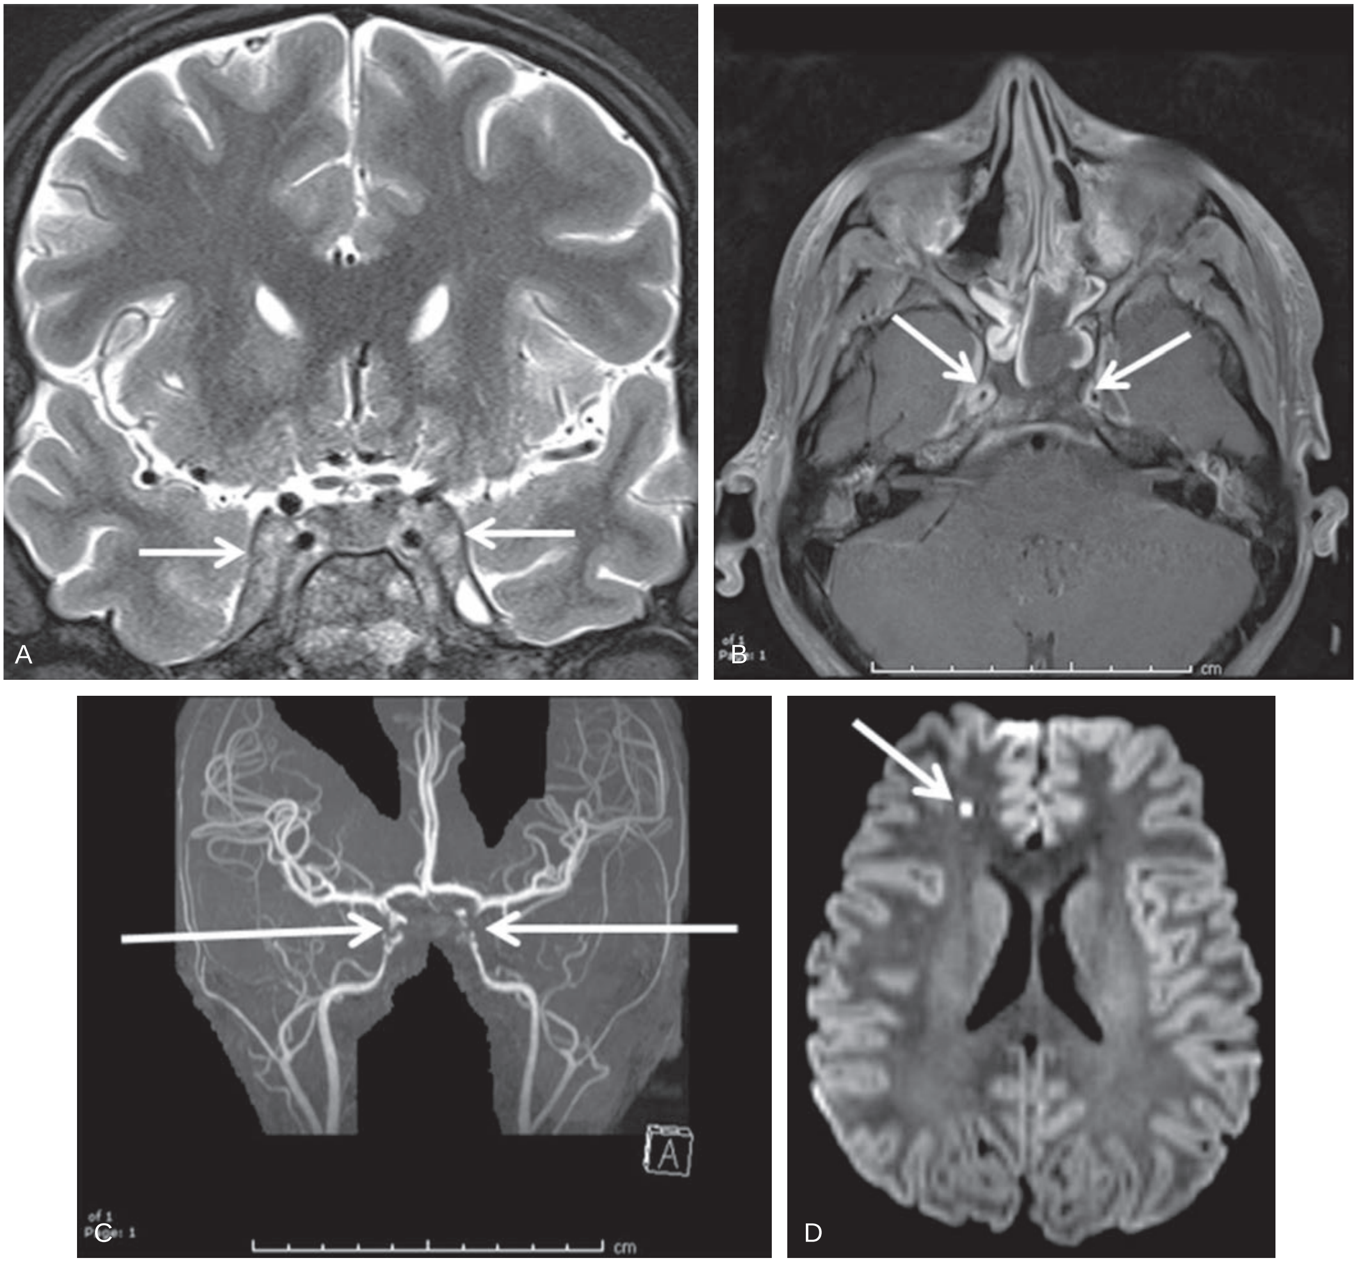

**Figure 37.8. Postinfectious vasculitis with infarct.** A 15-year-old female with bilateral sinusitis, cavernous venous thrombosis, gram-negative bacteremia, and skull base osteomyelitis with high fevers and new impaired horizontal eye movements. (A) Coronal fat-saturated FSE T2-weighted MR image demonstrates enlarged thrombosed bilateral cavernous sinuses *(arrows)*. (B) Axial fat-saturated postcontrast T1-weighted MR image demonstrates wall thickening and stenosis of the cavernous internal carotid arteries *(arrows)*, consistent with arteritis. Extensive sinusitis is present. (C) 3D TOF MRA confirms bilateral cavernous carotid involvement with irregular narrowing *(arrows)*. (D) DWI demonstrates a punctate acute embolic infarct *(arrow)* in the right frontal deep white matter.

Imaging findings of SVT in children are similar to those discussed previously. CT should only be considered in children who cannot obtain an adequate MR without sedation or for whom sedation risks during MRI outweigh the risks of radiation exposure. MR sequences are helpful for evaluation of SVT and venous infarct include DWI, GRE/SWI, MRV, and T1-weighted precontrast and postcontrast high-resolution sequences. DWI is both sensitive and specific for the evaluation of venous infarct. GRE or SWI may be useful for demonstrating thrombus, which frequently "blooms" on these sequences. MRV is prone to artifacts that may simulate clot; contrast-enhanced T1-weighted images are more reliable for delineation of venous filling defects and may be confirmatory for suspected findings on MRV.[32]

## ALTERNATIVE DIAGNOSES

Numerous diseases have similar clinical presentations as stroke and should be considered before diagnosis, including migraine

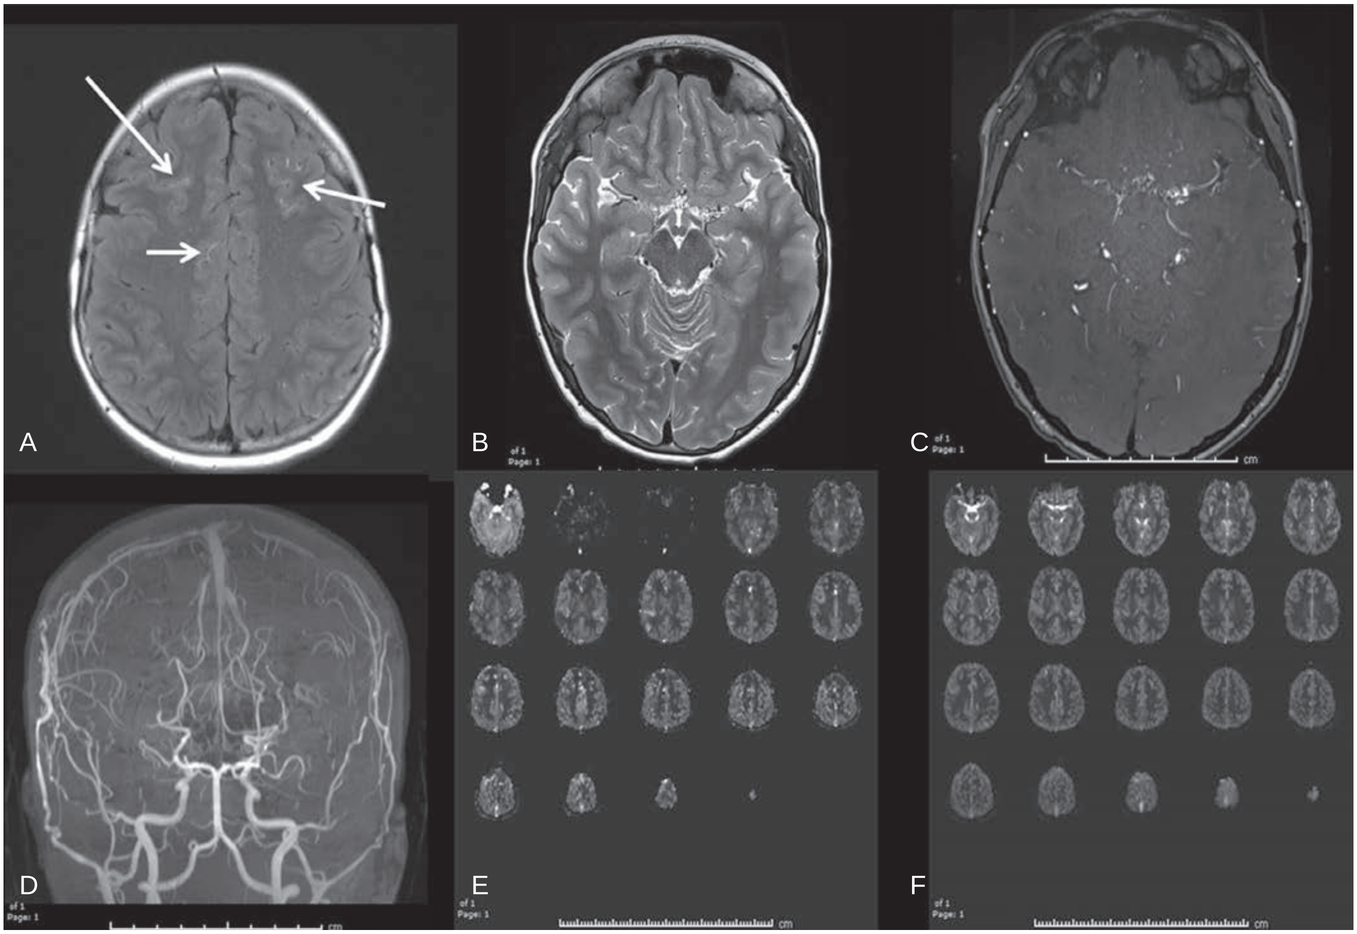

**Figure 37.10. Moyamoya disease vasculopathy.** Asymptomatic 13-year-old male with moyamoya disease status postpial synangioses. No known history of sickle cell disease or other causative etiologies. (A) Axial FLAIR image demonstrates hyperintense pial vessels *(arrows)*, consistent with slow flow in collateral vessels. (B) FSE T2-weighted, (C) TOF MRA and (D) coronal MIP from MRA show extensive lenticulostriate collateral vessels within the expected regions of the bilateral MCAs. (E) Perfusion ASL images show bright signal within the bilateral ACAs and MCAs due to delayed arrival of the labeled blood to the parenchyma. (F) Velocity selective ASL shows symmetric cerebral perfusion in the parenchyma consistent with successful synangiosis and current asymptomatic state.

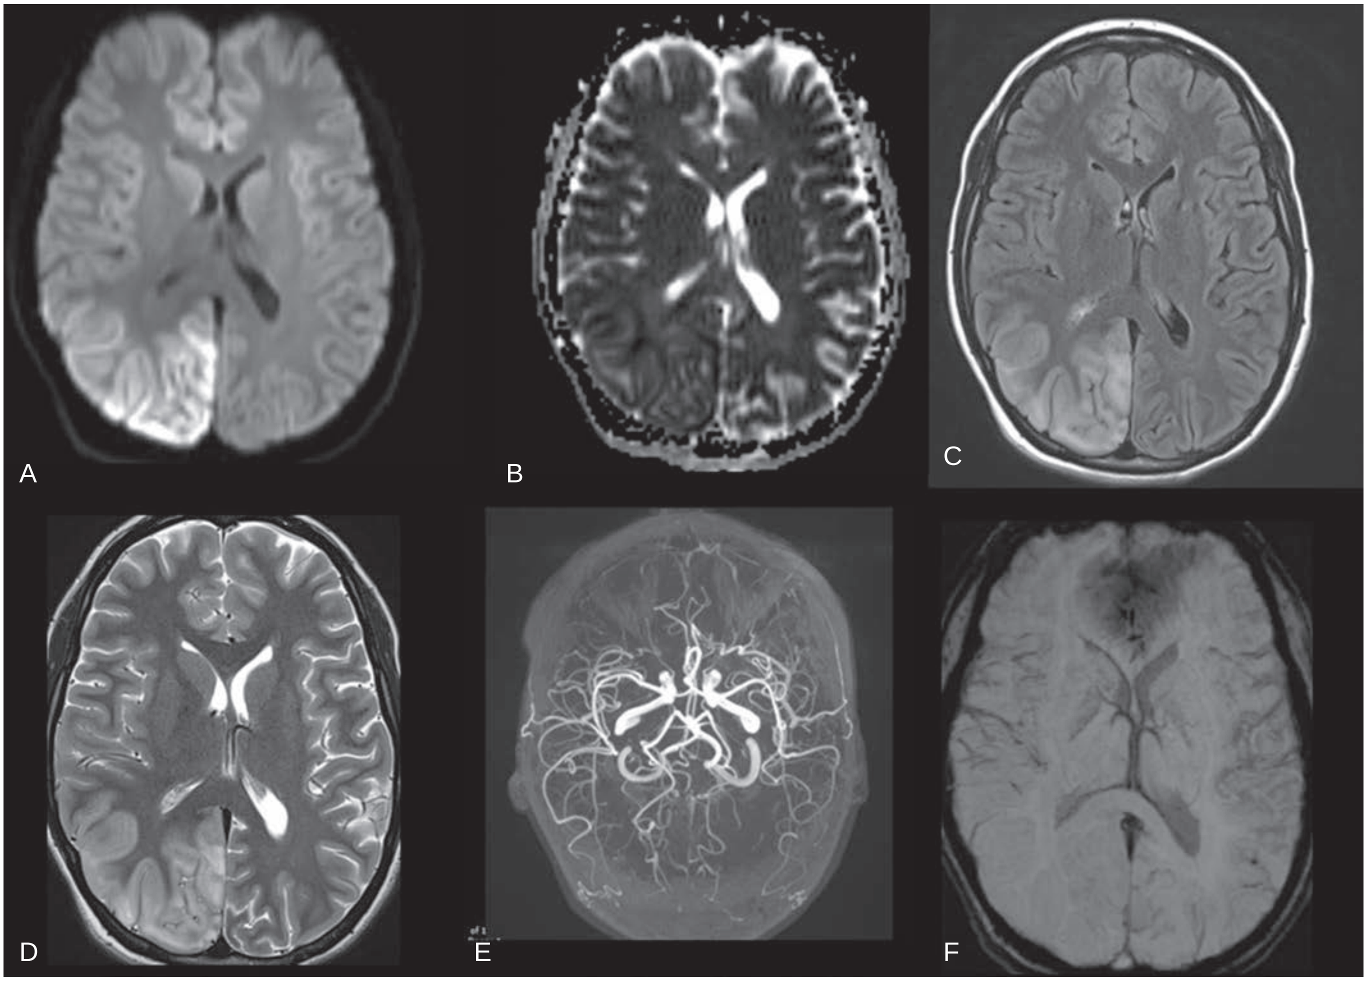
disorders, postictal state, Bell palsy, and conversion disorders.[5] Additionally, several disease processes have imaging findings of decreased diffusion on MRI DWI sequences, which could be confused with ischemic infarcts. Hemiplegic migraine, mitochondrial disorders, demyelinating disease, and status epilepticus may have regions of decreased diffusion that should not be mistaken for acute infarct. Transient neurologic symptoms in patients with migraine can simulate stroke symptoms clinically, and decreased diffusion has been described in hemiplegic migraine disorders.[55] Migraine with aura has an increased risk of stroke in the adult population, and some case reports indicate a relationship between infarcts and migraine in adolescents.[56] The association between migraine and stroke may be related to a dysfunction of cerebral arteries during migraine attacks. Mitochondrial disorders, such as MELAS (mitochondrial encephalopathy, lactic acidosis, and strokelike episodes), are frequently complicated by strokelike events. These disorders can be clinically indistinguishable from AIS, but the imaging findings do not conform to a vascular territory (e-Fig. 37.11). Demyelinating disease, such as multiple sclerosis, typically presents with white matter lesions that may demonstrate decreased diffusion acutely. However, clinical history and multiple lesions of differing ages on imaging may argue for a demyelinating disorder, as opposed to infarct. Status epilepticus or prolonged seizures can also result in transient decreased diffusion in the peri-ictal phase. On imaging, this finding usually does not conform to a vascular distribution. However, caution is required, particularly in neonates, as neonatal infarcts often present as seizures.

## SUMMARY

Stroke is an important cause of morbidity and mortality in the pediatric population across all ages. Despite advances in imaging, stroke poses numerous diagnostic challenges, particularly because the diagnosis is frequently not considered until the subacute to chronic phase, when imaging findings may be more difficult to interpret. The often complex, overlapping risk factors and disease processes in pediatric stroke are in striking contrast to the adult population, in which stroke is usually attributed to atherosclerotic vascular disease. Management of pediatric stroke is controversial due to the current lack of large-scale, disease-specific risk and outcomes data. As such, pediatric stroke treatment is an important, active area of research. Increased awareness of pediatric stroke is necessary to facilitate prevention, early diagnosis and intervention in children of all ages.



**e-Figure 37.11. Alternative considerations in the setting of decreased diffusion—MELAS.** A 15-year-old with MELAS and new neurologic symptoms of numbness of LLE and blurry vision. (A) DWI and (B) ADC map demonstrate decreased diffusion in a nonvascular distribution involving the right parietal region. In addition, the ADC is atypical for arterial ischemic infarct, as there is subcortical edema. (C) FLAIR and (D) T2 hyperintense signal with significant swelling is inconsistent with an acute AIS. (E) 3D TOF MRA shows no evidence of vascular occlusion and, in fact, shows slight prominence of the right PCA. (F) SWI shows decreased venous deoxyhemoglobin in the involved region consistent with increased perfusion.

## KEY POINTS

- Stroke is a significant cause of morbidity and mortality in all pediatric age groups but particularly common in the neonatal population.
- Determining the etiology of a stroke is often not possible. No definite cause of perinatal AIS is determined in 25% to 50% of cases. In venous infarcts, the true incidence is difficult to determine as venous thrombus is often not visualized at imaging.
- The patterns of stroke indicate the mechanism of injury. Perinatal AIS leads to focal ischemic injury in an arterial distribution, most commonly in the MCA territory and may be hyperperfused at diagnosis. Venous infarcts may involve superficial or deep medullary venous territories, with quite different patterns.
- In fetal stroke, the age of the fetus at the time of infarct can contribute to the subsequent pathology and pattern of injury.
- The diagnosis of stroke in children is frequently not considered until the subacute to chronic phase, when imaging findings may have partially resolved and become more difficult to interpret. Early consideration of stroke as part of the differential diagnosis and timely imaging is therefore important for treatment and prognosis.

# 38 Neuroimaging in Pediatric Epilepsy

Elysa Widjaja

## OVERVIEW

Epilepsy is a common pediatric neurologic disorder. In North America, the overall incidence of epilepsy is approximately 50/100,000 per year, highest for children below 5 years of age and the elderly.[1,2] Children are at higher risk for developing epilepsy than adults. Atypical, idiopathic, and focal epilepsy as well as epileptic syndromes require evaluation with magnetic resonance imaging (MRI). Approximately 30% of children with epilepsy become refractory to medical therapy.[3] In this group of children with refractory focal epilepsy, neuroimaging is critical for identifying an epileptogenic substrate responsible for the epilepsy, particularly in those potentially undergoing surgery. Epilepsy surgery in those with normal MRI has been reported to have poorer surgical outcomes compared with those with an identifiable lesion.[4] Epileptogenic substrates include malformations of cortical development (MCD), developmental tumors, anoxic-ischemic injuries, prior cerebrovascular disease, neurocutaneous syndromes, and Rasmussen encephalitis. Concurrent lesions such as MCD, hippocampal sclerosis, and developmental tumors can occur in approximately 13% to 20% of cases.[5,6] Another important role of imaging in presurgical epilepsy evaluation is to identify the location of eloquent cortex and white matter tracts.

MRI is the imaging study of choice for identifying an epileptogenic substrate. Higher field strengths such as 3 T is preferred. A dedicated epilepsy protocol is required to improve lesion detection and has been shown to improve seizure-free surgical outcome.[7] The epilepsy protocol in children should include volumetric T1-weighted imaging, and T2-weighted and fluid attenuation inversion recovery (FLAIR) imaging in at least two orthogonal planes covering the entire brain.[8] Additional sequences such as proton density, 3D FLAIR, inversion recovery, and gradient echo/susceptibility-weighted imaging may be helpful. Epilepsy protocols in neonates and infants younger than 1 year require a different set of sequences due to immature myelination and should include volumetric T1-weighted, and axial and coronal T2-weighted images covering the entire brain. FLAIR and proton density images are less helpful in neonates and infants due to lack of myelination. Volumetric imaging section thickness of less than or equal to 1 mm provides excellent gray-white matter contrast, can be reformatted into any orthogonal or nonorthogonal planes, and can be used for anatomic integration of functional data, stereotactic electrode placement, and neuronavigation.[9–11] In temporal lobe epilepsy, the coronal plane should be acquired perpendicular to the long axis of the hippocampus. Contrast injection does not improve lesion detection but may help with lesion characterization. In cases where an epileptogenic focus is not identified, further evaluation with dedicated higher resolution MRI, image postprocessing, or additional imaging techniques including diffusion tensor imaging, magnetic resonance spectroscopy, functional imaging with interictal positron emission tomography (PET) or ictal/interictal single-photon emission computed tomography (SPECT), and magnetoencephalography (MEG) may help in identifying a lesion or the epileptogenic zone.[12,13]

## MALFORMATIONS OF CORTICAL DEVELOPMENT

MCD are a major cause of drug-resistant epilepsy,[14] in particular focal cortical dysplasia (FCD), hemimegalencephaly, and tuberous sclerosis. Other MCD such as lissencephaly, gray matter heterotopia, polymicrogyria, and schizencephaly are also associated with epilepsy.[15–18]

### Focal Cortical Dysplasia

***Overview.*** FCD is one of the most common causes of intractable epilepsy in children and accounts for up to 39% of pediatric epilepsy surgical cases.[19,20] The mechanism of epilepsy is still unclear. Postulated possibilities include abnormal firing from the dysplastic neurons rather than from balloon cells,[21] dysfunction of synaptic circuits with abnormal synchronization of the neuronal population, and abnormal organization of the inhibitory interneurons.[22] A consensus classification has been proposed by the International League Against Epilepsy (ILAE) in 2011 (Table 38.1).[23]

***Imaging.*** FCD can be located in any cortex of the cerebral hemisphere and can have variable size, from one gyrus to more than one lobar involvement. The MRI features of FCD include increased cortical thickness, blurring of the cortical–white matter junction, increased T2 or FLAIR signal in the cortex and subcortical white matter, high T1 signal in the cortex, and abnormal sulcation and gyration pattern. Taylor's FCD or FCD type IIB are more likely to demonstrate high T2/FLAIR signal that tapers toward the ventricle.[24–26] Type I FCD is more likely to demonstrate hypoplasia or atrophy of the white matter and mild increased T2 signal of the white matter. The high T2 signal in the white matter may be secondary to abnormal myelination, either due to the underlying disease or secondary to seizures. FCD, in particular FCD type I, are associated with hippocampal sclerosis.[27] The MR appearance of FCD may change with brain myelin maturation. In patients with focal epilepsy, MR during infancy may be normal, and repeat imaging after the age of 2 years may reveal FCD.[28] Therefore even when the MRI appears normal in an infant with refractory focal seizures, a repeat study is recommended at a later age[28] (Fig. 38.1). In contrast to the high T2/FLAIR signal in the white matter of FCD in children, the white matter adjacent to the dysplastic cortex may demonstrate low T2 and high T1 signal in neonates and infants. This is postulated to be secondary to early myelination in the white matter from repeated seizures.[29]

***Treatment and Follow-up.*** Up to 50% to 70% of patients with FCD achieve good seizure control or seizure-free outcome after surgical resection of FCD.[30–32] This compares favorably with the outcome of patients with hippocampal sclerosis[33] and low-grade neoplasms.[34] The reported surgical outcomes of subtypes of FCD are variable. Some studies reported better surgical outcome in those with Taylor's FCD,[26,35,36] while others reported better surgical outcomes in those with other subtypes of FCD, including type I FCD and mild MCD.[37,38] Differences in outcomes of subtypes of FCD may in part be related to the preponderance of type I FCD and mild MCD in the temporal lobe.[37]

### Hemimegalencephaly

***Overview.*** Hemimegalencephaly is a MCD characterized by one hemisphere being larger than the contralateral side. It may be sporadic or associated with a variety of syndromes, including proteus syndrome, epidermal nevus syndrome, hypomelanosis of Ito, linear nevus sebaceous syndrome, neurofibromatosis type I, and tuberous sclerosis. The sporadic form is considered a hemispheric variant of FCD.[39] On histology, the appearance is similar

## Abstract:

Epilepsy is a common pediatric neurologic disorder. Approximately 30% of children with epilepsy become refractory to medical therapy, and some of these patients are amenable to surgical treatment. MRI is important for identifying a lesion responsible for epilepsy. Detection of a lesion on MRI may influence epilepsy surgery outcome, and those with a lesion seen on MRI have better seizure-free surgical outcome relative to those with normal MRI. Lesion identification on MRI can be improved through the use of high-resolution dedicated epilepsy protocol on 3T and meticulous review of MRI, with knowledge of the clinical semiology, EEG, and functional imaging information such as PET, SPECT or MEG.

There is a wide range of brain abnormalities that can cause epilepsy. The two most common causes of intractable focal epilepsy are malformations of cortical development (MCD) and developmental tumors. Focal cortical dysplasia, a MCD, is one of the most challenging lesions to identify on imaging, as the MRI features can be subtle. The MRI appearance of focal cortical dysplasia may vary by age, with lower T2 and high T1 signal in the subcortical white matter in neonates and infants, postulated to be secondary to early myelination from repeated seizures. Hippocampal sclerosis is less common in children compared to adults with focal intractable epilepsy. Other less common lesions responsible for epilepsy include hypothalamic hamartoma, Rasmussen encephalitis, vascular lesions such as cavernomas, and meningioangiomatosis. Dual pathology may be encountered in about 15% of cases.

to FCD with abnormal gyration of the cortex, dyslamination, blurring of gray-white matter junction, giant neurons in both gray and white matter, and balloon cells in 50% of cases. The most common clinical presentation is early intractable epilepsy; other clinical presentations include hemiparesis, hemianopia, and intellectual disability.

***Imaging.*** The affected hemisphere is larger than the contralateral side. The cortex is dysplastic and thick, with broad gyri and shallow sulci (e-Fig. 38.2). The ipsilateral lateral ventricle may be enlarged. The ipsilateral white matter also demonstrates signal changes that are variable, depending on the age of the patient. Neonates and infants usually demonstrate high T1/low T2 white matter signal, suggestive of early myelination, while in older children, the white matter shows low T1/high T2 signal, suggestive of gliosis, and may be associated with calcification.[40–42] With recurrent seizures or status epilepticus, the enlarged hemisphere may later become atrophic.[43]

***Treatment and Follow-up.*** Hemispherectomy or functional hemispherotomy may be required.

### Tuberous Sclerosis Complex

***Overview and Imaging.*** Tuberous sclerosis complex (TSC) is an autosomal dominant neurocutaneous syndrome characterized by multisystem involvement including brain, eyes, heart, kidney, skin, and lungs. Seizures occur in about 80% to 90% of patients and are intractable in 25% to 30%.[44] Children with medically refractory epilepsy usually have multiple cortical/subcortical tubers that exhibit broad gyri, thick cortex, and abnormal signal in the cortex and subcortical white matter. The cortical/subcortical tubers may occasionally demonstrate calcification and cystic degeneration. A combination of structural and functional imaging such as FDG-PET, ictal/interictal SPECT, and MEG can be used to identify the epileptogenic tubers[45–48] (Fig. 38.3). Cerebellar tubers can also be identified and are more commonly seen in patients with high cerebral tuber burden. The subependymal nodules commonly calcify. Another manifestation of TSC is subependymal giant cell astrocytomas, which commonly occur in the region of the foramen of Monro.

## STURGE–WEBER SYNDROME

***Overview and Imaging.*** Sturge–Weber syndrome (encephalotrigeminal angiomatosis) is characterized by facial capillary vascular malformation or “port wine stain” in the trigeminal nerve distribution, ipsilateral leptomeningeal angiomatosis, and angiomatosis of the choroid in ipsilateral eye. Seizures are usually the initial neurologic manifestation in the first year of life. Children with early onset of epilepsy are more likely to have hemiparesis, status epilepticus, and developmental delay compared with those whose seizures start later in life.[49] Imaging findings include leptomeningeal angiomatosis, enlargement of the choroid plexus, parenchymal atrophy, calvarial changes, and calcification (Fig. 38.4). Leptomeningeal angiomatosis and choroid plexus hyperplasia appear earlier, while atrophy and calcification usually are evident later. Contrast-enhanced MRI is considered the most sensitive modality for depicting leptomeningeal enhancement, to reveal subtle bilateral hemispheric involvement, compensatory venous drainage, enlarged choroid plexus in the atria, as well as cerebellar and eye involvement.[50–52]

***Treatment and Follow-up.*** Medical therapy is the first line of treatment for controlling seizures. Functional hemispherotomy may be indicated when seizures are refractory to medical therapy.

## MESIAL TEMPORAL SCLEROSIS

***Overview and Imaging.*** Mesial temporal sclerosis (MTS) or hippocampal sclerosis is less frequently encountered in children compared with adults.[53–56] The etiology of MTS is unknown, but a link with febrile seizures has been suggested.[57,58] MTS is characterized by neuronal loss and gliosis in the hippocampus.[59] MRI features include atrophy and increased T2/FLAIR signal in the hippocampus[59–62] (Fig. 38.5). Other findings include loss of interdigitations of the hippocampal head,[63] atrophy of the ipsilateral mamillary body and fornix,[64] dilatation of the ipsilateral temporal horn, volume loss of the temporal lobe, and atrophy of the collateral white matter between the hippocampus and collateral sulcus.[62]

***Treatment and Follow-up.*** In patients who have medically refractory epilepsy, surgery offers good seizure control in 70% to 90% of cases.[65–68]

## EPILEPSY ASSOCIATED DEVELOPMENTAL TUMORS

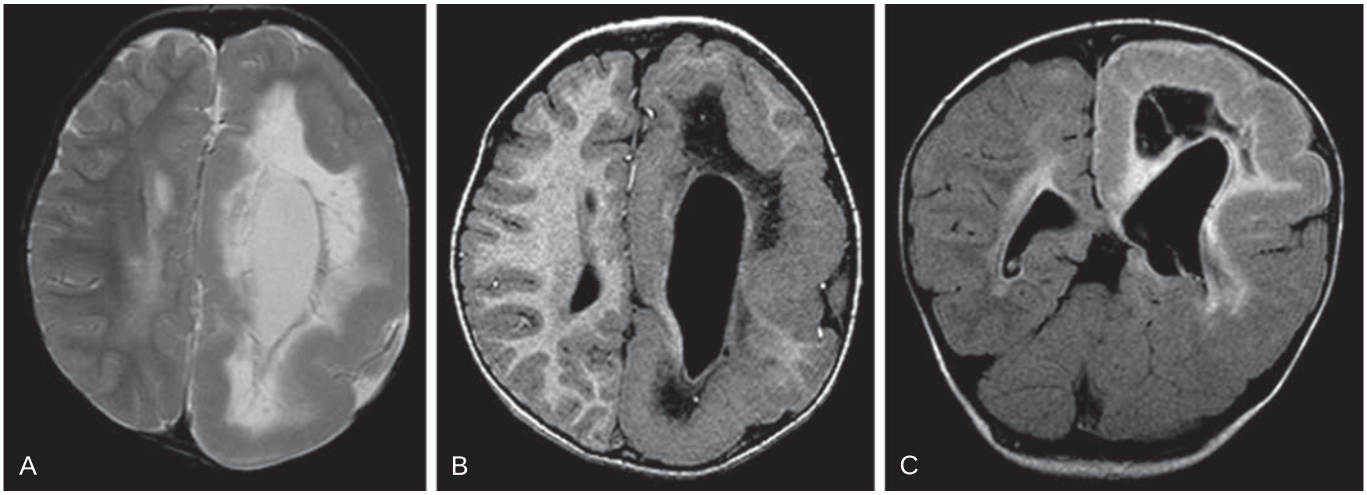
***Overview and Imaging.*** Epilepsy associated tumors account for up to two-thirds of pathologic substrates[69–72] in epilepsy surgery. They are usually associated with benign behavior and low proliferation index. The tumors include ganglioglioma, desmoplastic infantile ganglioglioma, dysembryoplastic neuroepithelial tumor (DNET), pleomorphic xanthoastrocytoma (PXA), and low-grade astrocytoma.[73]

### Gangliogliomas

The most common clinical presentation of this tumor is seizures; often complex partial and medically intractable.[74] They are larger in children than in adults[75] and are located mostly in the temporomesial (50%) or temporolateral (29%) location.[76] Gangliogliomas are composed of glial cells and neurons, and may present as a solid mass in 43%, a cyst in 5%, and a mixed lesion in 52%.[77,78] They involve the cortex and may cause remodeling of the adjacent bone. On CT, most are hypodense (38%), but iso- (15%), hyper- (15%), or mixed density masses (32%) can be found,[79] and calcification is seen in 30% to 50% of cases. On MRI, the solid part of the tumor may appear hypo- or isointense to gray matter on T1-weighted images and hyperintense on T2-weighted images (Fig. 38.6). Enhancement is present in up to 60% of cases; it can be nodular, ringlike, or solid. Gangliocytoma is a variant of ganglioglioma without any glial component and affects older children and young adults. On MRI, gangliocytoma may demonstrate low T1 and high T2 signal, and show enhancement.[80,81]

### Dysembryoplastic Neuroepithelial Tumor

DNET is a benign supratentorial cortical tumor that shows predilection for the temporal and frontal lobes. The tumor may



**e-Figure 38.2. Hemimegalencephaly in a 2-year-old.** (A) Axial T2-weighted, (B) axial volumetric T1-weighted, and (C) coronal FLAIR MR images demonstrate diffuse enlargement of the left cerebral hemisphere, associated with abnormally thick cortex, abnormal sulcation, and gyration pattern, as well as dysmorphic and enlarged left lateral ventricle. There is also abnormal increased T2 and FLAIR signal, and reduced T1 signal in the white matter of the affected hemisphere.

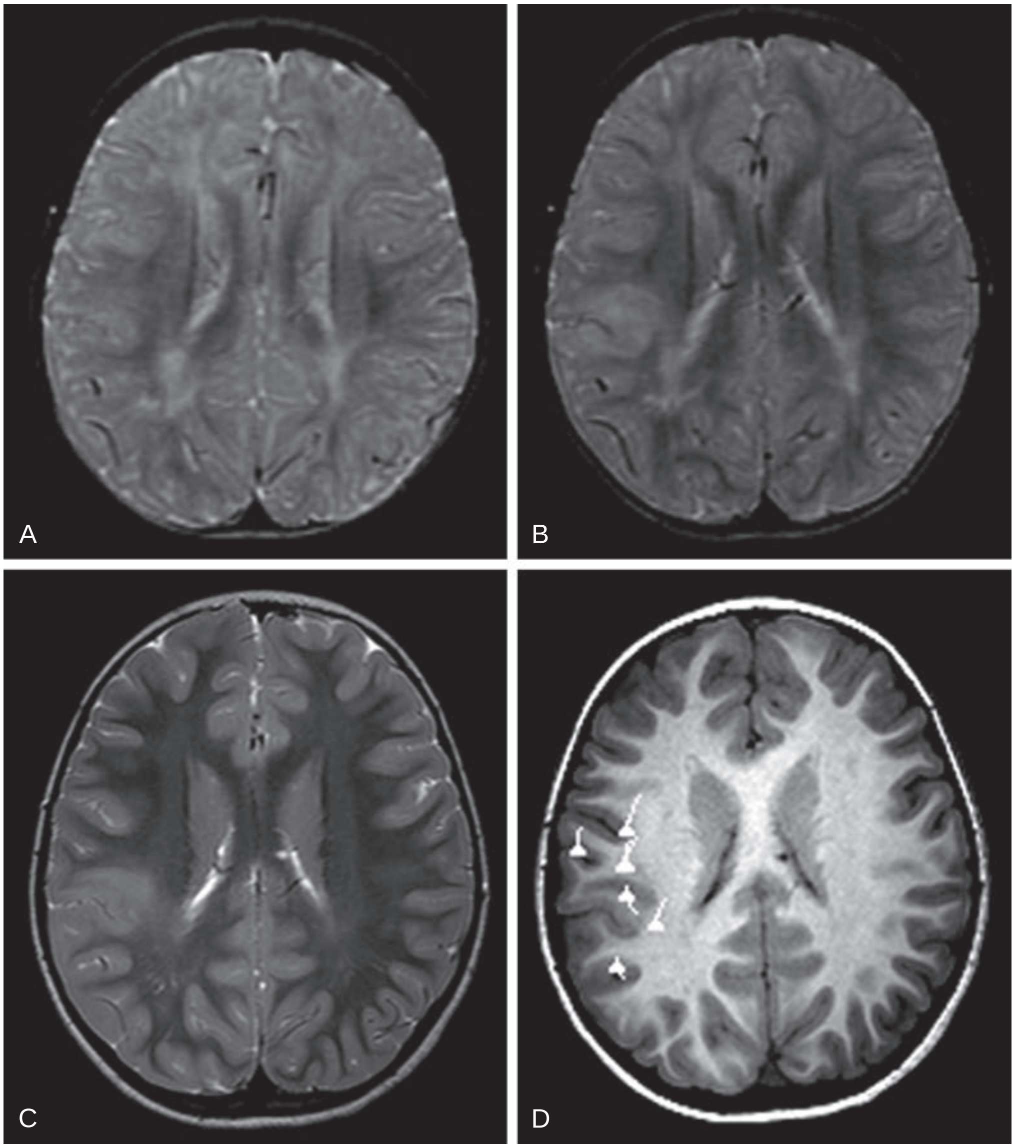


**Figure 38.1. Focal cortical dysplasia in a 5-year-old girl.** (A) Axial T2-weighted MR image at 12 months does not show a lesion. However, at 19 months (B) and 5 years of age (C), axial T2-weighted MR images demonstrate abnormal signal in the cortex and subcortical white matter, associated with blurring of gray-white matter junction. (D) MEG projected onto axial T1-weighted MR image demonstrates the dipoles, indicative of the epileptogenic zone, are located in and around the lesion. Surgical resection of the lesion and epileptogenic zone confirmed focal cortical dysplasia type IIB.

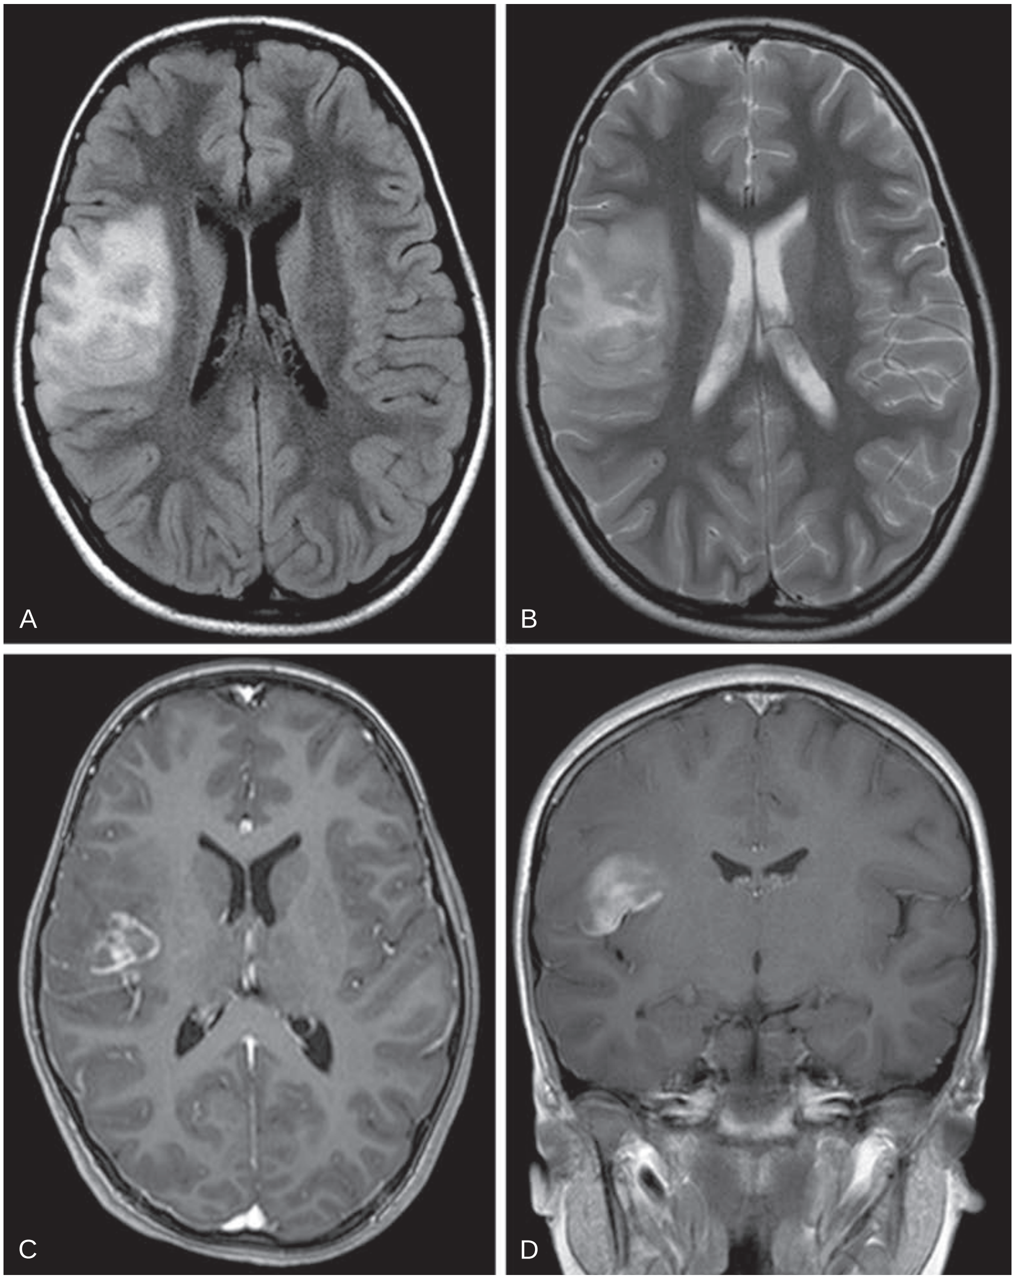
be associated to broadening of the gyri, effacement of the sulci, distortion of the ventricles, and remodeling of the overlying skull vault.[82,83] On CT, DNET tends to be hypoattenuated with a cystic appearance.[84] Calcification has been reported in 20% to 36% of cases.[83] On MRI, DNET demonstrates low T1/high T2 signal, often with multi-cystic and "bubbly" appearance,[82] and may have a thin rim of high FLAIR signal[85,86] (Fig. 38.7). Approximately one-third of cases show nodular, patchy or ring enhancement. The tumor may extend to the ventricle in 30% of cases. Hemorrhagic changes are rare.[85,87]

## Pleomorphic Xanthoastrocytoma

PXA is a rare localized glioma of astrocytic origin affecting children and young adults.[88] It is mostly temporal (49%) in location and less commonly parietal, frontal, or occipital.[89,90] They are large hemispheric cystic/solid mass close to the cortex. On CT, the tumor is predominantly hypodense with a mixed density enhancing nodule. On MRI, the cystic portion of the tumor are isointense to cerebrospinal fluid (CSF); the solid tumor is hypo- to isointense to gray matter on T1-weighted imaging and hyper to isointense on T2-weighted imaging. There is enhancement of the nodular solid component and adjacent meninges ("dural tail")[91] (e-Fig. 38.8). PXA may be associated with FCD.[92,93]

***Treatment and Follow-up.*** Patients with ganglioglioma have the best surgical outcome with respect to epilepsy control compared with other types of epilepsy associated tumors.[71,76,94] DNET has less favorable seizure outcome compared with ganglioglioma, which could be related to longer duration of epilepsy, incomplete resection of the tumor, or the presence of FCD beyond the margins of resected DNET.[94–96] The prognosis of PXA is generally good, but it may recur, and malignant degeneration occurs in 20%.[97]



**e-Figure 38.8. Pleomorphic xanthoastrocytoma in a 6-year-old.** (A) Axial FLAIR, (B) axial T2-weighted, (C) axial, and (D) coronal T1-weighted contrast enhanced MR images demonstrate a mass in the right inferior frontal gyrus that involves the cortex and subcortical white matter. The tumor demonstrates enhancement medially, and there is surrounding edema.

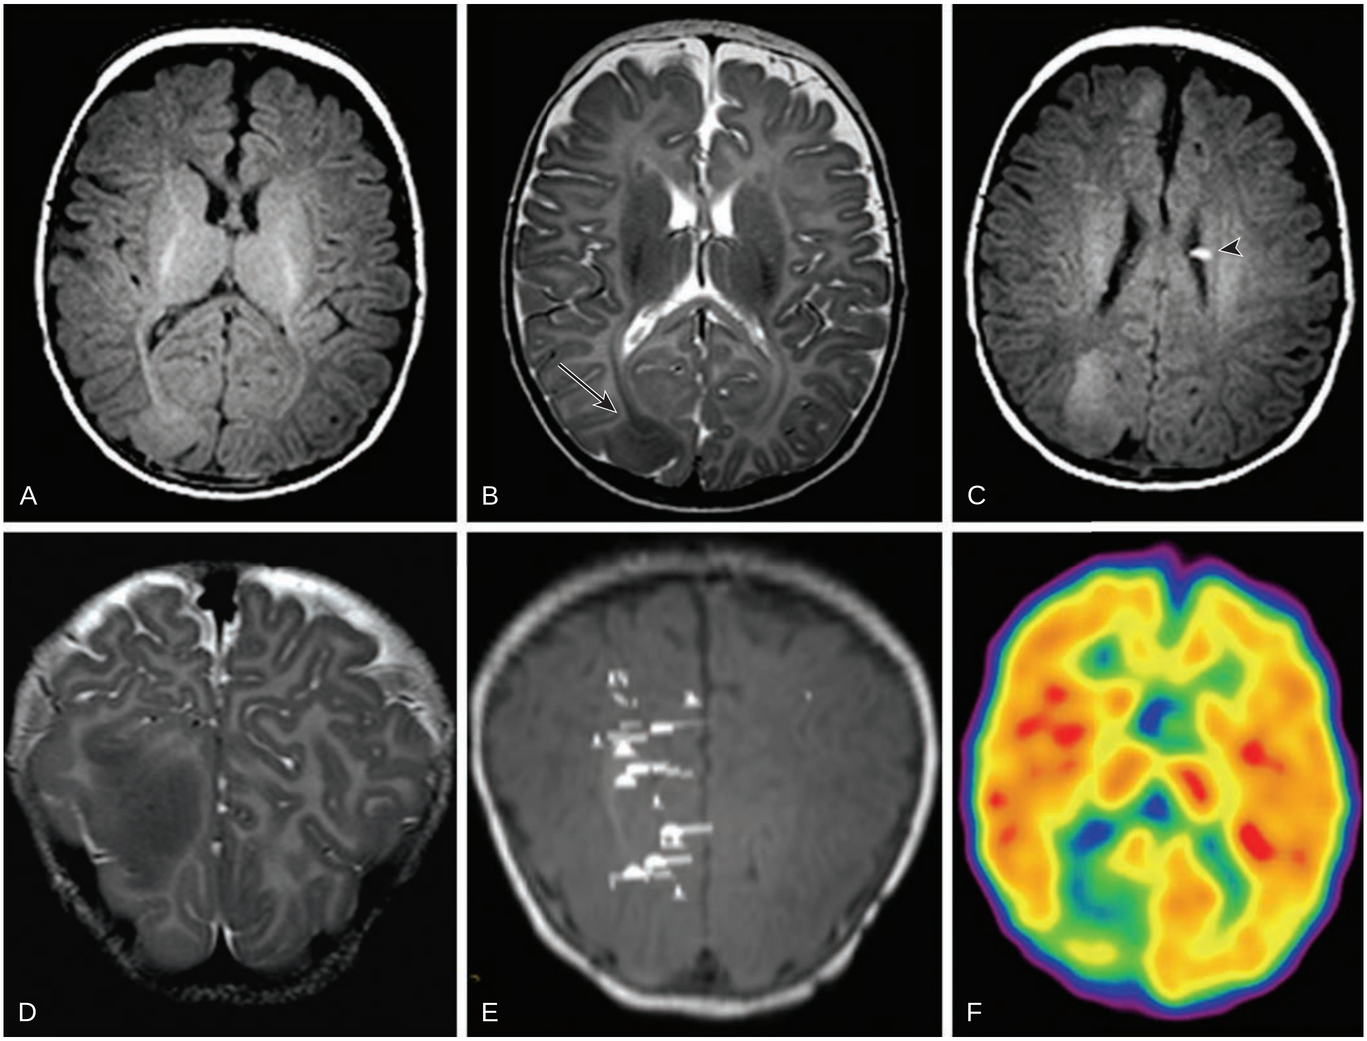


**Figure 38.3. Tuberous sclerosis complex (TSC) and right occipital lobe intractable epilepsy in a 3-month-old.** On (A and C) axial T1-weighted, (B) axial T2-weighted, and (D) coronal T2-weighted MR images, there are several cortical/subcortical tubers in the right frontal and occipital lobes *(arrow)* that demonstrate high T1 and lower T2 signal. There are also several subependymal nodules *(arrowhead)*. (E) MEG dipoles projected onto coronal T1 image demonstrates dipole cluster in the right occipital lobe. (F) FDG PET study shows hypometabolism that is more extensive than the right occipital tuber.

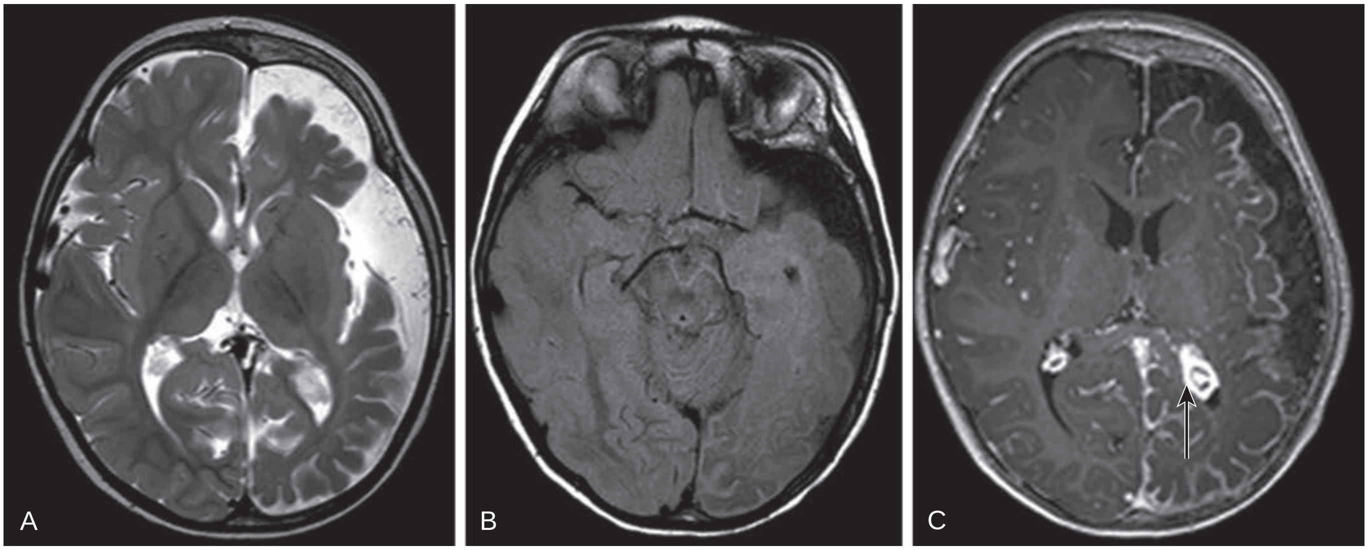

**Figure 38.4. Sturge–Weber syndrome in a 15-month-old boy.** (A) Axial T2-weighted and (B) axial FLAIR MR images show volume loss in the left cerebral hemisphere with enlargement of subarachnoid spaces, and high FLAIR signal in the left cerebral sulci. (C) Axial T1-weighted contrast-enhanced MR image shows pial enhancement over the left cerebral hemisphere, as well as enlarged choroid plexus in the left trigone *(arrow)*.

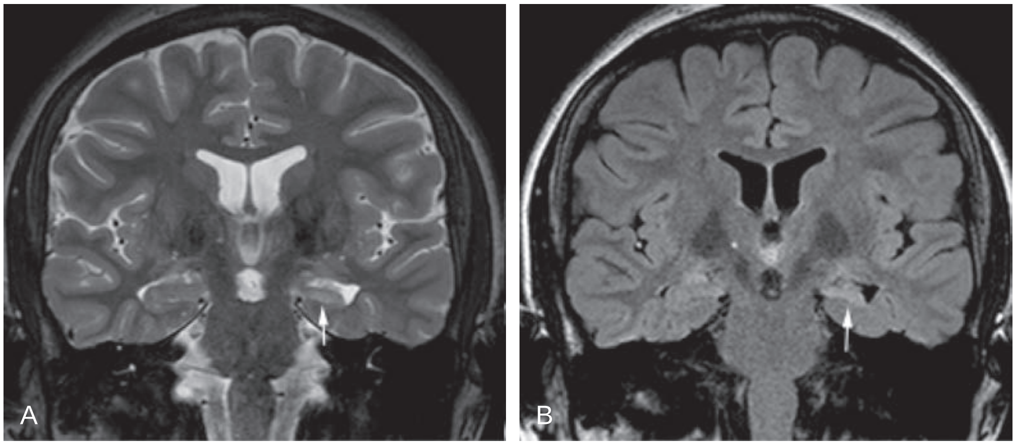

**Figure 38.5. Left mesial temporal sclerosis in an 11-year-old girl.** (A) Coronal T2-weighted and (B) coronal FLAIR MR images demonstrate high T2 and FLAIR signal, associated with volume loss in the left hippocampus *(arrow)*.

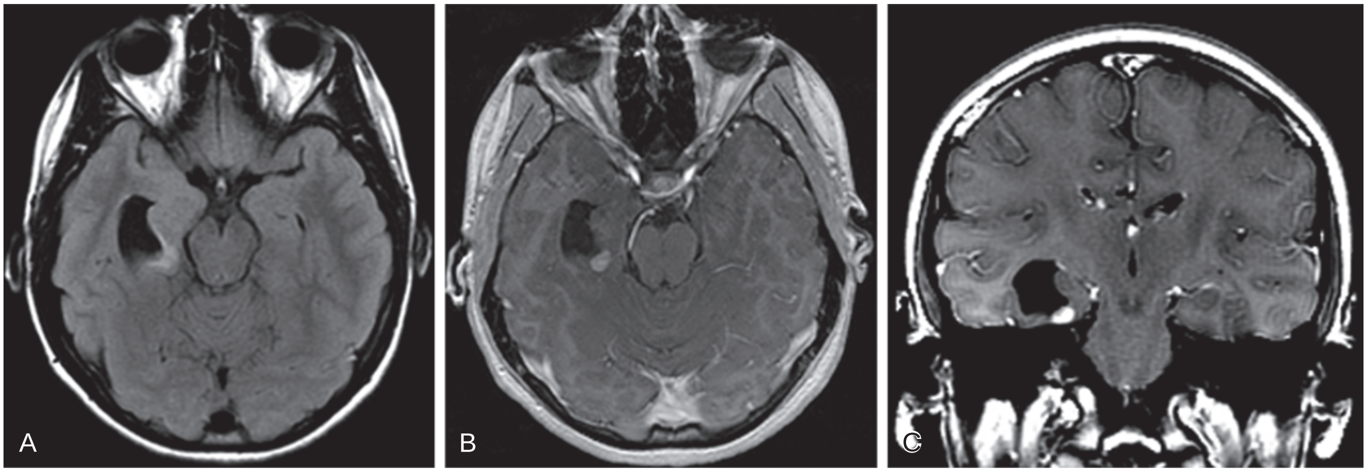

**Figure 38.6. Ganglioglioma in a 16-year-old girl.** (A) Axial FLAIR, (B) axial, and (C) coronal T1-weighted contrast-enhanced MR images show a cystic tumor with mural enhancing nodule in the right mesial temporal lobe.

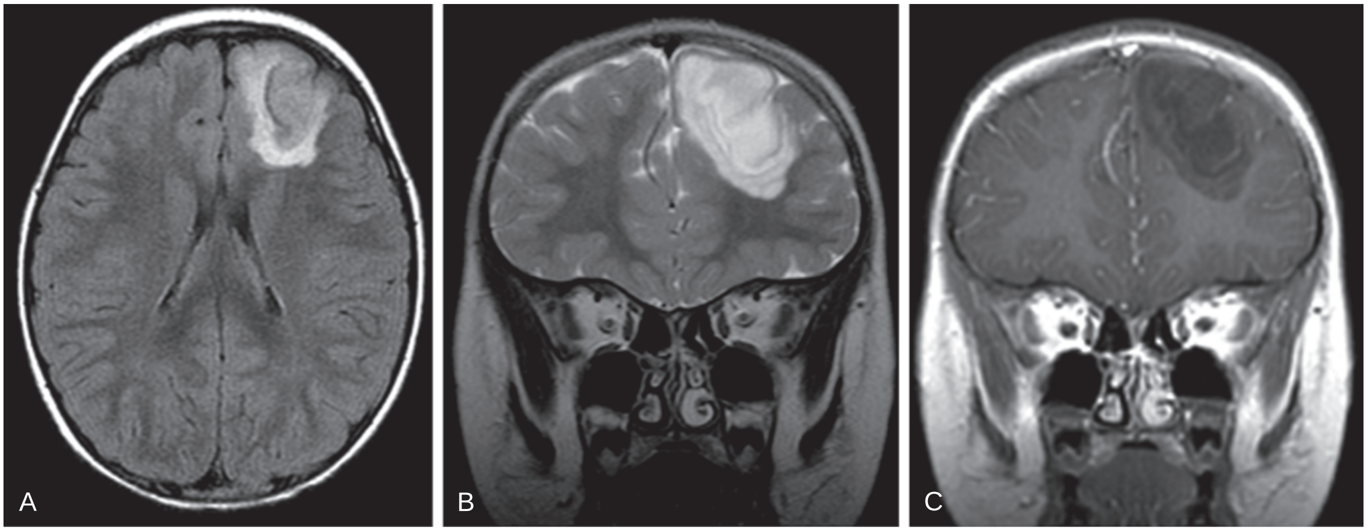

**Figure 38.7. Dysembryoplastic neuroepithelial tumor (DNET) in a 4-year-old boy.** (A) Axial FLAIR, (B) coronal T2-weighted, and (C) contrast-enhanced coronal T1-weighted MR images demonstrate a well-defined tumor in the left frontal lobe involving the cortex and white matter. The tumor extends to the margin of the frontal horn of the left lateral ventricle, has a rim of high FLAIR signal, and does not show enhancement.

## Hypothalamic Hamartoma

***Overview and Imaging.*** Hypothalamic hamartoma, also known as hamartoma of the tuber cinereum, is a congenital malformation of the hypothalamus that may be asymptomatic or manifest with precocious puberty or gelastic seizures.[98] Intrahypothalamic hamartomas that invade the third ventricle are associated with early occurrence of epilepsy, while the parahypothalamic hamartomas that do not involve the third ventricle more commonly present with central precocious puberty.[99,100] MRI demonstrates a mass at the tuber cinereum that is T1 hypointense, T2 iso- or hyperintense relative to gray matter, and FLAIR hyperintense. There is no enhancement and no calcification (e-Fig. 38.9). Careful examination of the hypothalamic region on MRI is needed, as hamartomas can be small and nonpedunculated.

***Treatment and Follow-up.*** The first line treatment is medical treatment with hormonal therapy and antiepileptic medications. However, if the child becomes refractory to medical treatment, surgical resection, radiosurgery, or laser therapy should be considered.[101–104]

## RASMUSSEN ENCEPHALITIS

***Overview and Imaging.*** Rasmussen encephalitis is a rare, chronic progressive encephalitis characterized by severe refractory epilepsy and unilateral brain atrophy.[105] Clinically, seizures begin abruptly in previously normal children and include focal seizures and epilepsia partialis continua. With disease progression, the patients develop hemiparesis or hemiplegia and cognitive decline. There is a possible autoimmune basis for the disease.[106–108] The histological findings include chronic encephalitis with lymphocytic infiltrations and perivascular cuffing; in the later stage of the disease, nonspecific findings such as atrophy and gliosis with minimal inflammatory cellular infiltrate are found.[109] In the acute stages, MRI can be entirely normal[110,111] or demonstrate cortical swelling with low T1 and hyperintense T2 and FLAIR signal, with no enhancement. With disease progression, MR shows progressive volume loss and progressive abnormal signal in the white matter and cortex[112] (Fig. 38.10). It is predominantly a unilateral disease, and the frontal and temporal lobes are more commonly involved.

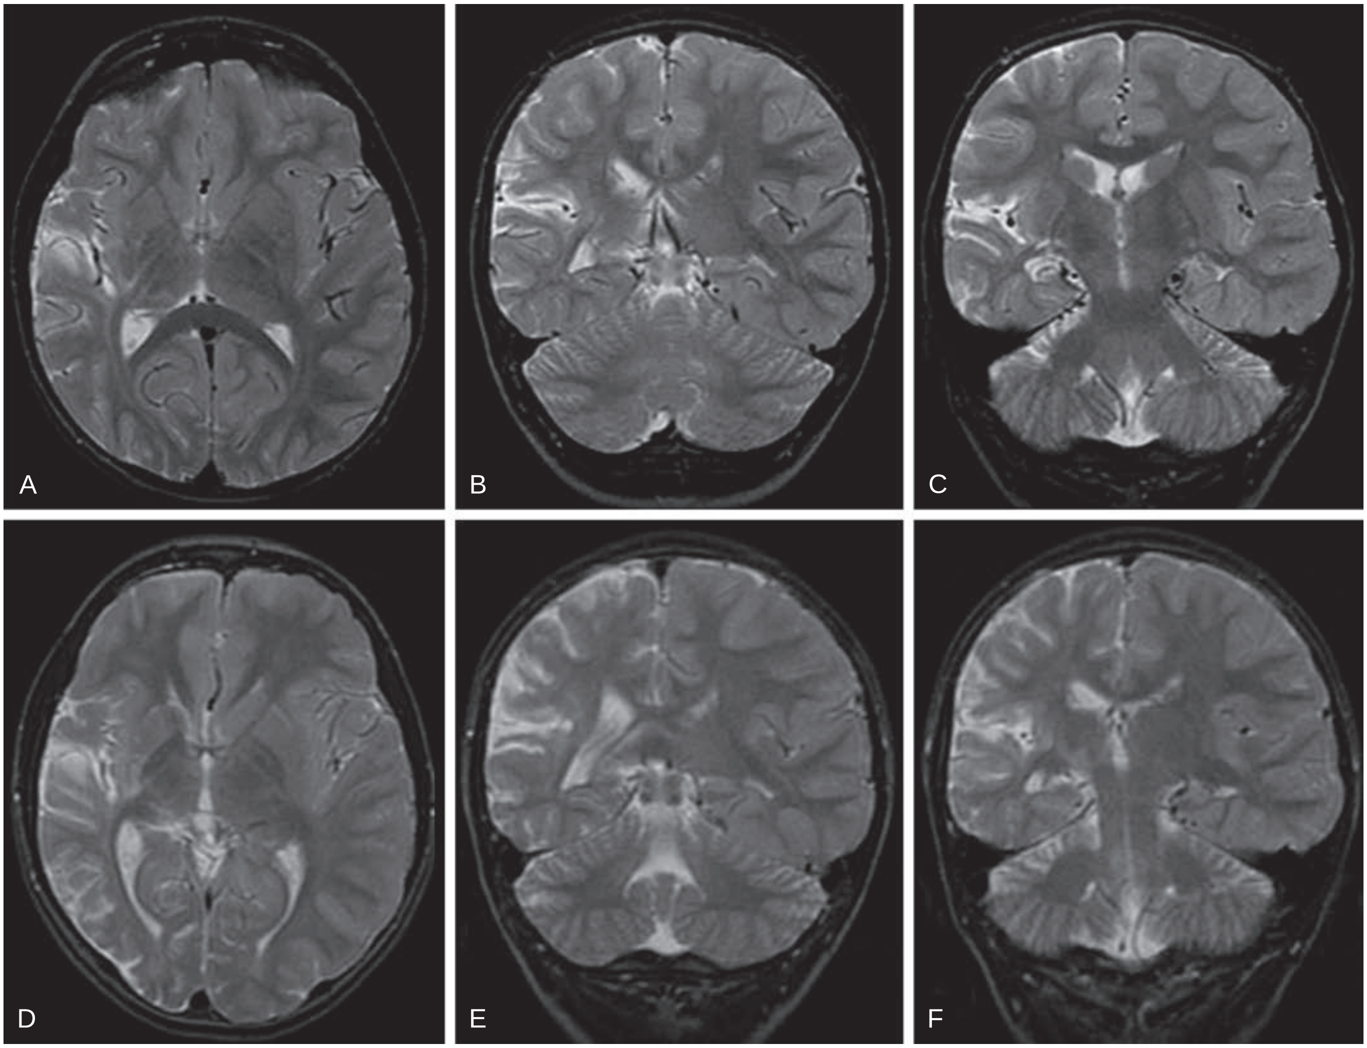

**Figure 38.10. Rasmussen encephalitis in a 5-year-old boy with presenting with epilepsia partialis continua.** At presentation, (A–C) axial and coronal T2-weighted MR images demonstrate mild volume loss in the right Sylvian and temporal lobe. Three years later, (D–F) axial and coronal T2-weighted MR images demonstrate progressive volume loss in the right Sylvian, temporal, and parietal lobes, with ex-vacuo dilatation of the right lateral ventricle.

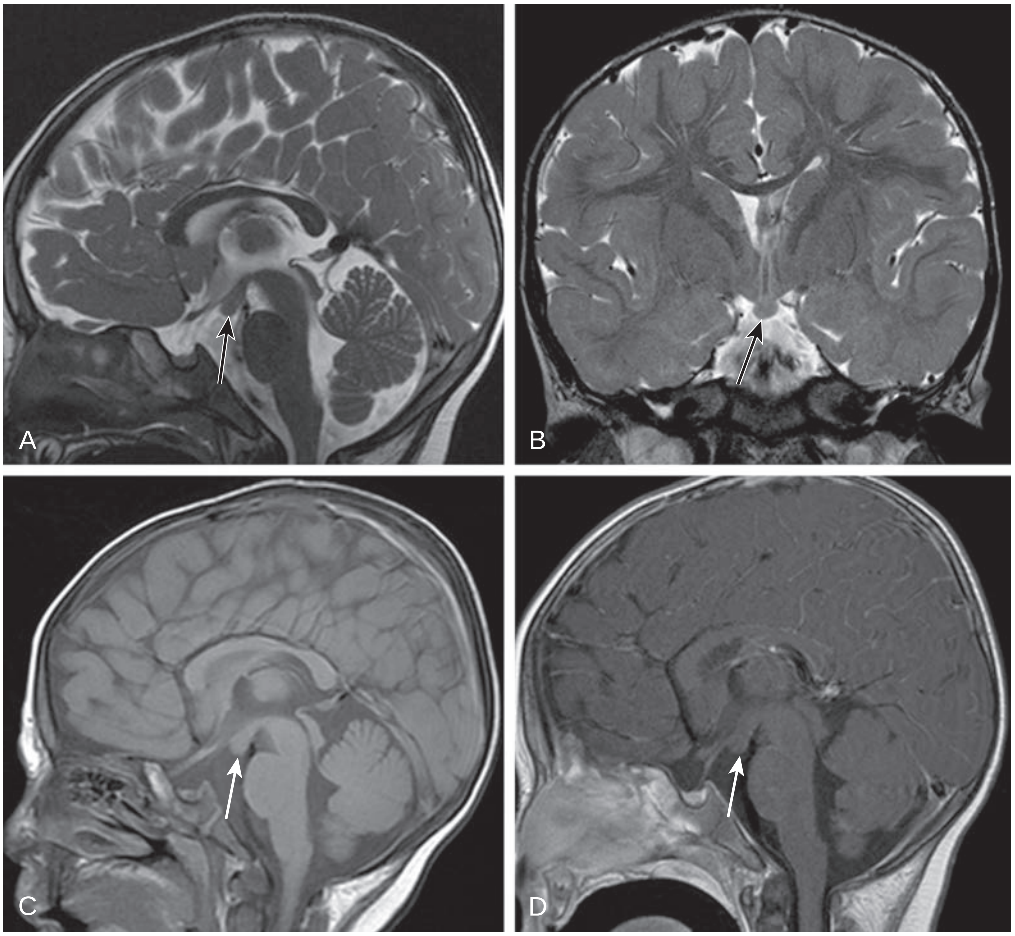

**e-Figure 38.9. Two-year-old with hypothalamic hamartoma *(arrow)*.** (A) Sagittal T2-weighted, (B) coronal T2-weighted, and (C) sagittal T1-weighted MR images show a focal lesion in the tuber cinereum *(arrow)* that has signal similar to gray matter on T1- and T2-weighted sequences. There is no enhancement of the lesion after gadolinium administration (D).

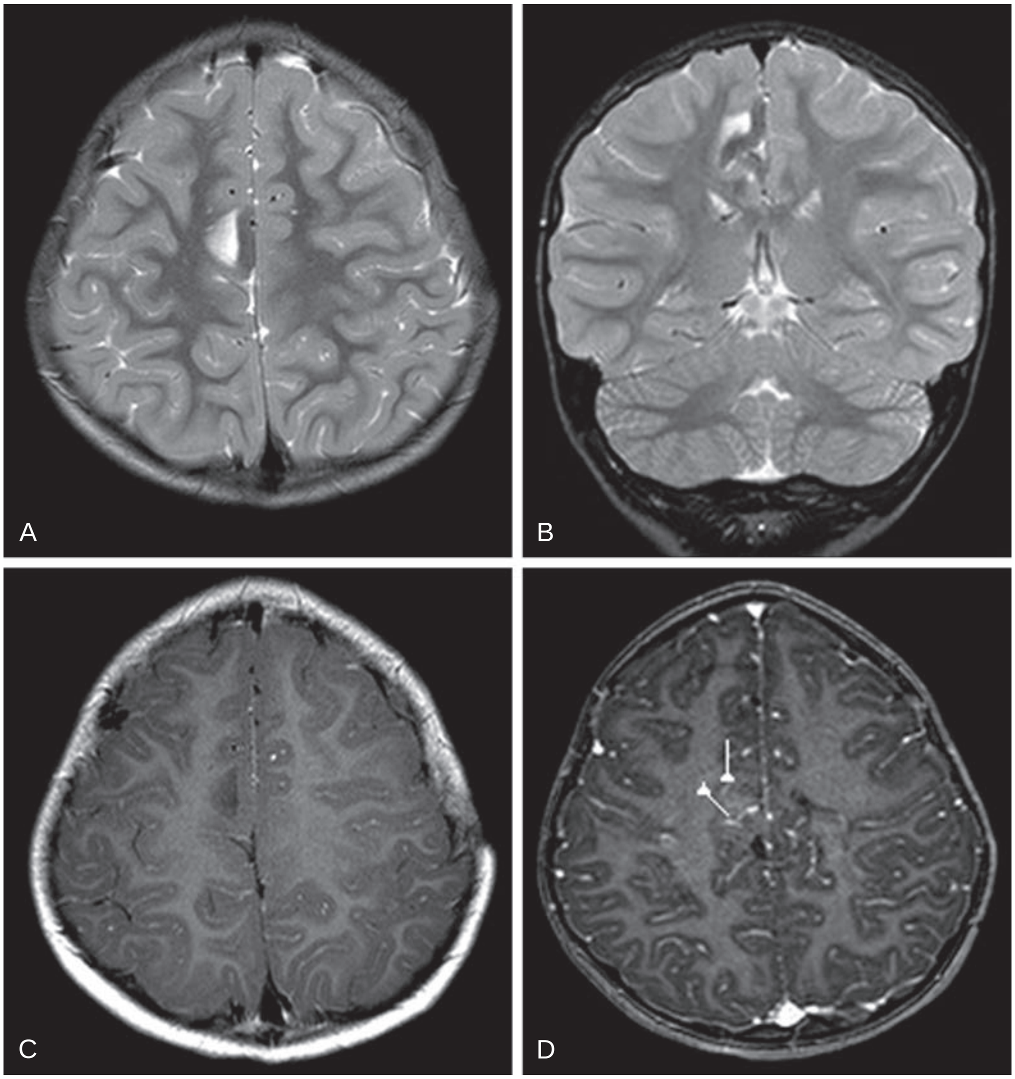

**Figure 38.11. Meningioangiomatosis in a 5-year-old boy with right frontal lobe epilepsy.** (A) Axial and (B) coronal T2-wrighted MR images show low T2 signal in the cortex and high T2 signal in the subcortical white matter of the lesion in right mesial frontal lobe. (C) Axial T1-weighted contrast-enhanced MR image shows no enhancement of the lesion. (D) MEG projected onto the contrast-enhanced MR image shows dipoles around the lesion.

***Treatment and Follow-up.*** Medical treatment include intravenous immunoglobulin, plasmapheresis, or immunosuppressive medications. Hemispherectomy or functional hemispherotomy is frequently necessary for seizure control and to prevent progression of cognitive impairment.

## CAVERNOMAS

***Overview and Imaging.*** In children, seizures are the most common symptom of cavernomas at presentation.[113–115] Cavernomas are more commonly supratentorial (80%) and can have variable size. On MRI, cavernomas have a combination of mixed high and low T1 and T2 signals, surrounding hemosiderin rim,[116] and are best depicted on T2* gradient echo imaging. Calcification may be seen on CT.

***Treatment and Follow-up.*** Cavernomas that present with refractory epilepsy should be treated surgically. The longer the duration of preoperative seizures, the greater the likelihood of continued seizures postoperatively.[117,118]

## MENINGIOANGIOMATOSIS

***Overview and Imaging.*** Meningioangiomatosis is a rare lesion characterized by vascular proliferation involving the cortex and leptomeninges. Sporadic lesions are usually solitary and present with refractory epilepsy. Those associated with neurofibromatosis type 2 are often multiple.[119] On CT, the lesion is hypodense and may contain calcification. On MRI, the cortex may have hypointense T1 and T2 signal due to calcification, the subcortical white matter may be T2 hyperintense, and enhancement may be seen (Fig. 38.11). Meningioangiomatosis may mimic other disorders such as tumors, FCD, and arteriovenous malformation.[120] Treatment is surgical resection, but seizure outcome is poorer compared with those with tumors or hippocampal sclerosis.[121]

## CONCLUSION

Neuroimaging plays a crucial role in identifying anatomic lesions responsible for epilepsy and can assist in localizing the eloquent cortex and white matter tracts for presurgical planning. In those with MRI-negative epilepsy, functional imaging with PET, SPECT, and MEG may help localize the epileptogenic zone and assist with the detection of subtle lesions.

## KEY POINTS

- Approximately 30% of patients with epilepsy become refractory to medical therapy, and surgery may be necessary to control seizures in some of these patients. Lesion identification on neuroimaging impacts surgical outcome.
- There is a wide range of brain abnormalities that can cause epilepsy. In children, the two most common causes of intractable focal epilepsy are MCD and developmental tumors. Hippocampal sclerosis is less common in children compared with the adult population with intractable focal epilepsy.
- Dual lesions can occur in approximately 15% of patients.
- Meticulous review of MRI is necessary to identify subtle lesions such as focal cortical dysplasia. MRI should be reviewed with knowledge of the clinical information, including seizure semiology and electroencephalography (EEG) findings.
- In patients with MRI-negative epilepsy, functional imaging with PET, ictal/interictal SPECT, and MEG may help to localize the epileptogenic zone.

## INCIDENCE AND ETIOLOGY

Head trauma and resulting traumatic brain injury (TBI) are among the most common causes of morbidity and mortality in children. Head trauma alone is responsible for 50% of deaths in children ages 1 to 14 years. Approximately 475,000 cases of TBI occur annually in children less than 14 years in the United States. Half of the cases occur in children under 5 years. Infants and children under 4 years and adolescents between 15 and 19 years of age are the two pediatric age groups at highest risk for TBI. Boys are more frequently injured than are girls (2:1). Motor vehicle accidents, especially car-versus-pedestrian accidents, are responsible for approximately 30% of TBI cases.

In infants younger than 2 years, the most common causes of head trauma are falls, an object striking the head, the infant being dropped, and nonaccidental trauma (NAT). NAT accounts for more than 80% of deaths from head trauma in this group. Skull fractures, subdural hematomas, cerebral edema, and parenchymal contusions are common injuries before 2 years of age. In children ages 3 to 14 years, falls, sporting activities, and all-terrain and motor vehicle accidents are the most common causes of head trauma. Fractures and parenchymal contusions are the most common injuries in this group. In older adolescents (>14 years), diffuse axonal injury (DAI) related to motor vehicle accidents predominates. Birth trauma is discussed in Chapter 23.

## IMAGING IN PEDIATRIC HEAD TRAUMA

### Computed Tomography

In general, computed tomography (CT) is the initial imaging modality used to evaluate patients with known or suspected head trauma to detect potentially life-threatening conditions that may require immediate surgical intervention. CT is widely available, easy to obtain, and quickly performed. Multidetector CT scanners have the advantage of producing multiplanar and three-dimensional (3D) images. These advances have increased the sensitivity of CT in detecting the sequelae of head trauma. CT angiography (CTA) is useful in the evaluation of traumatic vascular injury and has the advantage of speed and fewer flow-related artifacts compared with magnetic resonance angiography (MRA).

CT limitations include low contrast in the immature brain and beam hardening artifacts, which may obscure small extraaxial collections or subtle cortical contusions adjacent to bone. Although advances in CT scanners have improved their sensitivity in detecting TBI, CT underestimates the degree and extent of traumatic parenchymal injuries compared with magnetic resonance imaging (MRI). Nonetheless, acute CT findings have been proposed as criteria for grading and predicting outcome in TBI (the Marshall Classification and subsequent modifications by Maas et al.).[1]

Importantly, exposure of children to excess radiation has become a concern after Pearce et al.[2] demonstrated that children who underwent head CT had an increased risk of brain tumors years later. For patients with a minor head injury (Glasgow Coma Scale [GCS] score of 13 to 15), clinical guidelines for obtaining a head CT are available including the New Orleans Criteria, the Canadian CT Head Rule, and guidelines from the Pediatric Emergency Care Applied Research Network. These criteria are highly sensitive for detecting injuries that require neurosurgical intervention.[3] The American College of Radiology (ACR) also publishes Appropriateness Criteria for imaging in pediatric head trauma, including children under 2 years in whom clinical criteria are less reliable compared with older children.[4]

Adaptive statistical iterative reconstruction and other postprocessing techniques reduce image noise and improve low-contrast detectability and image quality. They provide higher diagnostic performance at a lower dose without loss of image quality.[5]

### Magnetic Resonance Imaging

Because of its more limited availability and longer scanning times, MRI is a secondary modality in acute head trauma evaluation. However, recent studies have compared the efficacy of rapid sequence MRI to CT in detecting intracranial injury. MRI demonstrated detection rates similar to CT in a select population without the risk of radiation.[6] MRI is more often performed in subacute and chronic trauma, especially when the CT findings do not correlate with the patient's clinical condition, or when patients have unexpected neurologic deterioration. MRI offers the advantages of multiplanar imaging and greater overall sensitivity and specificity for the detection of TBI. It is particularly useful in the detection of extraaxial hematomas, nonhemorrhagic intraaxial contusions, brain edema, posterior fossa abnormalities, and DAI.[7]

Specific MRI sequences are invaluable in TBI. Fluid attenuation inversion recovery sequences (FLAIR) null signal from cerebrospinal fluid (CSF) increasing detection of abnormal signal foci in the subarachnoid spaces and adjacent to ventricles.

T2* gradient-echo sequences (GREs) use a pair of bipolar gradient pulses to enhance magnetic susceptibility caused by magnetic field distortion. Susceptibility-weighted imaging (SWI) uses the signal loss from out-of-phase protons with different magnetic susceptibilities and is more sensitive than GRE for detection of blood products.[8]

Diffusion-weighted imaging (DWI) assesses the diffusion of water protons, which is normally along the MRI gradient signal. Areas of restricted diffusion retain the magnetic resonance signal, indicating ischemia/hypoxia due to acute injury. Reduced diffusion is also present in lesions with low nucleus-cytoplasm ratios. DWI is susceptible to the intrinsic T2* signal of the tissue because it is a gradient sequence. This is known as the T2 shine-through effect. To separate DWI signal from T2 shine through, the apparent water diffusion coefficient (ADC) is calculated by acquiring images with different gradient duration and amplitude (b-values), thus eliminating the T1 and T2* values.[9] Diffusion tensor imaging (DTI) assesses anisotropy of brain tissue by evaluating differences in direction of water diffusion in tissues. Although DTI can provide information about white matter tract integrity, it is currently mostly used for research purposes.

MRA and magnetic resonance venography, typically using the time-of-flight technique, are useful if a vascular injury is suspected.

Magnetic resonance spectroscopy (MRS) assesses the distribution and quantification of molecules within the central nervous system (see Chapter 25). The point-resolved spectroscopy sequence using

## Abstract:

Head trauma and resulting traumatic brain injury (TBI) are among the most common causes of morbidity and mortality in children. Head trauma alone is responsible for 50% of deaths in children ages 1 to 14 years. Approximately 475,000 cases of TBI occur annually in children less than 14 years in the United States. Half of the cases occur in children under 5 years. Head injury after nonaccidental trauma (NAT) is an important consideration in the pediatric population. Radiologic findings are an integral part of the workup and diagnosis of NAT as the clinical presentation is often nonspecific and highly variable. In general, CT is the initial imaging modality used to evaluate patients with known or suspected head trauma. In this chapter, head trauma is broadly classified by mechanism of head injury. Scalp hematoma, skull fractures, extraaxial and intraventricular hemorrhage, subarachnoid and traumatic parenchymal injury including non-accidental trauma are discussed highlighting important clinical and imaging findings that point to a specific diagnosis. Case examples are provided to familiarize the reader with expected imaging manifestations of both common and uncommon manifestations of head trauma. Head trauma is a frequent cause of morbidity and mortality in the pediatric population. A wide spectrum of traumatic head injuries occurs in children, many of which are unique to the pediatric population. Understanding the variable clinical presentations as well as imaging manifestations of head trauma is necessary to make a timely diagnosis and initiate prompt treatment when necessary.
